Glossary

allodynia Pain caused by stimuli that would not normally cause pain (i.e., non-noxious stimuli).

basic somesthetic activity Description of the ongoing activity in somatosensory pathways in the absence of any deliberate stimuli but including stimuli provided by the environment.

blink reflex Exteroceptive reflex of the orbicularis oculi muscles usually evoked by stimuli such as a mechanical tap on the glabella or by electrical currents delivered to the skin in the periorbital region.

Brown-Séquard syndrome Patient with a hemisection of the spinal cord of traumatic origin.

bulbospinal control A neural control mechanism originating in the brainstem and projecting to the spinal cord.

dermatome Area of skin innervated by nerves from a given segment of the spinal cord.

descending inhibition Inhibition of spinal cord function produced by pathways originating in the brain.

diffuse noxious inhibitory controls (DNICs) Neural controls triggered by noxious stimulation of widespread areas of the body which exert an inhibitory influence on wide-dynamic-range (WDR) neurons.

electromyography (EMG) All electrophysiological methods for exploring the physiology and pathophysiology of peripheral nerves and muscles.

excitatory receptive field Area of the body (surface or interior) which when stimulated will produce excitation of a given neuron.

hemianalgesia Loss of pain sensation from one half of the body.

heterotopic Part of the body remote from the area of interest (e.g., the excitatory receptive field of a neuron).

Hoffmann reflex (H reflex) Monosynaptic reflex from the calf muscles elicited by electrical stimulation of the sciatic nerve.

inhibitory receptive field Area of the body (surface or interior) which when stimulated will produce inhibitory effects on the activity of a given neuron.

jaw-opening reflex Exteroceptive reflex produced by stimulation of facial or intraoral afferents and involving activation of jaw opening muscles (e.g., the digastric) and/or inhibition of activity in jaw closing muscles (e.g., the masseter).

jerk reflex Myotatic monosynaptic reflex usually elicited by a percussion of a muscle's tendon using a reflex testing hammer.

Lasègue's maneuver Elevation of a lower limb in an extended position on a patient lying on a bed. This technique explores the Lasègue's sign which is the painful limitation of the angle of elevation in cases of radicular compression of the sciatic nerve.

microelectrophoretic application Application of a substance in its ionic form from a microelectrode by the application of electrical current.

monoarthritis Inflammation of a single joint.

mononeuropathy A disturbance of function or pathological changes in a single nerve.

nociceptive stimulus Stimulus that activates nociceptive afferents (which could be a noxious stimulus or an electrical stimulus).

noxious stimulus Stimulus that causes or threatens to cause tissue damage.

polyarthritis Inflammation of several joints.

propriospinal mechanism Neural mechanism mediated entirely within the spinal cord.

R_{III} reflex Electromyographic response elicited by electrical painful stimulation of the (purely cutaneous) sural or ulnar nerve by recording from the biceps femoris (lower limb) or biceps brachialis (upper limb), respectively. So-named because it involves activation of group III (Aδ) afferents.
subnucleus reticularis dorsalis (SRD) Brainstem nucleus located ventral to the cuneate nucleus, between trigeminal nucleus caudalis and the nucleus of the solitary tract.
supraspinal mechanism Neural mechanism that involves structures above the spinal cord.
tetraplegic Patient with a complete transection of traumatic origin at a high level of the spinal cord thus affecting all four limbs.
transcutaneous electrical nerve stimulation (TENS) Technique for inducing analgesia/hypoalgesia by electrically stimulating peripheral nerves through the skin (i.e., with electrodes placed on the skin).
trigeminal nucleus caudalis Most caudal part of the trigeminal sensory nuclear complex (or of the trigeminal spinal nucleus); also sometimes called the medullary dorsal horn.
ventrolateral quadrant Part of the spinal cord where spinoreticular and spinothalamic fibers travel.
Wallenberg's syndrome Patient with a unilateral lesion of the retro-olivary part of the brainstem resulting from the ischemia of a posterior cerebellar artery.
wide-dynamic-range (WDR) neurons Neurons of the dorsal horn activated by both noxious and non-noxious stimuli.

5.50.1 Introduction

Painful stimuli can diminish or even mask pain elicited by stimulation of a remote (extrasegmental) part of the body (see references in Melzack, R., 1989; Le Bars, D. and Willer, J. C., 2002). This phenomenon has been known since ancient times as illustrated by the Hippocrates' aphorism: "If a patient be subject to two pains arising in different parts of the body simultaneously, the stronger blunts the other." Numerous popular therapeutic methods for the alleviation of pain – some used spontaneously by patients – take advantage of this common clinical observation. It is often referred to as counter-irritation or counter-stimulation. In Kabylia, for example, healers treat rheumatic pain by placing a red-hot scythe close to the abdomen of the patient and then vibrating it at a frequency of about 3 Hz, in order to create a series of acute burning-type painful sensations.

A working hypothesis was developed that some of the neurons involved in the transmission of nociceptive signals might be inhibited by nociceptive stimulation of peripheral territories outside their own excitatory receptive fields. Such a hypothesis was found to be correct at as early a stage in the processing of nociceptive signals as the spinal cord. This phenomenon was termed diffuse noxious inhibitory control (DNIC). Since these spinal neurons are involved in mediating both pain and nociceptive reflexes, DNIC can be studied at three related endpoints: spinal neuronal activities, reflexes, and sensations. The first two are accessible in animals while the last two can be studied in human beings (Figure 1).

5.50.2 A Spinally Mediated Process

Combined psychophysical measurements and recordings of nociceptive reflexes in man have shown that the spinal cord is involved in the phenomenon of pain inhibiting pain (Willer, J. C. *et al.*, 1984). Electrical stimulation of the sural nerve at the ankle simultaneously induces a nociceptive reflex in a knee flexor muscle (the R_{III} reflex) and a pinprick type of painful sensation in the territory of the nerve (Willer, J. C., 1977). Both the reflex and the sensation have strong relationships with the stimulus intensities – with the thresholds for both parameters being practically identical.

One line of study involved recording these parameters (i.e., the reflex and pain) before, during, and after the application of heterotopic conditioning stimuli such as the immersion of a hand in a thermoregulated water bath at various temperatures (Figure 2, upper panels). When the temperature of the bath was lower than 45 °C, the immersion of the

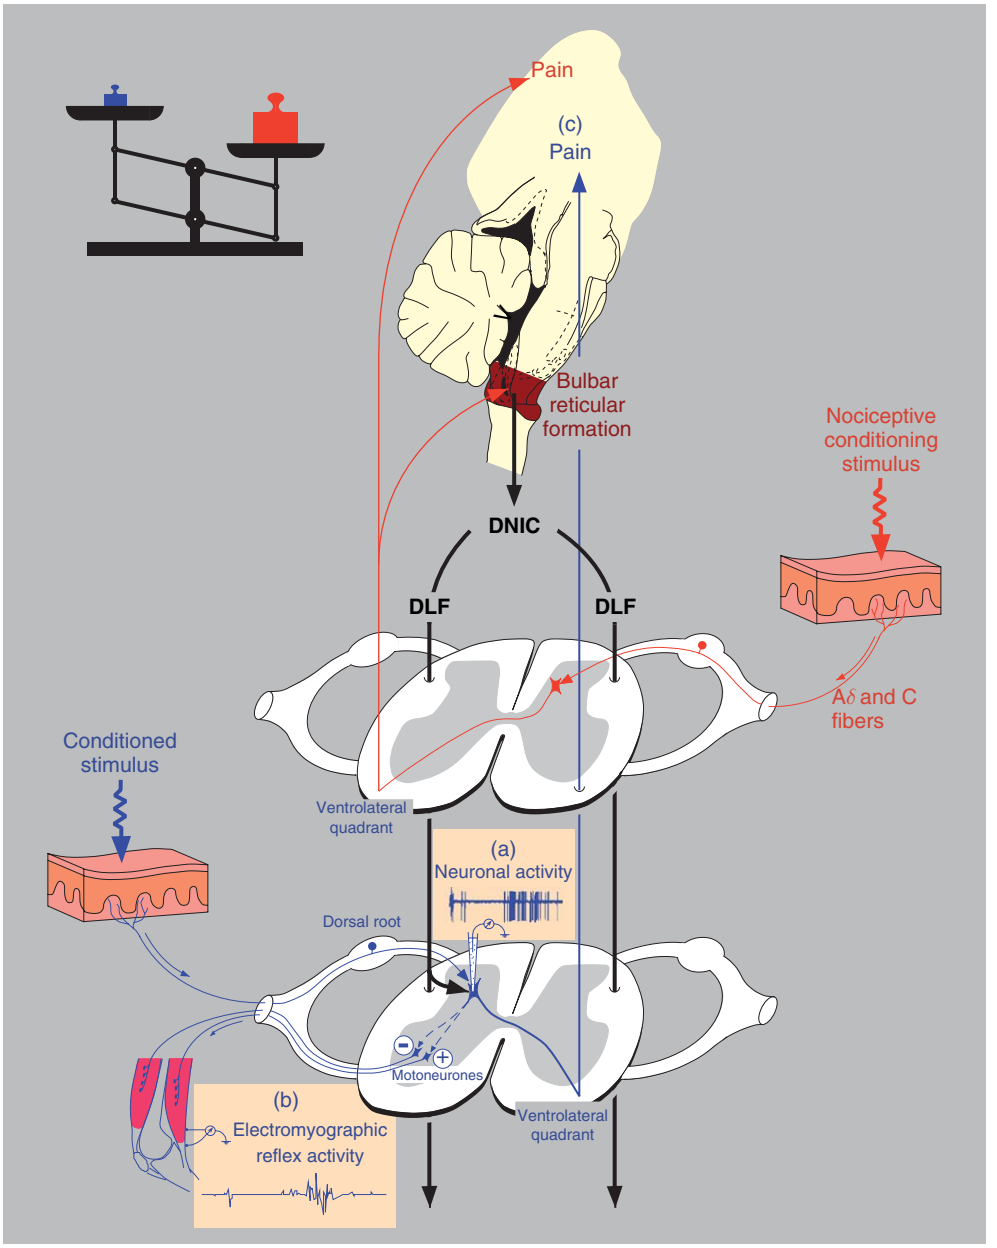

Figure 1 Nociceptive signals activate dorsal horn neurons, which in turn transfer the information to the brain to elicit pain and to spinal interneurons (broken blue line) to elicit somatic and vegetative reflexes. The effects on motoneurons through polysynaptic pathways trigger a movement that moves the stimulated area away from the stimulus. This movement results from both excitatory (e.g., contraction of flexor muscles) and inhibitory mechanisms – the latter affecting antagonist muscles. In animals, one can record from neurons (a) and from muscles (b) but the sensation (c) cannot be assessed. In man, on the other hand, one cannot record from neurons but it is possible to monitor both the sensation and the reflex activities. In an experimental paradigm designed for the study of pain inhibiting pain phenomena, one requires a conditioned stimulus (here in blue) with the corresponding endpoints (a, b, or c) and a conditioning stimulus (here in red). A painful focus activates dorsal horn neurons that send an excitatory signal through the ventrolateral quadrant toward higher centers, including the lower brainstem. This signal activates DNICs, which will inhibit WDR neurons through the dorsolateral funiculi (DLF). With two painful foci, the resulting sensation will depend on the balance of the nociceptive information elicited from the two sources. The power of such nociceptive information depends on the three dimensions of any nociceptive stimulus, namely strength, duration, and area. In an experimental situation designed to observe inhibitions of the response to the conditioned stimulus, the beam of the balance should tilt in favor of the conditioning stimulus. This is illustrated in Figure 2 where the response to a 20 ms duration series of electrical pulses is inhibited by the stimulation of the hand for 2 min.

hand did not elicit any change in the stimulus–response relationships. By contrast, temperatures between 45 and 47.5 °C caused the stimulus–response curves to shift to the right as a direct function of the temperature. Similar effects were observed when other painful procedures were applied as conditioning stimuli (e.g., cold, pressure, exercise under ischemia, high-intensity transcutaneous electrical nerve stimulation) (Willer, J. C. *et al*., 1984; 1989; Danziger, N. *et al*., 1998; France, C. R. and Suchowiecki, S., 1999; Sandrini, G. *et al*., 2000).

The temporal evolution of these phenomena can be studied by applying a heterotopic conditioning stimulus while the sural nerve is stimulated at a constant intensity (Figure 2, lower panels). This procedure revealed aftereffects of long duration. For example, a 2 min immersion of the hand in a 47 °C water bath completely abolished the R_{III} reflex and it took more than 9 min to achieve a full recovery (Figure 2(A)). Very similar effects were produced by visceral stimulation (gastric or rectal distension) in healthy volunteers (Bouhassira, D. *et al*., 1994; 1998). During gastric distension for example (Figure 2(B)), the inhibitory effects increased with the volume of distension and the resultant sensation. As with the inhibitions elicited by stimulation of somatic structures, these visceral-evoked inhibitions were correlated to the intensity of the conditioning stimuli. However, they could be triggered by stimuli which were unpleasant but not quite painful (Figure 2(C)). When they become clearly painful, the duration of the inhibitory effects outlasted the duration of the distension by several minutes.

Clinical pains can also activate this type of inhibition. Thus, in patients suffering from sciatic pain due to a herniated disk, a Lasègue's maneuver of the affected leg, which elicits a typical radicular pain, also blocks the R_{III} reflex, both in the affected and

Figure 2 (Upper panels) Experimental setup for recording the nociceptive R_{III} flexion reflex from the biceps femoris muscle in the lower limb using surface electrodes. The reflex is evoked by electrical stimulation of the ipsilateral sural nerve. The insert shows typical examples of electromyographic (EMG) responses elicited by increasing stimulus intensities (from top to bottom). The subjective sensation was estimated by the subject on a 10-level scale (box with switches shown in insert), with the pain threshold being defined as level 3. Examples of stimulus–response curves for the nociceptive reflex and subjective reports of sensations produced by a wide range of stimulation intensities applied randomly are shown on the left and right graphs, respectively. Note the close correlations between (1) the reflex threshold (T_r) and the pain threshold (T_p) around 10 mA; and (2) the stimulus intensities producing maximal responses, that is, the threshold of the maximal reflex recruitment (T_{mr}) versus the threshold of unbearable pain (T_{up}). Such recruitment curves were built before and during a 2 min period of immersion of the right hand in a thermoregulated water bath. No effects were seen at lower temperatures but a shift of the curves to the right was elicited when the temperature reached painful levels (45 °C and above). The shift applied to the reflex (a, b) and sensation (c, d) thresholds. (Lower panels) The temporal evolution of the reflex can be monitored by employing repeated, constant, stimulation of the sural nerve (1.2 times threshold every 6 s). The individual R_{III} reflex is expressed in terms of the percentages of the mean value recorded during a control period. Each vertical bar represents the mean of ten responses recorded during 1 min. Graphs show pooled data from several subjects. (A) Effects of immersion of the hand. The nonpainful temperature (42 and 44 °C, left) did not modify the reflex. By contrast, the painful temperatures (45, 46, and 47 °C) depressed the reflex during and after the period of conditioning. The extent of these depressions was temperature dependent. Note the long duration (around 10 min) of the inhibitory posteffects following the application of the highest temperature (47 °C, right). (B) Effects of visceral stimulation. Gastric distension by means of a balloon introduced into the proximal part of the stomach was applied for a 3 min period. The inflation of the balloon in volumes of 200 or 400 ml did not modify the R_{III} reflex, whereas volumes of 600, 800, and 1000 ml produced inhibitions correlated to the volume of distension. The 600 and 800 ml distensions were unpleasant while the 1000 ml volume was clearly painful. (C) Effects of nociceptive electrical stimuli (20–25 mA) applied to the upper limb of healthy volunteers or patients with lesions of the spinal cord or the brain. (a) In healthy volunteers; (b) in tetraplegic patients, the conditioning stimulus did not inhibit the R_{III} reflex; (c) in patients with a Wallenberg syndrome (unilateral lesion of the retro-olivary part of the brainstem) the conditioning stimuli did or did not inhibit the R_{III} reflex depending on whether it was applied to the normal hand (ipsilateral to the brain lesion) or the analgesic hand (contralateral to the brain lesion); and (d) in patients with thalamic lesions, the conditioning stimulation applied to the analgesic hand (contralateral to the brain lesion) did produce inhibition of the R_{III} reflex. (Upper panels) Adapted from Willer, J. C., Roby, A., and Le Bars, D. 1984. Psychophysical and electrophysiological approaches to the pain relieving effect of heterotopic nociceptive stimuli. in the nonaffected leg (Willer, J. C. *et al.*, 1987). When the Lasègue's maneuver is performed on the healthy limb, it is painless and has no effect on the reflex. In patients suffering from neuropathic pain, the R_{III} reflex is inhibited when pain is triggered by pressure ('static allodynia'), but not when it is triggered by light brushing ('dynamic allodynia') (Bouhassira, D. *et al.*, 2003). Interestingly, it is generally agreed that the former is due to the activation of nociceptive processes via Aδ- and C-fibers, while the latter is due to the activation of Aβ-fibers.

In summary, a painful conditioning stimulus can depress both a preexisting pain and its associated nociceptive reflex at the first spinal relays for the transmission of nociceptive information. Interestingly, nociceptive brainstem reflexes such as the blink or jaw-opening reflexes are also inhibited by remote painful stimulation (Pantaleo, T. *et al.*, 1988; Maillou, P. and Cadden, S. W., 1997; Ellrich, J. and Treede, R. D., 1998). By contrast, nonnociceptive reflexes such as jerk or Hoffmann reflexes remain unaffected during such procedures. One must stress here that there has to be an obvious imbalance between the conditioned and the conditioning stimuli for a clear depressive effect to be seen. For instance, in the examples shown in Figure 2, the conditioned stimuli were short (20 ms) trains of electrical shocks, whereas the conditioning stimuli were applied over time periods of several seconds to large areas of the body. Clearly, spatiotemporal summation is required to elicit visible inhibitory effects because of the reciprocal nature of the phenomenon triggered by two remote painful foci. A balance, the beam of which tips (or does not tip) in favor of one or other pain, could symbolize the net result of such a reciprocal process (Figure 1, upper left). Of course, clinical situations are always much more complicated than these experimental situations which are deliberately designed to simplify the problem under analysis. More particularly, it seems likely that the existence of multiple painful foci would produce very complicated interactions between excitatory and inhibitory processes.

5.50.3 A Spinally Mediated Process Involving Supraspinal Structures

Are the inhibitory mechanisms described above due to propriospinal mechanisms or do they involve supraspinal structures? To answer this question, the effects on the R_{III} reflex in the right leg, of nociceptive conditioning stimuli applied to the fourth and fifth fingers of the left hand were compared in normal subjects and tetraplegic patients with lesions of traumatic origin at the cervical-5–7 level (Roby-Brami, A. *et al.*, 1987). In the normal subjects (Figure 2(Ca)), the painful conditioning stimuli strongly depressed both the R_{III} reflex and the associated pain. By contrast, in the tetraplegic patients, nociceptive stimulation of the same territories, which, being in the cervical-8 and thoracic-1 dermatomes, were clinically unaffected by the spinal lesion, and did not produce any depression of the R_{III} reflex (Figure 2(Cb)). One can therefore conclude that the inhibitory effects triggered by heterotopic nociceptive stimuli are sustained by a loop that includes supraspinal structures.

In order to identify, or at least localize, these supraspinal structures, observations were made on patients with cerebral lesions causing contralateral hemianalgesia (De Broucker, T. *et al.*, 1990). These were patients with either a lesion of the retro-olivary part of the medulla (Wallenberg's syndrome, Figure 2(Cc)) or a unilateral thalamic lesion (Figure 2(Cd)). In the former group, no inhibitions were observed when the (not felt) nociceptive conditioning stimulus was applied to the affected side of the body, contralateral to the brain lesion. If this stimulus was applied to the normal side, ipsilateral to the brain lesion, it was felt as painful and triggered inhibitory effects very similar to those seen in normal subjects. By contrast, in the patients with a thalamic lesion, the R_{III} reflex was strongly depressed, as in normal subjects, by the nociceptive conditioning stimulus applied to the affected side (which was not felt as painful). Thalamic structures and consequently spinothalamic pathways, are therefore not involved in DNIC, whereas brainstem – probably reticular – structures seem to play a key role in these phenomena. These observations also demonstrate unambiguously that such phenomena can be elicited in the absence of a painful sensation, provided the nociceptive nature of the information reaches some brain structures. This suggests that the observed phenomenon does not result from a competition between the two attentional foci that the conditioned and the conditioning pain represent in the healthy volunteers. This is an important observation as it is known that the perception of pain is sensitive to attentional processes (Bushnell, M. C. *et al.*, 1985; Willer, J. C. *et al.*, 1979).

An exceptional case was also reported in a patient with a Brown-Séquard syndrome due to a hemisection

of the spinal cord (left side, T6 level) produced by a knife-stab in the back (Bouhassira, D. *et al*., 1993). The R_{III} reflexes elicited by stimulation of cutaneous afferents in the ulnar and sural nerves were studied in the upper and lower limbs by recording from the biceps brachialis and biceps femoris muscles, respectively. For each limb, the R_{III} reflex was elicited regularly before, during, and after periods of nociceptive electrical conditioning stimulation applied successively to the other three limbs. Inhibitions of around 90% followed by strong poststimulus effects were observed in all situations except that (1) no inhibition could be obtained when the conditioning stimuli were applied to the lower right limb (contralateral to the spinal lesion), and (2) the R_{III} reflex in the lower left limb was completely insensitive to any of the conditioning stimuli. These results strongly suggest that in human beings (1) the ascending part of the loop subserving DNIC is completely crossed at the spinal level, and (2) the descending part is confined to the white matter ipsilateral to the limb being tested.

5.50.4 A Model in the Rat

Another nociceptive reflex – this time recorded in the anaesthetized rat – is the C-fiber reflex which can be elicited by electrical stimulation of the sural nerve and recorded from the biceps femoris muscle. This reflex can be strongly inhibited by both mechanical and thermal noxious heterotopic stimuli applied to the muzzle, a paw or the tail, and by colorectal distension. These inhibitory effects on the C-fiber reflex did not occur in spinal animals, or ipsilateral to a rostral unilateral lesion of the dorsolateral funiculus (DLF). Such observations are consistent with several reports showing the inhibition of reflexes or the increase of nociceptive thresholds elicited by heterotopic noxious conditioning. For example, the reflex discharge in the common peroneal nerve following electrical stimulation of the sural nerve in the rat was inhibited by pinching the muzzle or tail; the gastrocnemius medialis reflex evoked by sural nerve stimulation in the decerebrate rabbit was inhibited by electrical stimulation of the contralateral common peroneal or of the ipsi- or contralateral median nerves; the digastric reflex evoked by tooth pulp stimulation in the cat was inhibited by toe pinch, percutaneous electrical stimulation of a limb or electrical stimulation of the saphenous nerve. In behavioral experiments, intraperitoneal or cutaneous injections of an irritant agent or noxious heat all produce an increase in nociceptive thresholds in distant somatic structures, notably the tail (e.g., tail flick test) and paws (e.g., paw withdrawal test). (See references in Le Bars, D. *et al*., 2001.)

5.50.5 The Role of Wide-Dynamic-Range Neurons

In several species (rat, mouse, cat, and probably monkey), most WDR and some nociceptive-specific neurons are strongly inhibited by a noxious stimulus applied outside their excitatory receptive fields. Such effects do not appear to be somatotopically organized but apply to the whole body. Figure 3 shows examples of recordings from lumbar WDR neurons in the rat. The activities of these neurons – whether elicited by pinching their receptive field or by applying an excitatory amino acid to their membranes – were strongly inhibited by noxious mechanical (pinch of the muzzle, the contralateral hindpaw or the tail) or thermal stimuli (immersion of the tail in a 52 °C water bath) (Figure 3(A)). These examples illustrate the whole body inhibitory receptive fields of WDR neurons as recorded in intact rats. Interestingly, such inhibitory controls are exacerbated during clinical pains, for example, when an animal suffers from monoarthritis, polyarthritis or a peripheral mononeuropathy (Danziger, N. *et al*., 2000; 2001).

These properties of dorsal horn neurons were observed at the level of various segments of the spinal cord and in both nucleus caudalis and nucleus oralis of the trigeminal system – thus suggesting a general organization. In keeping with the human studies shown in Figure 2, there is a clear relationship between the intensity of the conditioning stimulus and the strength of the resultant DNIC. With strong stimuli, the inhibitory effects are powerful and followed by long-lasting poststimulus effects, which can persist for several minutes. In some cases, the inhibitory effects can involve a complete abolition of activity for a long period of time following removal of the conditioning stimuli ('switch off') and the activity can be restored to preconditioning levels by further manipulations of the excitatory receptive field ('switch on') (Cadden, S. W., 1993). (See references in Le Bars, D., 2002.)

With regard to the viscera, some differences should be noted: visceral stimuli, for example, distension of the colon or urinary bladder, generally produce inhibitions with slower rates of onset and recovery but

starting at intensities below a painful level (Cadden, S. W. and Morrison, J. F. B., 1991). It was proposed that these differences might have reflected different amounts and patterns of activity in the relevant primary afferent fibers rather than being due to different central neural mechanisms. Again, this is consistent with human studies (e.g., Figure 2(B)).

In any case, these data suggest that DNICs are triggered specifically by the activation of peripheral nociceptors whose signals are carried by Aδ- and C-fibers. In order to investigate further the types of peripheral fiber involved in DNIC, use was made of the facts that (1) trigeminal and spinal dorsal horn neurons respond with relatively steady discharges to the microelectrophoretic application of excitatory amino acids; and (2) DNICs act by a final postsynaptic inhibitory mechanism involving hyperpolarization of the neuronal membrane. It was found that when trigeminal WDR neurons were directly excited by the microelectrophoretic application of glutamate, the percutaneous application of single square-wave, electrical stimuli to the tail always induced a biphasic depression of the resultant activity. Both the early and late components of this inhibition occurred with shorter latencies when the base rather than the tip of the tail was stimulated. Such differences in latency were used to estimate the mean conduction velocities of the peripheral fibers triggering the inhibitions: the means were found to be 7.3 and 0.7 m s^{-1}, which fall into the Aδ- and C-fiber ranges, respectively. Such biphasic inhibitions could be elicited from any part of the body and recorded from any WDR neurons. Figure 3(B) shows a recording from a lumbar WDR neuron with an excitatory receptive field located on the extremity of the ipsilateral hind paw: two components of inhibition were induced by the activation of Aδ and C-fibers, respectively, when a single 2 ms duration shock of 10 mA was applied to the muzzle, the base or the tip of the tail.

DNICs are not observed in anesthetized or decerebrate animals in which the spinal cord has been sectioned. It is therefore obvious that the mechanisms underlying DNICs are not confined to the spinal cord and that supraspinal structures must be involved. Such a system is therefore completely different from segmental inhibitory systems, which work both in intact and in spinal animals, and can be triggered by the activation of low-threshold afferents. DNICs are also very different from the propriospinal inhibitory processes that can be triggered by noxious inputs. It should also be noted that DNIC are blocked by increasing the anesthetic regimen (Jinks, S. L. *et al.*, 2003).

The ascending and descending limbs of this loop travel through the ventrolateral and dorsolateral funiculi, respectively. Since thalamic lesions do not affect DNICs, it has been proposed that they result from a physiological activation of some of the brainstem structures that produce descending inhibition

Figure 3 (A) Example of inhibitions of a spinal WDR neuron elicited by noxious heterotopic stimuli. Recordings were made in the lumbar dorsal horn from a WDR neuron with a receptive field located on the ipsilateral hind paw. The neuron was activated either by a sustained pinch of its receptive field or by regular (once a minute) microelectrophoretic applications of the excitatory amino acid, glutamate (GLU, 20 nA, horizontal bars). Conditioning stimuli were pinch of the muzzle, the contralateral hind paw or the tail, and immersion of the tail in a 52 °C water bath (from top to bottom, respectively). Note that all these conditioning stimuli virtually blocked both the pinch-evoked and the DLH-induced firing. In the latter case, the inhibitions remained for several minutes in most cases, suggesting that WDR neurons were hyperpolarized for a long time following the conditioning stimulation. (B) Example of heterotopic activation of Aδ- and C-fibers triggering inhibitions in a spinal WDR neuron. Left: Schematic representation of the experimental design. Recordings were made in the lumbar dorsal horn from a WDR neuron with a receptive field located on the ipsilateral hind paw. The continuous microelectrophoretic application of the excitatory amino acid, DL-homocysteic acid (DLH) induced a steady discharge from the neuron under study. The repetitive application of individual percutaneous electrical stimuli of adequate intensities to the contralateral muzzle (a), the base (b), or the tip (c) of the tail induced biphasic depressions of the neuronal activity. Right: Peristimulus histograms (bin width 5 ms) prepared during the continuous microelectrophoretic application (15 nA) of DLH onto the membrane of the neuron. The broken white lines show the timing of percutaneous electrical stimulation (10 mA; 2 ms duration; 0.66 Hz; 200 ms delay; 100 sweeps). The broken black line represents the mean firing calculated during the prestimulation control period (−200 to 0 ms). Two waves of inhibition can be seen. They occurred earlier when the base of the tail (b) was stimulated instead of the tip (c). The time gaps are shown as yellow areas between the histograms, for both inhibitory components. The gap was 7 and 25 ms for the beginning and the end of the first component; it was 150 and 290 ms for the beginning and the end of the second component. Knowing that the distance between b and c was 100 mm, one can easily calculate the conduction velocities of fibers that elicited the first and second components: 4–14 m s^{-1} and 0.3–0.7 m s^{-1} respectively. These fibers therefore belong to the Aδ- and C- groups, respectively. (A) Adapted from Villanueva, L., Cadden, S. W., and Le Bars, D. 1984. Evidence that diffuse noxious inhibitory controls (DNIC) are mediated by a final post-synaptic inhibitory mechanism. Brain Res. 298, 67–74.

(see Chapter 5.49). Surprisingly, DNICs were not modified by lesions of the following structures: the periaqueductal gray (PAG), cuneiform nucleus, parabrachial area, locus coeruleus/subcoeruleus, rostral ventromedial medulla (RVM). By contrast, lesions of subnucleus reticularis dorsalis (SRD) in the caudal medulla strongly reduced DNICs. The SRD is located ventral to the cuneate nucleus, between trigeminal nucleus caudalis and the nucleus of the solitary tract and contains neurons with characteristics that suggest they have a key role in processing specifically nociceptive information (Villanueva, L. *et al*., 1996). Indeed, they are preferentially or exclusively activated by nociceptive stimuli from a whole-body receptive field; they encode the intensity of cutaneous and visceral stimulation within noxious ranges; and they are activated exclusively by activity in Aδ- or Aδ- and C-peripheral fibers. In addition, they send descending projections through the dorsolateral funiculus that terminate in the dorsal horn at all levels of the spinal cord. The fact that the supraspinal loop sustaining DNICs is confined to the most caudal part of the medulla was confirmed in a series of experiments where the potency of DNIC was tested in animals with complete transections at different levels of the brainstem.

5.50.6 Summary and Conclusions

There is a body of evidence, based on both human and animal experiments, which strongly suggests that the phenomenon of 'pain inhibiting pain' is sustained by a well-defined neurological substratum based on a spino-reticulo-spinal loop. DNICs are in fact a very special and generalized case of lateral inhibition and it is very likely that they subserve a related function. Although lateral inhibition is sometimes thought of in terms of creating illusions, such phenomena play an important role in other senses (see Chapters 1.01 and 3.30). It is very probable that DNICs, as revealed by the empiric observation that pain inhibits pain, also play an important role in pain processing, probably by focusing the pain network onto a particular part of the body. The DNIC system could be understood as a filter allowing the extraction by the brain of a clear signal of pain from a basic somesthetic activity provided by dorsal horn WDR neurons (see Chapter 5.25). If these statements are correct, then defocusing should alleviate the unpleasantness of pain. Interestingly, the reference analgesic drug, morphine, blocks DNICs in both man and animals (Le Bars, D. *et al*., 1992).

Many sources of descending inhibition from the brain that modulate the spinal transmission of nociceptive information have been described in animals (see Chapters 5.41 and 5.49). To date, the only descending inhibitory mechanisms that have been described in man are DNICs.

Glossary

chronic pain Pain for more than 3 months.

central sensitization Increased sensitivity to painful stimuli due to functional changes of the central nervous system (neuroplasticity).

peripheral sensitization Increased sensitivity to painful stimuli due to decreased thresholds of primary nociceptive afferents.

tender point (TP) Nine paired body areas at tendon insertion points of the neck, chest, buttocks, as well as all upper and lower extremities as defined by the 1990 American College of Rheumatology. TPs represent areas of mechanical allodynia (pain threshold $\leq 4\,\mathrm{kg\,cm^{-2}}$). Eleven or more TPs as well as chronic widespread pain are required to fulfill fibromyalgia criteria.

trigger point (TrP) Painful muscle areas that show increased muscle tension (taut bands), a twitch response to palpation, and referred pain.

wind-up Central pain mechanisms that depend on *N*-methyl-D-aspartate and substance P receptor mechanisms.

5.51.1 Introduction

Chronic nonmalignant pain is very frequent in the general population (Croft, P. *et al.*, 1993). Fibromyalgia (FM) represents the combination of chronic widespread pain with mechanical allodynia and disproportionably affects women (ratio women:men 9:1). Like many other syndromes, FM has no single specific feature but is a symptom complex of self-reported or elicited findings. In 1990, the American College of Rheumatology (ACR) published diagnostic criteria for FM which include chronic widespread pain (>3 months) and mechanical tenderness in at least 11 out of 18 tender points (TP; Wolfe, F. *et al.*, 1990). Most

TP sites are located at tendon insertion areas and have shown few detectable tissue abnormalities. Besides musculoskeletal pain and mechanical tenderness most FM patients also complain of insomnia, fatigue, and distress. In addition FM coaggregates with major mood disorders (Raphael, K. G. *et al.*, 2004).

5.51.2 Pathogenesis of Fibromyalgia

FM can be characterized as a pain amplification syndrome of patients who often display widespread hyperalgesia and allodynia to mechanical, thermal, and chemical stimuli. However, the hypersensitivity of FM patients is not limited to pain, but also includes light, sound, and smell. The cause for this heightened sensitivity is unknown, but central nervous system (CNS) sensory processing abnormalities have been reported in several studies (Desmeules, J. A. *et al.*, 2003; Staud, R., 2004). Most of these studies found evidence of central sensitization of dorsal horn neurons of the spinal cord and the brain including those that are related to pain. The pathogenesis of central sensitization in FM is unclear but may be related to prior stressors, including infections and traumas. Because most FM patients relate their pain to deep tissues, particularly muscles, these structures may play an important role in the initiation and maintenance of central sensitization and pain. No consistent tissue abnormalities have been reported in FM patients that would explain persistent pain. However, focal muscle areas, like trigger points (TrPs), may play an important role for FM pain because little nociceptive input from peripheral tissues is required for the maintenance of central sensitization (Bengtsson, M. *et al.*, 1989).

5.51.3 Muscle Nociception

Nociceptive input from muscle may be particularly relevant for FM pain. Muscle pain travels in myelinated A-delta fibers (group III) and in unmyelinated type C fibers (group IV). Pain receptors are mostly located at free nerve endings which are concentrated around small arterioles and capillaries between the muscle fibers. The cell bodies for these nerves are found in the dorsal root ganglion and synapse in lamina I and IV–V of the dorsal horn of the spinal cord. Activation of peripheral nociceptors leads to a release of neurotransmitters in the spinal cord, mostly substance P and calcitonin gene-related peptide (CGRP). There is also a retrograde migration of substance P from cell bodies which is then released in the region of the free nerve endings. This retrograde flow can sensitize tissues and increase their responsiveness to less intense stimuli. Muscle nociceptors are activated by mechanical stimuli (stretching or pressure), bradykinin, serotonin, and potassium ions, but are not activated by normal muscle movements or even increased muscle tension. Sensory input from muscle, as opposed to skin, is a much more potent effector of central sensitization and this may be particularly relevant for FM (Wall, P. D. and Woolf, C. J., 1984).

5.51.4 Triggering Events for Fibromyalgia

The onset of FM has frequently been associated with certain triggers or stressors include physical trauma, infections, emotional distress, endocrine disorders, and immune activation (Greenfield, S. *et al.*, 1992; Middleton, G. D. *et al.*, 1994; Waylonis, G. W. and Perkins, R. H., 1994). These stressors have been associated with the degree of pain, disability, life interference, and affective distress of FM patients (Turk, D. C. *et al.*, 1996). Strong evidence for trauma as a trigger of FM symptoms comes from studies of patients with acute injuries who developed chronic widespread pain at much higher rates than controls (Al Allaf, A. W. *et al.*, 2002; Buskila, D. and Neumann, L., 2002). Additional evidence for such an association include postinjury reported sleep abnormalities (Berglund, A. *et al.*, 2001), local injury sites as a source of chronic distant regional pain (Arendt-Nielsen, L. and Svensson, P., 2001), and recent evidence of injury-related CNS neuroplasticity in FM (Carli, G., 2000). Further prospective studies, however, are needed to confirm these associations and to identify the mechanisms that are relevant for posttraumatic FM pain (White, K. P. *et al.*, 2000).

5.51.5 Abnormal Response to Stressors

The biological response to stressors appears predictable in animals and humans. Particularly, events that are perceived as inescapable or unavoidable, or which appear unpredictable, evoke the strongest adverse biological responses (Gold, P. W. *et al.*, 1988a;

1988b; Chrousos, G. P. and Gold, P. W., 1992; Viau, V. *et al.*, 1993; Sapolsky, R. M. *et al.*, 2000). This may explain why victims of trauma appear to develop much higher rates of FM than persons with self-inflicted injuries (Greenfield, S. *et al.*, 1992). In addition, early life stressors can have a permanent and profound impact on subsequent biological responses to stress in animals and humans. Studies in rodents have demonstrated that exposure to multiple stressors including trauma or separation in the neonatal period can lead to permanent changes in the biological response to stress (Sapolsky, R. M., 1996; McNamara, R. K. *et al.*, 2002). This permanent effect of early stressors could explain the higher than expected incidence of traumatic childhood events in individuals who later develop chronic pain (Anderberg, U. M. *et al.*, 2000; Bailey, B. E. *et al.*, 2003).

5.51.6 Posttraumatic Stress Disorder and Fibromyalgia

Posttraumatic stress disorder (PTSD) often occurs after a significant traumatic event and is characterized by behavioral, emotional, functional, and physiological symptoms. Relevant traumatic events related to PTSD are usually perceived as threatening one's life or physical integrity and can lead to emotional responses including horror, helplessness, or intense fear. The psychological symptoms of PTSD include re-experience of the traumatic event, avoidance, and increased arousal. It has been shown that the experience of trauma is associated with increased somatic and physical complaints, including pain (Beckham, J. C. *et al.*, 1997; 1998). More than 50% of patients with FM suffer from PTSD in the USA and Israel (Sherman, J. J. *et al.*, 2000; Cohen, H. *et al.*, 2002). Compared to the prevalence of PTSD in the general population (6%), FM patients show greatly increased rates similar to Vietnam veterans and victims of natural disasters (Shore, J. H. *et al.*, 1986; Green, M. M. *et al.*, 1993). Not surprisingly, the incidence of FM is also increased in patients with PTSD (21%) and often associated with increased pain ratings, more distress, and higher functional impairment (Amir, M. *et al.*, 1997). As with several other disorders, however, it is unclear whether PTSD is the cause or consequence for FM.

5.51.7 Fibromyalgia and Affective Spectrum Disorders

Several studies have reported that FM is comorbid with major depressive disorder (MDD; Arnold, L. M. *et al.*, 2000; White, K. P. *et al.*, 2002). In addition, anxiety is very prevalent in patients with FM (Thieme, K. *et al.*, 2004). The outcome of a recent large family study of FM probands was consistent with the hypothesis that FM and MDD are characterized by shared, genetically mediated risk factors (Raphael, K. G. *et al.*, 2004). Although the findings of this study should not be interpreted that MDD and FM represent different forms of the same syndrome, they strongly suggest that FM and MDD share important CNS mechanisms.

5.51.8 Central Sensitization in Fibromyalgia

Whereas peripheral sensitization is related to changes of primary nociceptive afferent properties, central sensitization requires functional changes in the CNS (neuroplasticity). Behaviorally, centrally sensitized patients, like FM sufferers report abnormal or heightened pain sensitivity with spreading of hypersensitivity to uninjured sites and the generation of pain by low threshold mechanoreceptors that are normally silent in pain processing (Torebjork, H. E. *et al.*, 1992). Thus, tissue injury may not only cause pain but also an expansion of dorsal horn receptive fields and central sensitization.

5.51.9 Temporal Summation of Second Pain (Wind-Up)

In 1965, Mendell and Wall described for the first time, that repetitive C-fiber stimulation can result in a progressive increase of electrical discharges from second-order neurons in the spinal cord (Mendell, L. M. and Wall, P. D., 1965). This important mechanism of pain amplification in the dorsal horn neurons of the spinal cord is related to temporal summation of second pain or wind-up (WU) and has been used in FM patients for the evaluation of central sensitization (Staud, R. *et al.*, 2001). This technique reveals sensitivity to input from unmyelinated (C) afferents and the status of the *N*-methyl-D-aspartate (NMDA) receptor systems that are implicated in a

variety of chronic pain conditions. Temporal summation depends upon activation of NMDA transmitter systems by C nociceptors, and chronic central pain states like FM can result from excessive temporal summation of pain (Staud, R. and Smitherman, M. L., 2002).

5.51.10 Abnormal Wind-Up of Fibromyalgia Patients

Several recent studies have demonstrated psychophysical evidence that input to central nociceptive pathways is abnormally processed in patients with FM (Staud, R. and Domingo, M., 2001a; 2001b; Staud, R. *et al.*, 2001; Vierck, C. J. *et al.*, 2001; Price, D. D. *et al.*, 2002; Staud, R., 2002). When WU pain is evoked both in normal controls and FM patients, the perceived magnitude of the experimental stimuli (heat, cold, pressure, electricity) is greater for FM patients compared to controls, as is the amount of temporal summation within a series of stimuli. Following a series of stimuli, after-sensations are greater in magnitude, last longer, and are more frequently painful in FM subjects. These results indicate both augmentation and prolonged decay of nociceptive input in FM patients and provide convincing evidence for the presence of central sensitization.

5.51.11 Wind-Up Measures as Predictors of Clinical Pain Intensity in Fibromyalgia Patients

The important role of central pain mechanisms, like WU, for FM patients is also supported by their ability to predict clinical pain intensity. Thermal WU ratings correlate with clinical pain intensity (Pearson's $r = 0.529$), thus emphasizing the important role of these pain mechanisms for FM. In addition, statistical prediction models that includes TP count, pain-related negative affect, and WU ratings have been shown to account for nearly 50% of the variance in FM clinical pain intensity (Staud, R. *et al.*, 2003; 2004).

5.51.12 Fibromyalgia and Other Chronic Pain Conditions

Many systemic illnesses can also present with diffuse pain similar to FM, including polymyalgia rheumatica (Gowin, K. M., 2000), rheumatoid arthritis, Sjogren's syndrome, inflammatory myopathies (Sultan, S. M. *et al.*, 2002), systemic lupus erythematosus (Tench, C. *et al.*, 2002), multiple sclerosis, and joint hypermobility syndrome (Nef, W. and Gerber, N. J., 1998). Furthermore, several infectious diseases including hepatitis C, Lyme disease, coxsackie B infection, HIV, and parvovirus infection, frequently result in chronic pain states (Barkhuizen, A., 2002). Although the majority of FM patients report the insidious onset of pain and fatigue, approximately half of all patients describe the start of chronic pain after a traumatic or infectious event.

5.51.13 Myofascial Pain Syndrome

Myofascial pain or regional musculoskeletal pain is one of the most common pain syndromes encountered in clinical practice. Myofascial pain represents the most common cause of chronic pain, including neck and shoulder pain, tension headaches, and lower back pain (Granges, G. and Littlejohn, G., 1993; Fricton, J. R., 1994; Macfarlane, G. J. *et al.*, 1996; Borg-Stein, J. and Simons, D. G., 2002). The term myofascial pain was introduced in the early 1950s by Janet Travell. She also defined the term myofascial TrP and demonstrated with David Simons that individual muscles have specific nondermatomal patterns of TrP pain referral (Simons, D. G. *et al.*, 1999). In 1983, both authors first described the clinical picture and pathophysiology of a new syndrome which they named myofascial pain syndrome (MPS; Long, S. P. and Kephart, W., 1998; Simons, D. G. *et al.*, 1999). MPS has been defined as a chronic pain syndrome accompanied by TrPs in one or more muscles or groups of muscles. Similar to FM, it is more frequently found in women compared to men. Besides the presence of TrPs and referred pain, MPS is frequently associated with limitation of movement, weakness, and autonomic dysfunction (Long, S. P. and Kephart, W., 1998) similar to FM.

5.51.14 Trigger Points

TrPs represent areas of local mechanical hyperalgesia that can be found in MPS and several chronic pain conditions, including FM, osteoarthritis, and rheumatoid arthritis. They are defined as specific areas of hyperirritability in muscle, but can also be detected in ligaments, tendons, periosteum, scar tissue, or skin (Han, S. C. and Harrison, P., 1997; Simons, D. G. *et al.*,

1999). TrPs are located in palpable taut bands and produce local and referred pain, which is specific for the particular muscle. When TrPs are mechanically stimulated, so-called taut bands within a muscle, rather than the entire muscle, will contract (Chu, J., 1998). They are often associated with a local muscle twitch response, which can easily be elicited by needling or palpation of the TrP (Chu, J., 1998; 1999). Latent TrPs are similar to active TrPs, but they are not associated with spontaneous pain and no referral of pain occurs. However, latent TrPs are painful when palpated.

5.51.15 Relationship between Myofascial Pain and Fibromyalgia

Approximately 70% of patients with FM have TrPs (Granges, G. and Littlejohn, G., 1993). A TP is considered to be different from a TrP because of the absence of referred pain, local twitch response, and a taut band in the muscle. The distinction between TPs and TrPs requires careful physical examination. TrPs are frequently located in areas of muscular TPs of patients with FM (Wolfe, F. *et al*., 1992; Borg-Stein, J. and Stein, J., 1996) suggesting that some muscular TPs in patients with FM may actually be TrPs (Inanici, F. *et al*., 1999). The presence of TrPs in most if not all FM patients represents evidence for local muscle abnormalities in this chronic musculoskeletal pain syndrome. Although it is unclear if TrPs are the cause or effect of muscle injury, they represent abnormally contracted muscle fibers. This muscle contraction can lead to accumulation of histamine, serotonin, tachykinins, and prostaglandins, which may result in the activation of local nociceptors. Prolonged muscle contractions may also result in local hypoxemia and energy depletion (Simons, D. G. *et al*., 1999).

5.51.16 Inflammatory Connective Tissue Diseases

Many patients (up to 25%) with chronic arthritis have also wide-spread pain similar to FM. These patients may also present with symptoms of chronic fatigue, impaired memory and concentration, and mood abnormalities. Most of these patients, however, will have findings suggestive of inflammation, including joint pain/swelling, rashes, muscle weakness, as well as laboratory abnormalities, like elevated erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), anemia, autoantibodies (rheumatoid factor, cyclic citrullinated peptide antibodies, anti-nuclear antibodies (ANA)), etc.

5.51.17 Treatment of Fibromyalgia

Treatment of patients with chronic widespread pain like FM needs to be individually tailored to each patient's needs. This includes the assessment of biopsychosocial abnormalities which are readily detectable in most FM patients. Importantly the identification of pain generators is essential for an effective treatment plan. Thus patients with arthritis, particularly osteoarthritis of the spine will benefit from muscle relaxants, physical therapy, and massage. In addition, these patients may respond well to therapy with cyclo-oxygenase (COX) inhibitors. Identification and treatment of mood abnormalities is crucial because affective spectrum disorders seem to share important mechanisms with FM.

Pharmacotherapy for FM has been most successful with antidepressant, muscle relaxant, or anticonvulsant drugs. These drugs affect the release of various neurochemicals (e.g., serotonin, norepinephrine, substance P) that have a broad range of activities in the brain and spinal cord, including modulation of pain sensation and tolerance. None of these drugs, however, is currently approved by the US Food and Drug Administration for the treatment of FM.

Most FM patients will respond to low-dose tricyclic medications, such as amitriptyline and cyclobenzaprine, as well as cardiovascular exercise, cognitive behavioral therapy (CBT), patient education, or a combination of these for the management of FM. Also tramadol, selective serotonin reuptake inhibitors (SSRI), selective norepinephrine re-uptake inhibitors (SNRI), and anticonvulsants have been found to be moderately effective. There is some evidence for the efficacy of strength training exercise, acupuncture, hypnotherapy, biofeedback, massage, and warm water baths. However, many commonly used FM therapies like guaifenesine have been found to be ineffective.

The efficacy of FM patients to manage their pain seems to correlate with their functional status. Brain imaging and psychological profiles have identified at least three FM subgroups, that is, patients who are highly dysfunctional, interpersonally distressed, or are effective copers (Giesecke, T. *et al*., 2003). Such

studies provide an explanation why some treatments seem to be differentially effective in individual patients. Thus optimal FM management will require a combination of pharmacological and nonpharmacological therapies with patients and healthcare professionals working as a team.

5.51.18 Prognosis of Fibromyalgia

FM can be mild or disabling, but often has substantial emotional and social consequences. About 50% of all patients have difficulty with or are unable to perform routine daily activities. Estimates of patients who have had to stop working or change jobs range from 30% to 40%. Patients with FM suffer job losses and social abandonment more often than people with other conditions that cause pain and fatigue. Although FM symptoms seem to remain stable, several long-term studies indicate that physical function and pain worsen over time (Forseth, K. O. *et al.*, 1999; Baumgartner, E., 2002). Significant life stressors often result in a poor outcome, including diminished capacity to work, poor self-efficacy, increased pain sensations, disturbed sleep, fatigue, and depression. A recent study reported increased mortality in patients with widespread pain compared to those without chronic pain (McBeth, J. *et al.*, 2003). Although this study did not specifically evaluate FM, these findings may be relevant for FM patients. The higher mortality was mostly associated with malignancies, although the cause for this association is currently unknown.

5.51.19 Conclusions

The pathogenesis of FM pain is currently unknown, but up to 50% of the variance can be explained by central sensitization and distress. However, additional mechanisms like tonic peripheral nociceptive input may play an important role for the initiation and maintenance of the increased pain sensitivity of FM patients. FM, like many other chronic pain syndromes, is treatable, and remission can occur in many patients who actively participate in effective disease management programs. New treatment strategies, however, may benefit from interventions that improve peripheral and central pain sensitization as well as the affective disorders of FM patients.

Glossary

alpha EEG wave intrusion The intrusion of fast-frequency electroencephalographic (EEG) alpha (7.5–11 Hz) activity into slow wave sleep (SWS) or into deep sleep (stages 3 and 4). SWS is dominated by large and slow EEG waves of delta type (0.5–4.0 or 0.75–4.5 Hz); it also characterizes sleep stages 3 and 4. SWS is not a specific biological marker of pain during sleep.

sleep awakening (major arousal) A sudden increase in EEG and heart rate frequency with a rise in muscle tone that lasts more than 10 or 15 s. Subject is not usually aware of external influences. An excessive number of major arousals during sleep is frequently followed by a complaint of unrefreshing sleep and cognitive impairment the following day.

cyclic alternating pattern Repetition of micro-arousals every 20–60 s as a sentinel that allows for a reset of physiological functions (e.g., heart rate, respiration, muscle tone) or prepares the body for an appropriate response in relation to potential disrupting events.

micro-arousal A sudden increase, during sleep, in EEG activity and heart rate frequency under a cardiac sympathetic dominance with a possible rise in muscle tone. It should last more than 3 s but less than 10 or 15 s depending on scoring method. A sleeping subject is normally unaware of this physiological activity; it tends to be repeated 8–15 times per hour of sleep.

nociception The receiving and transmitting of noxious sensory signals from the periphery to the central nervous system.

pain An unpleasant and sensory, cognitive, and emotional experience normally associated or not with tissue damage, which usually requires a minimal level of consciousness for expression.

pain threshold The lowest experimental stimulation perceived as being painful by a conscious subject in 50% of the trials.

sleep A natural physiological and behavioral state usually characterized by a partial isolation from the environment except when an unpleasant or potentially harmful or life-threatening event is present.

sleep stage A division of the specific sleep period into sleep stages (St): light sleep (St 1 or 2), deep sleep (St 3 and 4) are both described as non-REM sleep, and the REM or paradoxical sleep. Most body movements occur in light non-REM sleep (periodic limb movement, sleep bruxism). Sleep apnea (cessation of breathing for more than 10 s) is dominant in deep sleep and in REM sleep. REM behavior disorder (RBD) is characterized by sudden movement in REM sleep that is normally associated with muscle hypotonia (behaviorally described as motor paralysis).

sleep fragmentation Interruption of any sleep stage by isolated or repetitive events such as sleep stage shifts (deeper to lighter), micro-arousals, frank awakenings, with or without low duration of deep St 3 and 4 sleep and possible alpha EEG wave intrusion. As a result, sleep continuity may be impaired and poor sleep quality (e.g., unrefreshing) is frequently reported upon awakening.

5.52.1 Pain in Relation to Sleep

5.52.1.1 Definition, Epidemiology, and Relevance

Pain is a sensation that usually requires a certain level of consciousness before it is interpreted as an unpleasant sensory experience. Most persistent pain states can trigger complaints of poor sleep quality. Poor sleep quality is reported in 50–90% of patients with the following chronic pain conditions: arthritis, cervical and orofacial pain, low back pain, cancer pain, fibromyalgia. (Atkinson, J. H. *et al.*, 1988; Dao, T. T. T. *et al.*, 1994; Morin, C. M. *et al.*, 1998; Smith, M. T. *et al.*, 2000; Dauvilliers, Y. and Touchon, J., 2001; Riley, J. L. III *et al.* 2001; Roizenblatt, S. *et al.*, 2001; McCracken, L. M. and Iverson, G. L., 2002). Sleep quality is also impaired in the presence of other medical conditions of which pain is a common symptom, including: headaches, irritable bowel syndrome, spinal cord injury, and metastatic breast cancer (Cohen, M. *et al.*, 2000; Menefee, L. A. *et al.*, 2000; Moldofsky, H., 2001; Widerstrom-Noga, E. G. *et al.*, 2001; Rains, J. C. and Penzien, D. B., 2002; Koopman, C. *et al.*, 2002; Okifuji, A. and Turk, D. C., 2002; Lavigne, G. J. *et al.*, 2005). According to a recent survey from the National Sleep Foundation (USA), up to 20% of the adult population reports that their sleep is disrupted by somatic discomfort and pain.

The interaction between pain and poor sleep is supported by cohort and case control studies. Patients with orofacial pain are 3.7 more times at risk of reporting poor sleep (Macfarlane, T. V. and Worthington, H. V., 2004). In a survey done in the USA with 1506 community women and men aged between 55 and 84, it was found that bodily pain was associated with a risk for complaints of insomnia (e.g., difficulty falling asleep, middle of the night/early morning awakenings, or nonrestorative sleep). Odds ratios for insomnia among those reporting bodily pain were estimated to be between 1.88 and 2.68 (Foley, D. *et al.*, 2004). It has also been reported that the prevalence of insomnia is 2 times higher in Canadian chronic pain patients in comparison to the general population without pain (Sutton, D. A. *et al.*, 2001; Moldofsky, H., 2001). A cross-sectional study done in Hungary with over 12 643 adults showed that insomnia-related complaints were 3 times higher in chronic pain patients than in nonpain subjects (Novak, M. *et al.*, 2004). Finally, the concomitance of sleep disorders and pain may modify the subjective sensation related to sleep quality (e.g., refreshing) since 50% of insomnia patients with pain reported that pain interfered with daily activities (Novak, M. *et al.*, 2004). Moreover, in the presence of bodily pain there is an increase (OR of 1.73) in self-reports of daytime sleepiness (Foley, D. *et al.*, 2004) a topic further described in the next section.

In explorations of the interaction between high pain intensity and poor sleep, it is important to consider that chronic pain is frequently concomitant with anxiety, fatigue, mood disturbance, depression, and poor physical fitness (Menefee, L. A. *et al.*, 2000b; Riley, III. J. L. *et al.*, 2001; Smith, M. T. *et al.*, 2000; McCraken, L. M. and Iverson, G. L. 2002b; Nicassio, P. M. *et al.*, 2002; Sayar, K. *et al.*, 2002; Yatani, H. *et al.*, 2002). For example, fatigue is frequently reported in chronic pain patients and can explain 6.5% of the variability between pain intensity and complaints of poor sleep. Depression may further explain up to 40% of this variability. The presence of frank sleep apnea, a major risk for fatigue and daytime sleepiness, seems to be relatively low in chronic pain patients, as reported in a recent review (Dauvilliers, Y. and Touchon, J. 2001; Donald, F. *et al.*, 1996). However, the cumulative effect of poor sleep over a given night and possibly over several nights also needs to be considered. While it is recognized that daytime sleepiness may result from long interruptions of respiration (more than 10 s is defined as sleep apnea), less information is available on the cumulative consequence of several briefer hypoxic events, which may alter cognitive function and brain metabolism (Bonnet, M. H. 1985; Wesenten, N. J. *et al.*, 1999; Stepanski, E. J., 2002; Martin, S. E. *et al* 1996; Van Dogen, H. P. *et al.*, 2003; Gozal, D. and O'Brien, L. M., 2004). Recent work in fibromyalgia, for instance, suggests the possibility of a high rate of sleep-related upper airway resistance syndrome that

when reversed by continuous positive airway pressure therapy, may improve daytime function (Gold, A. R. *et al.*, 2004). The impact of the above-mentioned variables on pain and sleep interaction and their reversal by continuous positive airway pressure (CPAP) needs to be further assessed in controlled and blind studies.

5.52.1.2 Cognitive Disturbances

Very few studies have investigated the effect of pain on cognitive functions such as memory and attention. Three studies using chronic musculoskeletal pain and fibromyalgia patients suggest a causative association (Kewman, D. G. *et al.*, 1991; Landro, N. I. *et al.*, 1997; Côté, K. A. and Moldofsky, H., 1997). The impact of cognitive deficits and their potential aggravation by disturbed sleep needs to be further studied. The potential impact of several classes of pain medication (e.g., opioids, anticonvulsants, muscle relaxants, antidepressants) on sleep and daytime alertness is also a particularly important line of research with real-life consequences ranging from sleep-related industrial accidents to impaired driving ability (George, C .F. P., 2003; Chapman, S., 2001). A recent experimental study done in normal volunteers showed that a one night infusion of morphine during sleep time can alter sleep quality by reducing deep-sleep duration and increasing sleep stage 2 duration (Shaw, I. R., *et al.*, 2005). Evidence-based data on long-term use of morphine on sleep homeostasis are missing.

5.52.1.3 Sleep Fragmentation and Deprivation

Sleep fragmentation is usually characterized by a rapid shift from a deeper sleep stage to a lighter one or by an increase in the number of brief arousals up to longer awakenings during the night (see Glossary for definitions). The number of body movements and respiratory disturbance events, which are often associated with arousals, seems to have an additive effect on daytime functioning over the following day or days. Sleep deprivation is a more general term that either characterizes the absence or very short duration of a given sleep stage and/or the near absence or reduction of sleep as tested by experimental manipulations. As recently demonstrated, measures of the impact of chronic sleep loss fall into a clear hierarchy: mood measures being more sensitive than cognitive tasks, which are in turn more sensitive than performance of motor tasks (Bonnet, M. H., 2005).

The increase in sleep fragmentation in normal subjects or in patients with sleep apnea seems to be clearly associated with a reduction in next-day performance, sleepiness, and impaired alertness (Bonnet, M. H., 1985; Wesenten, N. J. *et al.*, 1999; Stepanski, E. J., 2002; Martin, S. E. *et al.*, 1996; Van Dogen, H. P. *et al.*, 2003). A minimum of 5–6 h of sleep seems to be the threshold below which daytime performance is altered and, interestingly, several days are required before a return to baseline levels (Van Dogen, H. P. *et al.*, 2003). There is still no definitive evidence indicating that lack of deep sleep (St 3 and 4) or of slow wave EEG activity (SWA) increases pain sensitivity, although some animal and human experimental studies suggest such a link (see review from Kundermann, B. *et al.*, 2004a; Kundermann, B. and Lautenbacher, S., 2007). To our knowledge only one study has compared deep-sleep deprivation with other sleep stages or total sleep deprivation (Onen, A. H. *et al.*, 2001). Moreover, the absence of deep sleep is a feature of all chronic-pain conditions (Okura, K. *et al.*, 2004).

Before summarizing the studies on sleep deprivation and changes in pain perception, it is important to reiterate that study design and data analysis need to control for: (1) the differences between groups for age, since after 40 years of age, slow wave density, a dominant feature of deep sleep, tends to decline; (2) presence of respiratory disturbances during sleep, since patients with fibromyalgia who complain of daytime hypersomnolence tend to present with more micro-arousals, a higher number of short respiratory disturbances and longer oxygen desaturation periods than matched normal controls, an effect reversed by CPAP (Sergi, M. *et al.*, 1999; Gold, A. R. *et al.*, 2004); (3) the concomitant effect of fatigue, mood depression, anxiety, poor lifestyle habits, etc., as described above. In addition to the above issues, it is also important to note that the literature of sleep deprivation and pain is generally limited by experimental studies done with small sample sizes and a lack of adequate control groups.

Several studies have been conducted in normal subjects to assess the effect of deep-sleep deprivation on next-day pain perception. The disruption of sleep stage 4 or SWS by sound was associated with an increase in muscle tenderness and a reduction in pain threshold (mechanical pressure) the next morning, but this effect was less dominant when studies controlled for concomitant influences of fatigue (Moldofsky, H. and Scarisbrick, P., 1976; Lentz, M. J. *et al.*, 1999; Older, S. A. *et al.*, 1998). Negative findings have been reported by others (Drewes, A. M. *et al.*, 1997; Kundermann, B.

et al., 2004a; Older, S. A. *et al.*, 1998; Arima, T. *et al.*, 2001; Smith, M. T., *et al.*, 2007). Surprisingly, when normal subjects were deprived of SWA sleep, REM sleep or total sleep duration, no change in thermal pain threshold was noted during any of the sleep interruptions (Onen, A. H. *et al.*, 2001). In this study, however, total sleep deprivation slightly reduced mechanical pain tolerance scores (8%) and in the period after sleep recovery, a significant rebound effect was noted, such that mechanical pain tolerance was 15% higher. A recent study done in normal volunteers showed that two nights of total sleep deprivation reduced both heat and cold pain thresholds, but had no effect on warmth and cold detection threshold; results suggested that change in pain threshold was not specific to alterations in somatosensory function (Kundermann, B. *et al.*, 2004b). Kundermann and colleagues also suggested, in a comprehensive review, that the role of stress and changes in endogenous serotonin and opioid activity can also play an important role in arousal and changes in pain perception (Kundermann, B. *et al.*, 2004a).

It is important to clarify that experimental sleep deprivation, which has been induced in the above studies, is an extreme manipulation that may be different from the natural ongoing sleep disruption experienced by chronic pain patients. As described above, fragmentation or deprivation, not necessarily limited to St 3 and 4, seems to alter cognitive function and memory consolidation; all sleep stages seem to be equally important for the preservation and maintenance of daytime functions (Stickgold, R. *et al.*, 2000; Mednick, S. *et al.*, 2003; Gais, S. *et al.*, 2000).

5.52.1.4 Circadian Variation in Pain Perception

Surprisingly, most studies using normal nonpain subjects without mood alteration have failed to demonstrate a clear circadian variation in experimental pain threshold or pain intensity reports over a 24 h schedule or when comparing evening and morning data (Rogers, E. J. and Vilkin, B. 1978; Strian, F. *et al.*, 1989; Koltyn, K. F. *et al.*, 1999; Lavigne, G. J. *et al.*, 2000; Bentley, A. J. *et al.*, 2003; Lavigne, G. J. *et al.*, 2004). In patients with chronic pain, however, symptom presentation often has a typical circadian pattern. Arthritic pain is often worse in the morning, while pain levels related to fibromyalgia, myofascial orofacial pain, and some headache conditions are typically higher in the afternoon (Bellamy, N. *et al.*, 1991; Reilly, P. A. and Littlejohn, G. O., 1993; Dao, T. T. T. *et al.*, 1994). Furthermore, not all pain conditions involve pain that directly interferes with sleep; in patients with torticolis, pain is rapidly reduced by adopting the supine posture (Lobbezoo, F. *et al.*, 1996; Bentley, A. J., 2007).

5.52.2 Perception of Pain during Sleep: Nociception or Sleep Arousal

5.52.2.1 Nociception – Pain Perception during Sleep

While awake, tactile and thermal sensory input of sufficient intensity can activate A delta, A beta, and C sensory fibres projecting to the thalamus and several cortical areas (Bromm, B. and Lorenz, J. 1998; Coghill, R.C. *et al.*, 1994; Le Pera, D. *et al.*, 2000; Peyron, R. *et al.*, 2000). The long duration of painful hypertonic saline infusions seems to activate A delta and C afferent fibers that in the wake state reach the thalamus, amygdale, and other cortical areas associated with pain processing (Le Pera, D. *et al.*, 2000; Zubieta, J. K. *et al.*, 2001). During sleep, however, a putative gating process of somatosensory inputs is thought to prevent awakening resulting from irrelevant input or non-life-threatening events. Several studies suggest that sleep-preserving sensory gating mechanisms are likely to be located at the upper brain stem area (see Figure 1) in the so-called reticular activating system (Pompeiano, O. and Swett, J. E. 1963; Hernandez-Peon, R. *et al.*, 1965; Soja, P. J. *et al.*, 2001; Soja, P. J., 2007; Nofzinger, E. and Derbyshire, S. W. G., 2007). However, the balance between wakefulness system(s) and sleep-promoting neuronal network(s) in relation to sensory discrimination and pain during sleep is poorly understood and requires further investigation.

Regarding sensory perception during sleep, it is crucial to discriminate between studies made using sound and those using tactile stimulations. The results of sound studies have made it apparent that acoustic stimulation triggers more sleep arousals and awakenings in non-REM light sleep stages (St 1 and 2) than in deep sleep (St 3 and 4) or in REM sleep (Rechstaffen, A. and Kales, A., 1968; Carley, D. W. *et al.*, 1997; Kato, T. *et al.*, 2004). Sound is a different sensory modality from pain: its main function with respect to sleep is to alert the individual to wake up (alarm clock) or to parental duties (a baby's cry). Tactile stimulation, however, is more likely to be interpreted as a touch to the body, which may or may not enforce the awakening process and is likely to be interpreted differently than sound by a sleeping

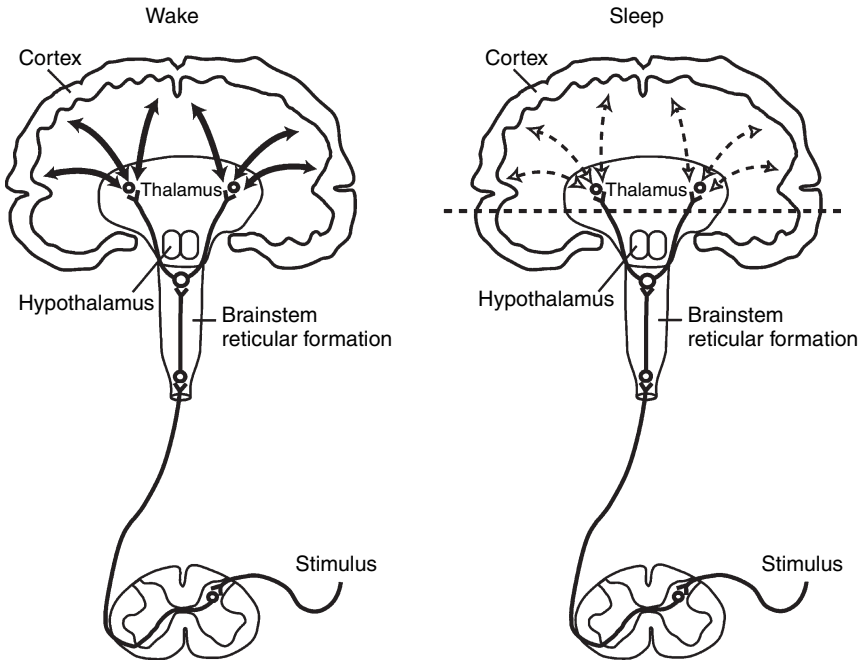

Figure 1 During wake state, there is a free flow in neuronal activity from spinal cord or/and brainstem to and from thalamus and cortical networks. During sleep, a gating mechanism seems to isolate the upper brain from most incoming inputs originating at somatosensory level. However, some circuits, for example, auditory processing, remain fully active. The exact anatomical site of the separation (see dashed line) between spinal and brainstem networks and thalamo-cortical pathways remain to be demonstrated.

brain (Velluti, R. A. *et al.*, 2000; Kato, T. *et al.*, 2004; Soja, P. J. *et al.*, 2001) Moreover, during sleep the term nociception is probably more accurate to describe the process of potentially harmful inputs, interpreted in conscious and awake subjects as pain (Bromm, B. and Lorenz, J., 1998; Lavigne, G. J. *et al.*, 2000).

Studies done in the 1960s, using tactile-cutaneous sensory stimulations during wake/sleep states, are a rich source of information (Pompeiano, O. and Swett, J. E., 1963; Hernandez-Peon, R. *et al.*, 1965) It was suggested that a filtering mechanism is active during synchronized or non-REM sleep at the first relay of neurons in the brainstem mesencephalic-reticular formation and in the trigeminal sensory nucleus. More recent work lends further support to the concept that sleep involves a selective isolation from the external milieu. Recordings of ascending spinoreticular and trigemino-thalamic tract neurons show that a gating mechanism seems to be present during sleep when brief sensory or pain stimulations are applied to the skin of the animal. Furthermore, the neurons behaved differently across sleep stages, that is, during non REM or REM sleep: air puff activated trigemino-thalamic tract neurons during REM sleep whereas neuronal activity following tooth pulp stimulation was suppressed (Cairns, B. E. *et al.*, 1996; Soja, P. J. *et al.*, 2001). It was further suggested that the serotoninergic and nonserotoninergic brainstem raphe magnus cells are involved to an important extent in the sensory modulation of pain inputs (Foo, H. and Mason, P., 2003). Interestingly, recording of thalamic cells in one human has confirmed previous animal findings suggesting that thalamic neurons discharge differently during states of waking and sleeping. It was observed that the discharge of thalamic neurons was in a tonic mode while the patient was awake and in a bursting mode when the patient was in light sleep; nevertheless none of these cells had a clear sensory receptive field in the periphery (Tsoukatos, J. *et al.*, 1997). These findings are similar to those from animal studies showing that thalamic neurons are under a global inhibition during sleep while cortical neurons, by contrast, are highly active (Steriade, M. and Timofeev, I., 2003). The exact location of the mechanism(s) supporting the somatosensory dissociation during sleep remains under investigation (see Figure 1). The balance between mechanisms that maintain vigilance or promote sleep continuity, however, seems to be state-dependent and related to the modulation of neuronal networks at the level of the reticular activating system.

The initiation of an awakening and conscious reaction during sleep may be secondary to a decrease in the sensory gating in sleep resulting in the recovery of the free flow between ascending and descending brainstem, thalamus and cortical activities (Siegel, J., 2004; Skinner, R. D. *et al.*, 2004). In other words, it is as if the reptilian brain maintains basic survival function during sleep, and interaction with thalamo-cortical networks depends on the nature (sound, touch, and harmful stimulus), magnitude, and duration of the stimulation. Obviously, this hypothesis needs to be supported by further evidence.

A recent paper summarizing the evidence on brain activation during sleep provides relevant information (Peigneux, P. *et al.*, 2003). During light sleep, pontine tegmentum and thalamus are deactivated while mesencephalic regions remain active. In deep sleep, all three structures are relatively deactivated while activity is largely maintained at the cortical temporal and insular lobe levels. Paradoxically, all the above structures are activated during REM sleep, although a strong dissociation is present: there is no peripheral efferent activity (e.g., the motor cortex does not trigger a movement except in the presence of sleep pathology: the REM behaviour disorder). There is little evidence strongly supporting a clear-cut gating of sensory information at the lower brain level, to prevent awakening from irrelevant sensory inputs. However, the role of the amygdala and the hypothalamus is discussed in the interpretation of sensory gating outside the higher thalamocortical levels (Morrison, A. R. *et al.*, 2000; Lee, R. S. *et al.*, 2001). A review of behavioral animal and human studies is also useful for a better understanding of the modulation of sensory inputs during sleep.

The interaction between the pain system and vigilance versus sleep is further supported by a cat study using the classical tail flick sensory motor reflex (Kshatri, A. M. *et al.*, 1998). It was suggested that the gating of sensory inputs during sleep depends on the integrity of the cholinergic system at the medial pontine–reticular level. This work also clearly showed, in comparison to the wake state and in the absence of any medication, that the reflex latency was 3 times longer in non-REM sleep (quiet sleep in animal) and 5 times longer in REM sleep. This finding again supports the concept of higher responsiveness to brief sensory inputs during non-REM in comparison to REM sleep. However, another cat study revealed that under tonic sensory nociceptive influences (formalin injection in the foot) the animals tended to remain awake with delayed sleep onset for the first 2 days, and a reduction in duration of deep sleep (St 3 and 4 in humans) and REM sleep stages (Carli, G. *et al.*, 1987) Interestingly, after 2 days, the animals recovered, exhibiting total sleep time and deep sleep of longer duration; a typical pattern seen after sleep deprivation (Onen, A. H. *et al.*, 2001; Kundermann, B. *et al.*, 2004a). Another sleep and pain study in rats, using the experimental adjuvant arthritis model in both hind paws, also showed fragmentation of the typical sleep and wake pattern (Landis, C. A. *et al.*, 1988). The number of brief sleep periods was increased over the circadian rhythm; total sleep time and deep sleep duration were also shorter in rats with arthritis. The above-mentioned animal studies suggest that a sleeping brain is not completely isolated from the external milieu and that pain-nociception can activate networks related to vigilance and body protection. This activation appears to be related to the type (phasic versus tonic, intensity, etc.) and duration of the painful stimuli (Velluti R. A. *et al.*, 2000; Soja, P. J. *et al.*, 2001; Kato, T. *et al.*, 2004; Lavigne, G. J. *et al.*, 2004).

In humans, the perception of pain during sleep also depends on the duration and type of stimulus used; brief sensory nerve-related or mild duration thermal or long duration chemical or mechanical stimulations initiate different types of responses that need to be interpreted accordingly. In a study using the spinal motor responses, following brief stimulation of the leg sural nerve to evoke a flexion reflex, it was noted that the reflex latency was prolonged during sleep in comparison to wake state (Sandrini, G. *et al.*, 2001). In parallel, the threshold was 60% higher in non-REM and 200% higher in REM sleep than during wake state. This study supports the above-mentioned animal findings, suggesting that during sleep lower brain neurons modulate pain inputs in such a way that a hypoalgesic response seems to be present. In contrast, when sensory processing from periphery to cortex was estimated with extremely brief (<60 ms) sensory-laser or electrical evoked responses to pain, the somatosensory cortically evoked potential completely disappeared during light sleep (Bedyoun, A. *et al.*, 1993; Wang, X. *et al.*, 2003). This absence of somatosensory evoked potentials during sleep stands in contrast to similarly present auditory stimuli in which evoked potentials are largely preserved during sleep. Sound appears to play a more sensitive role in preserving bodily integrity during sleep than tactile-somatosensory input (Kato, T. *et al.*, 2004). Alternatively, in collaboration

with the Italian Milano sleep group, we found that longer (6–12 s) moderate heat pain stimulation (46 °C) applied over the upper arm can evoke a clear sleep behavioral response: nearly twice the number of micro-arousals (see Glossary for definition) in light non-REM sleep compared to deep or REM sleep (Lavigne,G. J. *et al.*, 2000). These results were confirmed by another group that found that higher thermal pain temperatures were required to elicit arousal during deep sleep and REM in comparison to light sleep. These temperatures were closer to waking pain tolerance levels instead of pain threshold level (Bentley, A. J. *et al.*, 2003). More recently, with the objective of challenging sensory pain processing across sleep stages, we used a hypertonic saline infusion in the arm muscle to mimic longer clinical pain episodes (>100 s). A similar procedure has been used by others during sleep (Drewes, A. M. *et al.*, 1997). Interestingly, we found that micro-arousal responses were also more dominant in light sleep in comparison to deep and REM sleep, and a clear and dominant sleep awakening response was present with an equipotent response rate in all sleep stages (Lavigne, G. J. *et al.*, 2004).

This evidence suggests that when a painful stimulus or a clinical pain episode lasts long enough, the protective mechanism that maintains sleep continuity (the gating barrier to irrelevant input) is released and a clear behavioral response may occur with a potential return to consciousness. Recent clinical evidence for impaired somatosensory gating during sleep in chronic pain conditions has been suggested by findings of decreased sleep spindle activity in chronic low back pain and fibromyalgia patients (Harman, K. *et al.*, 2002; Landis, C. A. *et al.*, 2004). Thus it can be hypothesized that brief sensory stimuli, such as electrical or thermal pain, are too brief to be processed by a sleeping brain as potentially harmful, whereas longer-lasting or tonic painful stimuli akin to clinical pain states are more likely to elicit a full-blown arousal response.

5.52.2.2 Sleep Arousal: Brain and Autonomic Activation

The above arousal and awakening responses observed with thermal and deep muscle infusion are not only restricted to a cortical activation as seen on electroencephalogram. They are also associated with a clear increase in heart rate and a change in respiration that is frequently interrupted with the onset of the pain stimulation (Lavigne, G. J. *et al.*, 2000; Lavigne, G. J. *et al.*, 2001; Bentley, A. J. *et al.*, 2003; Lavigne, G. J. *et al.*, 2004). It is interesting to note that the so-called fast alpha EEG intrusion, which for a long time was believed to be a marker of pain in relation to sleep, is not considered to provide the sole explanation for poor sleep in pain patients (Moldofsky, H., 2001; Mahowald, M. L. and Mahowald M. W., 2000; Roizenblat, S. *et al.*, 2001; Rains, J. C. and Penzien, D. B., 2003). More recent thinking conceptualizes pain as a disruptor of sleep homeostasis that may increase sleep arousal instability, described as an augmentation in the normal cyclical alternating pattern in which brain and cardiac activation tends to recur in clusters (Staedt, J. *et al.*, 1993; Moldofsky, H., 2001; Roizenblatt, S. *et al.*, 2001; Parrino, L., Zucconi, M. and Terzano, M. G., 2007).

Cardiac activation during sleep is used as an indirect estimate of sympathetic (e.g., accelerator) and parasympathetic (decelerator or brake) balance during wake and sleep states. During wake state, a sympathetic dominance predominates, maintaining a high level of vigilance. Sympathetic-cardiac dominance is also present during REM sleep, a state with high cortical and cardiac activity but with a behavioral muscle paralysis. Conversely, during non-REM sleep, parasympathetic-cardiac activity is dominant and this may provide a recuperative function since there is an inverse coupling: a low sympathetic dominance is inversely coupled with a high degree of SWA in each consecutive non-REM to REM cycle (Brandenberger, G. *et al.*, 2001). Interestingly, in insomnia and fibromyalgia patients, a sympathetic dominance persists across NREM sleep cycles at levels similar to wake and REM sleep states (Bonnet, M. H. and Arand D. L., 1998; Martínez-Lavín, M. *et al.*, 1998). It has been hypothesized that enhanced sympathetic activity during sleep may over-facilitate arousal mechanisms and cyclical patterns of brain activation. However, this hypothesis was not supported in a study of medication-free women suffering from fibromyalgia in comparison to women with efficient sleep and no pain (McMillan, D. *et al.*, 2004). By contrast, when patients with chronic fibromyalgia (widespread pain) and pain (low back, etc.) presenting with poor sleep efficiency were matched for age and gender to normal sleepers, we found (see Figure 2) that the normal parasympathetic and sympathetic balance was lost in both pain groups during non-REM sleep with an inverse coupling of SWA, that is, a lower density of SWA was observed during consecutive sleep stages compared to control

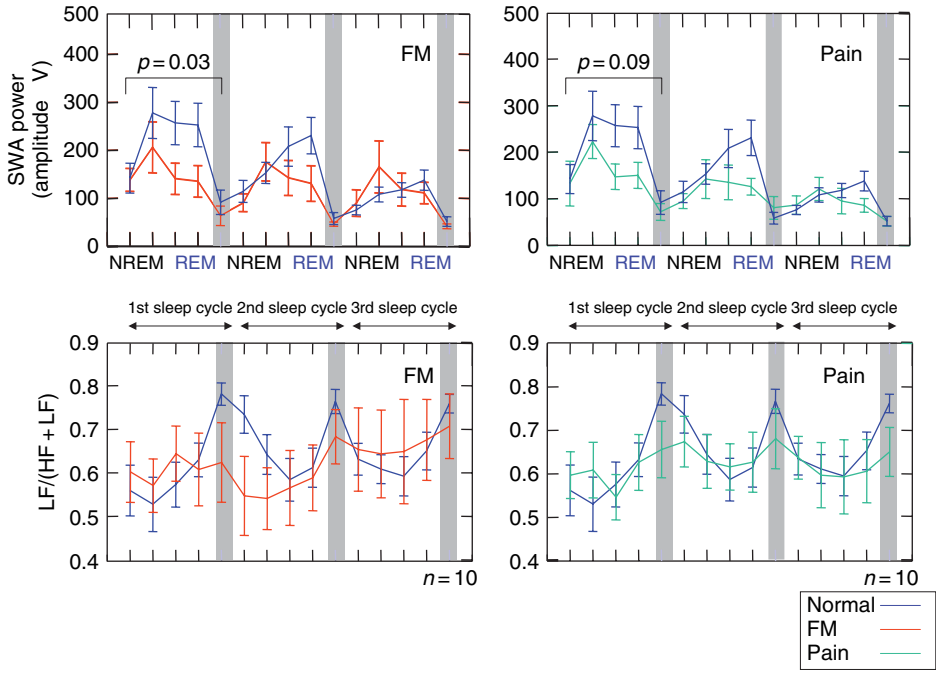

Figure 2 Dynamics of SWA and HRV over three consecutive sleep cycles. In normal subjects, SWA shows an inverse coupling with sympathetic activity (low-frequency divided by high-frequency plus low-frequency. One of the heart rate variability: HRV). During non-REM sleep, SWA was high when the sympathetic cardiac activity was low, and, conversely, SWA was low when HRV was high in REM sleep. In comparison to normal subjects, fibromyalgia (FM) chronic widespread pain patients showed a significant reduction in SWA for the first sleep cycle only (*t*-test: $p = 0.03$). Chronic pain patients (PAIN) also presented a similar trend in SWA, but not statistically significant (*t*-test: $p = 0.09$). PAIN patients did not show a rise in sympathetic activity during REM sleep ($p =$ NS: repeated ANOVA); FM patients showed a trend toward no rise in REM sleep.

subjects (Okura, K. *et al.*, 2005). Furthermore, like previous studies of men with fibromyalgia in a wake state, our preliminary analysis suggests that men maintain a high sympathetic activity across all sleep stages (Cohen, H. *et al.*, 2001). Women, however, do not show the usual rise in sympathetic activity during REM sleep. Our data differ from those of (Martinez-Lavin, M., *et al.*, 1998) since we separated data into consecutive non-REM and REM cycles. Caution is needed when interpreting the above-mentioned observations since parasympathetic and sympathetic balance tends to be altered with age and acute stress in relation to sleep (Brandenberger, G. *et al.*, 2003; Hall, M. *et al.*, 2004).

5.52.3 Circular Relation between Pain and Poor Sleep and Putative Consequence on Health Cost

The initiation of pain (e.g., acute post-op or trauma) usually precedes or coincides with the onset of poor sleep in close to 53–89% of patients (Morin, C. M. *et al.*, 1998; Smith, M. T. *et al.*, 2000; Riley, J. L., III *et al.*, 2001). In other words, in retrospective accounts, sleep disturbance is generally not considered a major problem for many patients until an injury is experienced; then pain and sleep become salient interacting issues. Intensive, time-series diary studies using multilevel modeling statistical techniques consistently show that over time, a day with intense pain is frequently followed by a poor sleep quality and subsequent ratings of poor sleep are in turn linked to next-day increases in clinical pain. This circular relationship, also described as a vicious circle, has been observed in patients with fibromyalgia, severe skin burns, and rheumatoid arthritis (Affleck, G. *et al.*, 1996; Raymond, I. *et al.*, 2001; Stone, A. A. *et al.*, 1997; Nicassio, P. M. *et al.*, 2002; Lavigne, G. J. *et al.*, 2005). As has been mentioned above, the influences of fatigue, mood alteration, other sleep disorders (such as sleep apnea or periodic limb movement), and medication use have not been well controlled for in these studies.

No direct data, to our knowledge, reports on the cost of pain and its interaction with poor sleep. However, an extensive study done in a Canadian

population (125 574 respondents) estimated that for every four patients seen by a family physician, three will report chronic pain (Meana, M. *et al*., 2004). When the potential cognitive disruption of pain medications is considered together with the rates at which analgesic, antidepressant, codeine, and hypnotics medications are used (3–4 times more often by women with chronic pain), it becomes apparent that the reduced ability of chronic pain patients with poor sleep to perform daily tasks is a societal burden (Meana, M. *et al*., 2004b). Moreover, given the aging population and the high prevalence of chronic pain (reported by over 50% of elderly of both genders), it is clear that health managers have a major challenge in planning service use (Harstall, C. and Ospina, M., 2003; Meana, M. *et al*., 2004).

The economic cost of chronic pain can probably be estimated in the order of billion dollars from headaches to pelvic pain; obviously specific estimation needs to be done. The large range of costs, for various pain symptoms and syndromes, reflects a lack of reliable information, although it is clear that chronic pain conditions are extremely costly (Latham, J. and Davis B. D., 1994). To date, an approximate estimate of the additional burden that poor sleep places on chronic pain costs can be only derived from cost studies of insomnia, which have yielded estimates ranging from 77 to 92 billion dollars (Stoller, M. K., 1994). If we agree that the suggested prevalence of chronic pain in adult population stands at 11% (Harstall, C. and Ospina, M., 2003) and that insomnia (defined as difficulties in sleep onset or in maintaining sleep and/or perception of nonrestorative sleep) is reported conservatively at a similar prevalence (Martin, S. A. *et al*., 2004) we can extrapolate, based on the assumption that one chronic pain patient in two will report similar insomnia complaints, that the overall direct cost is probably over 1 billion dollars. Indirect costs arising from as sick leave, hospitalization, and vehicular accident also need to be estimated, as has been done for other sleep disorders (Barbé, F. *et al*., 1998; George, C. F. P., 2003).

There is an obvious need for prospective and systematic studies of pain and economics that will estimate cost of health care, corrected for concomitant conditions such as aging, diabetes, obesity, cardiovascular problems, sleep disorders, depression, and anxiety (Lavigne, G. and Manzini, C., 2007). Moreover, indirect cost of absenteeism, low working performance, accident, reduced familial activities and risk of divorce also need to be factored into estimates of the cost of pain in relation to poor sleep.

5.53.1 Introduction

Chronic pain is a complex integration of sensory, affective, and cognitive processes encompassing a variety of clinical conditions that have been generalized as nociceptive (rheumatoid and osteoarthritis (OA)), neuropathic (postdiabetic neuropathy, posttraumatic neuralgia), or etiologically mixed (low back pain, cancer pain; for references see Merskey, H. *et al*., 2005; Campbell, J. N. *et al*., 2006). Pain conditions are etiologically diverse and there is limited understanding of clinical pain mechanisms and of environmental and social factors that aggravate pain such as stress and anxiety. In addition, it has been difficult to provide a unifying linkage of pain symptoms with the cellular mechanistic processes underlying these symptoms that would rationalize chronic pain therapy. The complexity of chronic pain is further reflected in the diversity of molecular targets considered to drive pain processes. Furthermore there is the evolving view that the pharmacology of pain may alter with time-dependent expression of targets, in the initiation versus the maintenance phases of pain, and that target expression is state-dependent (related to relative activity of the pain process or pathway). Thus poor understanding of pain pharmacology has seriously hampered the introduction of new drugs as there have been few drugs introduced with a new mechanism of action within living memory.

A recent step to building rational pain therapy has embraced a mechanism-based approach guided by advances in pain pharmacology. Thus major symptoms such as hyperalgesia, allodynia, and spontaneous pain have been linked with some of the identifiable, and often overlapping, neural cellular processes. The key processes are considered to be sensitization (reduced threshold for stimulation of pain pathways), hyperexcitability (amplification or

prolongation of nerve discharges in pain pathways), and spontaneous nerve activity (ectopic and/or spontaneous discharges in pain pathways). These processes or mechanisms are driven by molecular changes that provide the targets for pharmacological characterization and analgesia intervention (summarized in Figure 1). It is important to remember that for the most part these neural mechanisms and their molecular drivers have been explored in animal models and rarely consolidated to the same degree in human studies.

There have been a number of excellent reviews of pain mechanisms and molecules (Hunt, S. P. and Mantyh, P., 2001; Scholz, J. and Woolf, C. J., 2002; Watkins, L. R. and Maier, S., 2002) in the peripheral nervous system and central nervous system (CNS). Causative factors for pain are inflammatory mediators, factors released and made in response to nerve injury, phenotypic changes in neural pathways as well as supporting glial cells, structural modifications including nerve sprouting (sympathetic and sensory fibers), nerve rewiring (sensory and CNS fibers), and neurodegeneration of specific neurons in the CNS resulting in a hyperexcitable nervous system. Specific molecular interactions that drive the aforementioned excitability changes may differ according to the specific injury and consequent chemical environments that are created. The molecular interactions involve all major families of regulatory proteins (G-protein-coupled receptors (GPCRs), ion channels, regulatory enzymes, neurotrophins, kinases), offering an abundance of analgesic targets and therapeutic opportunities. The pharmacology of these targets is evolving and is dependent on the availability of reliable chemical and biopharmaceutical tools.

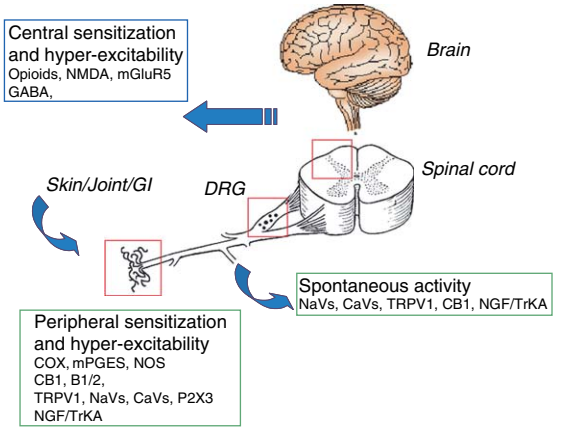

Figure 1 Mechanistic processes in chronic pain and key molecular drivers.

In this chapter I have selected from the emerging pharmacology of pain molecular approaches (summarized in Table 1) that will provide direction for future pain treatments.

5.53.2 G-Protein-Coupled Receptors

GPCRs have been a relatively tractable family of drug targets in a number of therapeutic arenas. A variety of GPCRs are involved in regulating neural excitability in pain pathways, often through the action of a variety of inflammatory mediators. These mediators act peripherally or centrally, via an equally large variety of specific membrane receptors (Scholz, J. and Woolf, C. J., 2002). In general, GPCRs signal via the production of second messengers (cyclic adenosine monophosphate (cAMP), cyclic guanosine monophosphate (cGMP), diacylglycerol (DAG), phospholipase C (PLC)) coupled with intracellular protein kinases and phosphatases (protein kinase A, several isotypes of protein kinase C (PKC)) which in their turn, phosphorylate and dephosphorylate specific cellular proteins including ligand- (e.g., TRPV1) and voltage-gated membrane ion channels (e.g., NaV1.8) which are important in regulating nerve excitability.

5.53.3 Opioids and Their Receptors

Opioids, and morphine in particular, are among the most effective pain medications. They act at peripheral, spinal, and supraspinal sites through a variety of opioid receptors (μ-, δ-, and κ-opioid receptors). These receptors are considered to be targets for an endogenous opioid system that has been extensively reviewed (Yaksh, T. L., 1997). μ-Opioid receptor activation commonly causes a variety of well-documented, target-related, CNS side effects including sedation, dysphoria, respiratory depression, and constipation. Thus there has been a vigorous attempt to exploit the peripheral antinociceptive actions of opioids as a means of avoiding CNS side effects. In support of this approach, sensory neurons express and transport opioid receptors to both the central and peripheral terminals. At central terminals, opioids reduce transmitter release from primary afferent nociceptors, thus blocking synaptic transmission while in the periphery opioid receptor activation directly hyperpolarize sensory neurons and attenuate nerve sensitization or hyperexcitability induced by inflammation or injury (Hurley, R. W. and Hammond, D. L., 2000; Sawynok, J., 2003).

Table 1 Pharmacological modulators of pain and emerging mechanisms of action and clinical indications.

Molecular Target	*Pharmacological tools*		*Analgesia mechanism and targeted tissue*	*Pain indications*
	Agonist	*Antagonist*		
μ-Opioid receptors	Morphine, fentanyl	Naloxone, naltrexone	Agonist: reduced peripheral and CNS excitability	Acute and chronic pain states
δ-Opioid receptor	Enkephalin, DPDPE, SNC80	Naltrindole	Agonist: Modulation of CNS pathways	Nociceptive and inflammatory
B1 receptor	Des Arg9 bradykinin	des Arg10, HOE-140; SSR240612, NVP-SAA 164	Antagonist: inflammatory tissue: pain pathway: PNS, CNS	Nociceptive and inflammatory
B2 receptor	Bradykinin	Icatibant, bradyzide	Antagonist: inflammatory tissue: pain pathway: PNS, CNS	Nociceptive and inflammatory
PAR2	Proteases	Unknown	Antagonist: PNS	Nociceptive and inflammatory
CB1	THC, anandamide, 2-arachidonylglycerol, palmitoylethanolamide, WIN55, 212-2, ajulemic acid	SR141716A (rimonabant), SR147778,	Agonist: Pain pathways PNS and CNS	Nociceptive and neuropathic
CB2	THC, anandamide, 2-arachidonylglycerol, palmitoylethanolamide, WIN55, 212-2, ajulemic acid, GW405833, HU-308, AM 1241	SR144428	Agonist: Pain pathways PNS and CNS	Nociceptive and neuropathic
SNSR	BAM8-22, γ2-MSH	Unknown	Antagonist: PNS	Nociceptive
COX-1 constitutive		Ibuprofen, naproxene	Inhibition of PG synthesis	Nociceptive and inflammatory
COX-2 induced		Ibuprofen, naproxene, celecoxib, rofecoxib	Inhibition of PG synthesis in PNS and CNS	Nociceptive and inflammatory
mPGES		Unknown	Inhibition of PG synthesis in PNS and CNS	Nociceptive and inflammatory
IL-1β	IL-1β	Unknown	Antibody versus ligand	Nociceptive and neuropathic
TNF-α	TNF-α	Anti-TNF, etanercept, adalimumab	Antibody versus ligand	Nociceptive and neuropathic
α-2	Clonidine, dexmedetomidine		Inhibition of neuroexcitability in PNS and CNS	Nociceptive and neuropathic
iGluR	Glutamate, kainate, AMPA, NMDA	LY293558, GV196771, ifenprodil, CP-101, 606	Antagonist: CNS pathways	Nociceptive and neuropathic
mGluR (5)	Glutamate	MPEP, SIB1757	Antagonist: CNS pathways	Nociceptive and neuropathic
$GABA_A$	Muscimol	Bicuculline	Agonist: reduced CNS excitability	Nociceptive and neuropathic
$GABA_B$	Baclofen	CGP35348	Agonist: reduced CNS excitability	Nociceptive and neuropathic
TRPV1	Capsaicin	Capsazepine, DD161515, SB705498	Antagonist: PNS excitability	Nociceptive and neuropathic
TRPA1	Cinnamaldehyde	Unknown	Antagonist: PNS	Neuropathic

(*Continued*)

Table 1 (Continued)

Molecular Target	*Pharmacological tools*		*Analgesia mechanism and targeted tissue*	*Pain indications*
	Agonist	*Antagonist*		
TRPM1	Menthol, icilin	Unknown	Antagonist: PNS	Neuropathic
P2X3	ATP, α, β-methy ATP	A-3174919	Antagonist: PNS	Nociceptive
P2X4	ATP	TNP-ATP	Antagonist: CNS	Neuropathic
P2X7	ATP	Unknown	Antagonist: CNS and PNS excitability	Nociceptive and neuropathic
ASIC1-3	Low pH	A-317567	Antagonist: PNS	Nociceptive
NaV1.3, NaV1.8, NaV1.7, NaV1.9		Lidocaine, mexiletine, lamotrigine	Blocker: PNS excitability	Nociceptive and neuropathic
CaV2.2		SNX-111, NMED-160	Blockers: PNS and CNS excitability	Nociceptive and neuropathic
CaV3.2		Ethosuximide	Blocker: PNS	Neuropathic
NGF	NGF	ALE0540, PD90780, RN624 (mAb)	Antiligand: PNS excitability	Nociceptive and neuropathic
P38-kinase	ATP	SB203580, CNI-14930	Blocker: PNS and CNS excitability	Nociceptive and neuropathic
iNOS		L-NAME, GW27415	Blocker: PNS and CNS excitability	Nociceptive and neuropathic

AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid; ATP, adenosine triphosphate; B, bradykinin; CaV, voltage-gated calcium channels; CB, cannabinoid; CNS, central nervous system; COX, cyclo-oxygenase; DPDPE, [D-Pen2,D-Pen5]-enkephalin; GABA, gamma-aminobutyric acid; iNOS, inducible nitric oxide synthase; L-NAME, L-N-nitro-L-arginine methyl ester; mGluR, metabotropic glutamate receptor; MPEP, 2-methyl-6-(phenylethynyl)-pyridine; mPGES, microsomal-associated prostaglandin E synthase; NaV, voltage-gated sodium channel; NGF, nerve growth factor; NMDA, *N*-methyl-D-aspartic acid; PAR, protease-activated receptor; PG, prostaglandin; PNS, peripheral nervous system; SNSR, sensory neuron specific receptor; THC, tetrahydrocannabinol; mAb, monoclonal antibody; TNP-ATP, 2′,3′-*O*-(2,4,6-trinitrophenyl) adenosine 5′-triphosphate.

In addition peripherally mediated opioid analgesia may be enhanced because μ-opioid receptor expression is increased by inflammation and nerve injury (Stein, C. *et al.*, 2003). This is also accompanied by a peripheral increase in the expression of opioids peptides. Novel opioids such as [8-(3,3-diphenyl-propyl)-4-oxo-1-phenyl-1,3,8-triazaspiro[4.5]dec-3-yl]-acetic acid (DiPOA) and the antidiarrheal drug loperamide, whose distribution is peripherally restricted, have shown efficacy in a number of post-operative, inflammatory, and neuropathic pain models (Whiteside, G. T. *et al.*, 2005a; Shidoda, K. *et al.*, 2006).

The pharmacology and analgesic efficacy of δ-opioid receptors (DOR) have also been explored since there is a potential for analgesic efficacy without the confounding side effects of other opioid (μ and κ) receptor therapies. A variety of studies have supported the concept that δ-selective ligands produce analgesia without notable sedation, respiratory depression, or inhibition of gastrointestinal motility. These studies have used genetic methods ranging from the knockdown of receptors to deletion of the DOR gene as well as pharmacological tools such as selective peptides and nonpeptide agonists ([D-Pen2,D-Pen5]-enkephalin (DPDPE), SNC80, AM-390) and antagonists (e.g., naltrindole; see Dray, A., 1999 for references).

δ Ligands may provide less analgesic efficacy than morphine but their effectiveness appears to depend on the pain stimulus, the type of injury, and the influence of their neurochemical environment. Thus, systemically administered δ ligands have low analgesic efficacy in acute pain models but show robust analgesia efficacy in a variety of chronic pain conditions accompanies by inflammation (Cahill, C. M. *et al.*, 2001). Enhanced activity has been attributed to stimulus-induced trafficking of DOR from the cytoplasm to nerve membranes in CNS neurons (Cahill, C. M. *et al.*, 2001). Activity and environment-dependent receptor trafficking also appears as an important regulatory mechanism in sensory neurons (Bao, L. *et al.*, 2003) but further studies are required to understand the significance of this in clinical pain and analgesia.

5.53.4 Kinins and Their Receptors

Bradykinin is an important peptidic mediator of inflammatory pain causing nociceptor activation and sensitization via constitutively expressed bradykinin B2

receptors (BK2) on peripheral nociceptors (Dray, A., 1997). It also stimulates the production and release of prostaglandin (PGs) cytokines and nitric oxide (NO). The abundant metabolite of bradykinin, des Arg9 bradykinin (kallidin), activates BK1 receptors which also occur constitutively, but in low abundance, in the periphery (Dray, A. and Perkins, M. N., 1993; Wotherspoon, G. and Winter, J., 2000) and in the primate CNS (Shughrue, P. J. *et al.*, 2003). Both receptors are coupled to similar transduction mechanism including G-αi and G-αq causing stimulation of DAG, PLC, and the release of intracellular calcium.

BK2 receptors are considered to undergo desensitization following prolonged kinin exposure, whereas BK1 receptors do not desensitize rapidly and thus may promote more prolonged pain and inflammation. In keeping with this, BK1 receptors are dramatically unregulated in many tissues, including sensory neurons (Levy, D. and Zochodne, D. W., 2000) and spinal cord (Fox, A. *et al.*, 2003; Ferreira, J. *et al.*, 2005), following tissue or ultraviolet injury (Eisenbarth, H. *et al.*, 2004) or traumatic nerve injury and by mediators such as interleukin (IL)-1β or the neurotrophin glial cell line-derived neurotrophic factor (GDNF; Fox, A. *et al.*, 2003; Valleni, V. *et al.*, 2004). These kinins cause a cascade of secondary changes, including prostanoid production, phosphorylation of signaling proteins such as PKC, and the sensitization of sensory transducers such as the TRPV1 receptor (Marceau, F. *et al.*, 1998). These events are linked with heat and mechanical hyperalgesia (Liang, Y. F. *et al.*, 2001; Fox, A. *et al.*, 2003).

There is an abundance of evidence supporting the analgesic potential of BK2 receptor antagonists (Stewart, J. M., 2004). For example, BK2 antagonists (icatibant [HOE-140], bradyzide) and BK1 antagonist (des Arg10 HOE-140; SSR240612) produce robust antihyperalgesic effects in a variety of animal models of inflammatory hyperalgesia (Burgess, G. M. *et al.*, 2000; Fox, A. *et al.*, 2003, Gougat, J. *et al.*, 2004) as well as in models of nerve injury-induced hyperalgesia (Gabra, B. H. and Sirois, P., 2003). In keeping with this deletion of the BK receptor genes reduces immune cell chemotaxis, spinal sensitization, as well as heat and mechanical allodynia following traumatic and diabetic nerve lesions (Pesquero, J. B. *et al.*, 2000; Ferreira, J. *et al.*, 2005; Gabra, B. H. *et al.*, 2005). To strengthen the translation of BK1 receptor therapy to humans, transgenic mice expressing human BK1 receptors, show robust inflammatory pain that was attenuated by the oral administration of the human-selective BK1 antagonist NVP-SAA 164 (Fox, A. *et al.*, 2005).

Kinin antagonists have not been extensively evaluated in clinical pain although they inhibit other kinin-mediated changes in humans, for example, cancer, allergy, and vasodilatation. However, recent clinical study using a single dose intra-articular joint administration of Icatibant (Flechtenmacher, J. *et al.*, 2004) produced long-lasting (up to 1 week) relief of movement-related pain in patients suffering from OA. This study highlights a strong proof of principle for BK2 involvement in OA and that localized monotherapy with a selective antagonist can produce significant pain relief.

5.53.5 Protease-Activated Receptors

Several proteases, from circulating inflammatory cells and vascular epithelium, cleave a variety of protease-activated receptors (PARs) that are associated with sensory neurons (Vergnolle, N. *et al.*, 2003). PAR2 in particular has been highlighted as a regulator of sensory nerve excitability and plays an important role in inflammatory hyperalgesia. Thus PAR2 agonists contribute to neurogenic inflammation through the stimulation of peripheral substance P and calcitonin gene-related peptide (CGRP) release and to spinal hyperexcitability via release of these neuropeptides in the spinal cord. PAR2 receptor activation directly increases dorsal root ganglion (DRG) excitability and sensitizes TRPV1 receptors via a PKC mechanism (Amadesi, S. *et al.*, 2004); thus contributing to inflammation-induced hyperalgesia. In keeping with this, deletion of the *TRPVR1* gene or pretreatment with the TRPV1 antagonist capsazepine, abolished PAR2-induced thermal hyperalgesia, suggesting that TRPV1 is required for PAR2-induced hyperalgesia. PAR1 is also coexpressed on peptide-containing DRGs, and although PAR1 agonists induce neurogenic inflammation they do not sensitize TRPV1 receptors, nor do they induce hyperalgesia. Overall these data suggest that PAR2 antagonists would have antihyperalgesic activity (Mantyh, P. W. and Yaksh, T. L., 2001)

5.53.6 Cannabinoids and Their Receptors

Two major cannabinoid receptor subtypes, CB1 and CB2 are associated with pain modulation and have received much attention in recent years (reviewed by Fox, A. and Bevan, S., 2005). These receptors are

widely distributed in the nervous system but CB1 receptors are located in greatest abundance in the CNS and on peripheral sensory neurons. CB2 receptors have been found mainly in peripheral tissues including immune tissues and keratinocytes (Hohmann, A. G. and Herkenham, M., 1999; Rice, A. S. C. *et al.*, 2002) but more recently on some sensory and CNS cells. Several fatty acids, for example, anandamide, 2-arachidonylglycerol, and palmitoylethanolamide, have been identified as endogenous ligands for these receptors and are termed endocannabinoids. They are released from postsynaptic nerve terminals to modulate postsynaptic excitability and transmitter release at presynaptic elements via Gi/Go-coupled activity. Specific antagonists such as SR141716A and SR147778 for CB1 and SR144428 for CB2 have been used to characterize receptor functions.

For the most part CB1 receptors are located on neurons where activation causes attenuation of presynaptic N-calcium channel activity and inhibition of transmitter release (Kreitzer, A. C. and Regeher, W. G., 2002). In contrast, activation of neuroglia (astrocytes, microglia) is accompanied by *de novo* expression of both CB1 and CB2 and increased release of endocannabinoids (Stella, N. 2004). Specifically CB2 receptors are expressed in spinal microglia following peripheral nerve lesions but not by peripheral inflammation (Zhang, J. M. *et al.*, 2003). The significance of this is presently unclear although prolonged CB receptor activation has been associated with increased expression of neuroprotective modulators such as brain-derived neurotrophic factor (BDNF; Marsicano, G. *et al.*, 2003).

Both CB1 and CB2 receptor types have been shown to have a key role in the modulation of nociceptors. Although CB1 effects have been best characterized, the mechanism and sites of action are incompletely understood. It is likely that an interplay of several CB1-driven systems occurs during acute or chronic pain. Brainstem structures appear to be important. For example, CB1-induced local activation of the periaqueductal gray (PAG; by stress-induced release of endocannabinoids) has been suggested to be involved in aversive responses and acute stress-induced analgesia (Finn, D. P. *et al.*, 2004; Hohmann, A. G. *et al.*, 2005). This was blocked by SR141716A (rimonabant, the CB1 antagonist) but not by naltrexone (μ-opioid antagonist). Paradoxically, recent data suggest that deletion of the CB1 receptor in mice is associated with a greater vulnerability to stress (Fride, E. *et al.*, 2005). Finally CB1-induced analgesia has been proposed to be driven by activation of descending inhibitory mechanisms. In keeping with this, block of the descending noradrenergic systems (Gutierrez, T. *et al.*, 2003) has been proposed to account, in part, for CB1-induced antinociception.

Several studies have now shown that CB2 agonists modulation acute pain, for example, AM1241 and GW405833 (incision model) (LaBuda, C. J. *et al.*, 2005) while GW405833 has been reported to exhibit efficacy in neuropathic and inflammatory pain models (Valenzano, K. J. *et al.*, 2005). Interestingly another CB2 agonist, JWH-133 shows antihyperalgesia as well as anti-inflammatory activity (Elmes, S. J. R. *et al.*, 2005). The effects of CB2 agonists appear not to be due to the release of endogenous opioids as actions were unaffected by naltrexone (Whiteside, G. T. *et al.*, 2005b).

Several clinical studies have supported the use of cannabinoids, such as tetrahydrocannabinol (THC), to reduce pain. However this action is commonly accompanied by adverse effect such as euphoria, dizziness, and sedation (Campbell, F. A. *et al.*, 2001; Wade, D. T. *et al.*, 2003; Svenden, K. B. *et al.*, 2004). The reduction of CNS side effects has been approached through targeting peripheral CB receptors, since both CB1 and CB2 receptor activation produce antinociception. In support of this approach, the systemic administration of WIN55,212-2, a nonselective CB agonist, attenuated inflammatory hyperalgesia and this action was reversed by peripheral (intraplantar) but not spinal administration of a CB1 antagonist (Fox, A. and Bevan, S., 2005). Moreover a peripherally restricted CB1 agonist (e.g., NVP-001, personal communication) was shown to reduced inflammatory hyperalgesia by directly reducing nociceptor excitability (Richardson, J. D. *et al.*, 1998). Finally, CT-3 (ajulemic acid) a nonspecific CB1 and CB2 agonist, with limited CNS availability produced analgesia in a number of inflammatory and neuropathic pain models (Burstein, S. H. *et al.*, 2004; Dyson, A. *et al.*, 2005) as well as in human neuropathic pain, at doses which cause minimal CNS side effects (Karst, M. *et al.*, 2003). The mechanism of action of CT-3 appears to involve mainly CB1 receptors and a number of other indirect actions including activation of peroxisome proliferator-activated receptor (PPAR)-γ receptors and inhibition of inflammatory cell activity and mediator release (Liu, J. *et al.*, 2003).

Selective CB2 ligands (HU-308, AM-1241, and GW405833) as well as nonselective compounds (HU-210 and CP55940) have shown antinociceptive effects in a variety of inflammatory and neuropathic

pain models (Malan, T. P. *et al.*, 2003, Valenzano, K. J. *et al.*, 2005). These effects are still present in CB1-knockout (KO) mice, absent in CB2-KO animals, can be revered by CB2 antagonist such as SR144528, and occur without major CNS side effects (sedation, catalepsy, or motor impairments). It is unclear how these effects are produced since CB2 receptors have not been found on sensory neurons (Sokal, D. M. *et al.*, 2003). Rather an indirect effect via immune cell modulation and the naloxone-reversible release of β-endorphin from keratinocytes has been proposed (Ibrahim, M. M. *et al.*, 2005). In contrast, a number of reports have suggested that CB2 agonists, for example, JWH-133, may reduce C-fiber excitability directly (Ross, R. A. *et al.*, 2001; Sagar, D. R. *et al.*, 2005). There is also a possibility that CB2 agonists cause antinociception via the CNS as CB2 receptors are expressed in spinal microglia after nerve injury (Zhang, J. M. *et al.*, 2003), and CB2 activation may modulate microglial activity (Water, L. *et al.*, 2003). Indeed the direct spinal administration of JWH-133 attenuated mechanical allodynia (Sagar, D. R. *et al.*, 2005). Clearly greater understanding is still required with respect to the mechanisms of CB2-mediated analgesia.

Other approaches to address the role of endogenous cannabinoid systems in pain and analgesia have targeted fatty acid amide hydrolysis (FAAH), the major degradation pathway for endogenous cannabinoids (Cravatt, B. F. and Lichtman, A. H., 2004). Thus in mice lacking this enzyme (Cravatt, B. J. *et al.*, 2001), or treatment of naïve mice with a novel FAAH inhibitor such as OL135 (Lichtman, A. H. *et al.*, 2004), increases the analgesic efficacy of anandamide and significantly elevated brain anandamide levels were measured. In addition, OL135 increased pain threshold in acute pain models, decreased the mechanical allodynia of neuropathic pain, and decreased thermal hyperalgesia in models of persistent pain (Chang, L. *et al.*, 2006). Surprisingly a CB2 rather than CB1 antagonist attenuated the effect of OL135 in the persistent pain models and its effects appeared to be mediated by a naloxone-reversible mechanism. In this latter respect several reports have indicated analgesic synergy, between μ-opioid and CB receptors. Thus combinations of these agonist have been shown to provide pain reduction with minimal side effects in acute pain models (Cichewicz, D. L. and McCarthy, E. A., 2003). However, it is still unclear whether such synergy can be exploited in chronic pain treatment.

5.53.7 Mrg-Related GPCR and Their Ligands

The mas-related gene (Mrg) family is a large family of GPCRs which vary in numbers depending on species, are rather exclusively expressed in subsets of small sensory neurons (Dong, X. *et al.*, 2001), and may be co-localized with markers for nociceptive neurons such as TRPV1 (Lembo, P. M. C. *et al.*, 2002). Selective manipulations of individual Mrgs have provided exquisite markers for subsets of small sensory neurons showing selective epidermal and spinal innervation, suggesting a close anatomical and functional relationship (Zylka, M. J. *et al.*, 2005).

Focus on the human mrgX subfamily (six genes in humans), also called sensory neuron-specific receptors (SNSR), has revealed a complex pharmacology. The endogenous ligand for SNSR is unconfirmed, but several mammalian peptide ligands have been identified with high affinity for this receptor. These peptides include bovine adrenal medullary peptide 22 (BAM22), and its fragment BAM8-22 derived from the endogenous opioid precursor pro-enkephalin A, as well as two unrelated peptides γ2-melanocytostimulating hormone (MSH) and CT-γ2-MSH. Apart from BAM22, these substances do not activate opioid receptors, rather they increase peripheral and spinal excitability to potentiate thermal and mechanical nociception (Grazzini, E. *et al.*, 2004). This suggests that the same gene products can facilitate as well as inhibit sensory neurons and that an SNSR antagonist should be sought to inhibit hyperalgesia. Although these data strongly support a role for SNSRs in the modulation of pain, the endogenous ligand for this receptor has not been confirmed and there is little direct evidence linking SNSRs in the etiology of acute or chronic pain.

5.53.8 Prostanoids and Receptors

A variety of prostanoid cyclo-oxygenase (COX) enzyme products (PGE_2, PGD_2, $PGF_{2\alpha}$, thromboxane, PGI_2) occur during inflammation but PGE_2 is considered to be the major contributor to inflammatory pain. Thus blocking the major synthetic enzymes, COX-1 (constitutive) and COX-2 (inducible), or inhibition of prostanoid receptors continue to be important approaches for reducing inflammatory pain (Flower, R. J., 2003). Experience with selective inhibitors of COX-2 (celecoxib, rofecoxib) shows

improved gastrointestinal tract safety but little improvement in analgesic efficacy. A relatively infrequent though increased cardiovascular risk (coronary constriction) has been observed with some COX inhibitors. The mechanism is not understood but has led to Vioxx (rofecoxib) being withdrawn from therapy and considerable clinical debate about the safety of future approaches to COX inhibition.

An alternative approach for the clinical improvement of COX inhibitors has been to combine COX inhibition with NO donation (CINOD). Such molecules (NO-naproxene, NO-ibuprofen) have been claimed to show improved efficacy and safety over the parent nonsteroidal anti-inflammatory drugs (NSAIDs) due to actions (improved side effects and efficacy) of cleaved NO (Fiorucci, S. *et al.*, 2001).

Recently a splice variants of COX-1 has been identified, COX-3 (Chandrasekharan, N. V. *et al.*, 2002). However it has low enzymic capability and its distribution and low abundance in the CNS and in periphery does not make this a compelling target for analgesia. However several NSAIDs (acetaminophen, diclofenac, phenacetin) show low efficacy but some degree of selectivity for COX-3. Overall however the analgesic efficacy of acetaminophen is poorly correlated with COX inhibition. Interestingly endogenous acetaminophen metabolism produces a conjugated arachidonic acid derivative (AM404) that shows cannabinoidlike analgesia properties (Hogestatt, E. D. *et al.*, 2005; Ottani, A. *et al.*, 2006). Furthermore gene deletion studies suggested that COX-3 inhibition may be linked with the antipyretic and analgesia properties of NSAIDs. Clearly further studies are needed to link this enzyme to inflammatory pain pathophysiology.

Another route of inhibiting PGE_2 synthesis is via the blockade of PGE synthase (PGES), a major route of conversion of PGH_2 to PGE_2. Two isoforms of the enzyme have been identified, membrane or microsomal-associated PGES (mPGES-1) and a cytosolic enzyme (cPGES/p23) which are linked with COX-2- and COX-1-dependent PGE_2 production, respectively (Jakobsson, P. J. *et al.*, 1999; Claveau, D. *et al.*, 2003). Both isoforms are upregulated by inflammatory mediators and gene deletion studies in mice indicate an important role for mPGES in acute and chronic inflammation and inflammatory pain (Trebino, C. E. *et al.*, 2003).

Apart from prominent roles in regulating peripheral excitability during inflammatory pain, COX-1 (glia) and COX-2 (ventral horn cells) are constitutively present in spinal cord and are increased by inflammation, peripheral nerve injury, or by administration of cytokines, leading to increased production of spinal PGE_2. In keeping with this, several NSAIDs have been shown to reduce inflammatory hyperalgesia via inhibition of spinal COX activity (Yaksh, T. L. *et al.*, 2001). Several mechanisms have been proposed for the PGE_2-induced increase in spinal excitability. Prominent are the contribution of EP1 receptors and spinal release of glutamate. Recently however the spinal effects of PGE_2 have been linked with a glycine receptor. Thus deletion of the GlyR3α subunit gene, reduced pain sensitivity caused by PGE_2 administration or inflammation (Harvey, R. J. *et al.*, 2004).

Finally, PGE_2 exerts its effects via a variety of EP receptors (EP1, 2, 3 4) present both in peripheral sensory neurons and in the spinal cord. Activation of these receptors produces a complexity of effects, ranging from Ca^{2+} influx to cAMP activation or inhibition. In the periphery, sensitization by PGE_2 as been shown to be cAMP mediated causing the enhancement of tetrodotoxin-resistant (TTX-r) sodium currents in nociceptors via channel phosphorylation (England, S. *et al.*, 1996; Gold, M. S. *et al.*, 1998). However in the spinal cord, excitability was enhanced by EP1 receptors but reduced by an EP3α agonist (ONO-AE-248) suggesting further complexity in the prostanoid regulation of pain mechanisms (Bar, K. J. *et al.*, 2004).

5.53.9 Cytokines, Chemokines, and Their Receptors

Cytokines are produced by a variety of immune cells as well as brain neuroglial cells in response to injury and inflammation. They are powerful mediators of hyperalgesia (see Abbadie, C., 2005).

Probably the most characterized are IL-1β and tumor necrosis factor (TNF)-α that act via specific receptors on sensory neurons. Their effects can be attenuated by receptor antagonists (IL-1-r) that sequester the ligand as well as by neutralizing antibodies. Indeed the TNF antibody, etanercept, has been developed for the treatment of chronic inflammation and the presence of TNF-α has been correlated with a number of painful inflammatory clinical conditions (Lindenlaub, T. and Sommer, C., 2003). Cytokines induce hyperalgesia by a number of direct and indirect actions. Thus IL-1β activates nociceptors directly and produces heat sensitization via intracellular kinase activation, but it may also

cause indirect nociceptor sensitization via the production of kinins and prostanoids (Sommer, C. and Kress, M., 2004). TNF-α also activates sensory neurons directly via TNFR1 and TNFR2 receptors, (Pollock, J. *et al.*, 2002; Ohtori, S. *et al.*, 2004) and initiates a cascade of inflammatory reactions through the production of IL-1, IL-6, and IL-8. It is significant that direct TNF-α application in the periphery induces neuropathic pain behavior that is blocked by ibuprofen and celecoxib (Schafers, M. *et al.*, 2004), while nerve ligation causes increased TNF-α in damaged as well as adjacent undamaged axons (Schafers, M. *et al.*, 2003a). Interestingly anti-TNF-α treatment with TNF antibody, adalimumab, produced a prolonged reduction of pain symptoms in OA (Grunke, M. and Schulze-Koops, H., 2006).

There appears to be a complex interplay between cytokines, and it should be noted that like other mediators of pain not all should be considered as detrimental. Thus IL-6 has been associated with potential beneficial effects after nerve injury including protection against cell death and the promotion of growth. However there is also compelling evidence of a strong association with this cytokine in several human pain conditions including herniated lumbar disc pain and pain caused by failed back surgery (De Jongh, R. F. *et al.*, 2003).

A variety of studies have demonstrated an important role for spinal inflammatory and neuroimmune processes triggered by peripheral inflammation and nerve injuries. These processes involve the regulation of a variety of receptors, channels, and enzymes with patterns that are likely to differentiate one pain state from another (Honore, P. *et al.*, 2000). In addition, activation of spinal neuroglial cells (microglia, astrocytes, satellite cells) stimulates a cascade of secondary excitability changes (Watkins, L. R. and Maier, S., 2002). Neuroglia make close-junctional connections with other cells, providing a means of spreading excitability changes beyond the boundaries of spinal segmental input. Neuroglia also secrete a number of mediators such NO, neurotrophins, IL-1β, TNF-α, free radicals, and glutamate. In addition, neuroglial mediators may contribute to spinal excitability by causing dysfunction or degeneration of inhibitory spinal neurons (Moore, A. K. *et al.*, 2002). In keeping with an important role for neuroglial mediators, treatments with anti-inflammatory agents or modulators of neuroglial activity such as propentofylline and minocycline inhibit glial activation and the release of glial products with reduced behavioral signs of hyperexcitability (Watkins, L. R. and Maier, S., 2002; Raghavendra, V. *et al.*, 2003).

Chemokines are important peripheral and central mediators of inflammation. The major chemokines and their respective receptors are macrophage-derived chemokine (MDC)/CCR4, regulated upon activation, normal T-cell expressed, and secreted (RANTES)/CCR5, fractalkine/CX3CR1, and SDF-1α/CXCR4. Receptors are located on leukocytes, on central neurons, sensory neurons, and neuroglial cells (Watkins, L. R. and Maier, S., 2002). Apart from their major chemoattractant effects, chemokines contribute directly to inflammatory hyperalgesia through G-protein-coupled activation and sensitization of sensory neurons (Oh, S. B. *et al.*, 2001). Block of CX3CR1 by a fractalkine receptor-neutralizing antibody induces antiallodynic effects in models of peripheral nerve inflammation (Milligan, E. D. *et al.*, 2005b). However some chemokines appear beneficial. Thus gene therapy (AV-333) has been used to increase IL-10 production through the delivery of viral and nonviral vectors by acute spinal intrathecal delivery. This experimental treatment has been shown to reverse mechanical allodynia in the chronic constriction injury (CCI) model of neuropathic pain (Milligan, E. D. *et al.*, 2005a).

5.53.10 Adrenoceptors

A number of chronic pain disorders termed sympathetically maintained pain have highlighted the importance of the release of sympathetic transmitters (epinephrine or norepinephrine) from sympathetic varicosities and the involvement of adrenergic receptors in pain etiology. For example following peripheral nerve injury sprouting of sympathetic nerve endings occurs at several sites. Thus sympathetic/sensory coupling at the level of the DRG (Zhang, J. M. *et al.*, 2004), at the site of injury (neuroma), and in the periphery (Shinder, V. *et al.*, 1999) have been demonstrated. In keeping with this some neuropathic pain symptoms have been attenuated by sympathetic blocks or surgical sympathectomy.

Other studies have shown the expression of α1- and α2-adrenoceptors on sensory neurons or postganglionic sympathetic terminals (Sato, J. and Perl, E. R., 1991; Tracey, D. J. *et al.*, 1995; Lee, D. H. *et al.*, 1999) after nerve injuries. Under these conditions sensory neurons can be directly activated by the endogenous release of sympathetic transmitters (via

α1 receptors) or in the clinic by intradermal injection of norepinephrine (Ali, Z. *et al*., 2000).

On the other hand, transdermal applications of the α2-agonist, clonidine via transdermal patches or creams, has proven efficacious in a variety of neuropathic pain conditions (Byas-Smith, M. G. *et al*.,1995). Since clonidine has been shown to decrease the excitability of small sensory neurons from nerve injured animals (Ma, W. *et al*., 2005) the antinociceptive efficacy of clonidine is considered to be due to α2 receptor-coupled inhibition. Clonidine and other α2-agonists such as dexmedetomidine have also been used systemically to inhibit of sensory transmission in the spinal cord by block of pre- and postsynaptic membrane excitability. Unfortunately sedation and hypotension are major target-related side effects of these compounds. Great efforts have been made to identify ligands with improved α2-receptor subtype selectivity, to avoid side effects, but thus far this has not been particularly successful.

5.53.11 Glutamate Regulation and Glutamate Receptors

Glutamate is the major excitatory neurotransmitter in the CNS with important regulatory roles for pain transmission. However there is also considerable evidence that it plays a role in pain processing in the periphery (Carlton, S. M. *et al*., 1995; Bahave, G., *et al*., 2001). Glutamate acts through receptor-coupled ligand-gated ion channels (α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)/kinate receptors: iGluRs) and GPCR-coupled receptors (metabotropic glutamate receptors (mGluRs)). Injections of glutamate or metabolically stable receptor-selective agonists such as *N*-methyl-D-aspartic acid (NMDA), AMPA, and kainate, cause a reduction in thermal and mechanical thresholds for pain, while application of iGluR and mGluR antagonists attenuate pain in acute models (Zhou *et al*.,1996; Bhave, G., *et al*., 2001).

Building upon this has been significant progress in development of a glutamate antagonist optimized for clinic testing. For example, the AMPA-kinate receptor antagonist, LY293558 has been shown to have efficacy in models of neuropathic pain (Blackburn-Munro, G. *et al*., 2004) and to reduce capsaicin-induced pain in human volunteers as well as clinical dental pain with minimal side effects (Sang, C. N. *et al*., 1998).

There has been a great deal of information linking NMDA receptors in central sensitization and CNS excitability during chronic pain and repetitive stimulation of pain pathways. Indeed NMDA antagonists show robust attenuation of pain behaviors but provoke a number of side effects (sedation, confusion, and motor incoordination) and thus have an insufficient therapeutic window. There has been a refocus on more specific NMDA-receptor subtype blockers (NR1 and NR2) directed toward the glycine modulatory site to avoid side effects. This site actively modulates the NMDA channel only during the sustained stimulation of the receptor, which is considered to occur during chronic pain. Selective NR1-Gly antagonists have been claimed to reduce pain with reduced side effects (Danysz, W. and Parsons, C. G., 1998; Quartaroli, M. *et al*., 2001). However clinical experience has not yet confirmed this. GV196771 did not show efficacy against clinical pain, possible due to inadequate penetration into the CNS (Wallace, M. S. *et al*., 2002).

Alternative initiatives have targeted other NMDA receptor subtypes such as the NR2B receptor, which has a specific distribution in sensory pathways. Blockade of this receptor has also been claimed to produce antinociception (ifenprodil, CP-101,606) with reduced side effects (Taniguchi, K. *et al*., 1997). This concept has yet to be evaluated in the clinic.

Metabotropic glutamate receptors, particularly mGluR1 and mGluR5, have been reported to play a key role in sustaining heightened central excitability in chronic pain with minimal involvement in acute nociception. Thus spinal administration of selective agonists such as dihydroxy phenyl glycine produced allodynia, while mGluR5 was shown to be significantly overexpressed in some, but not all, chronic pain models (Hudson, L. J. *et al*., 2002). Furthermore antisense-oligonucleotide and antibody treatments, directed at these receptors, reduce chronic inflammatory and neuropathic pain behaviors (Fundytus, M. E. *et al*., 2002). In keeping with these observations, the mGluR5-selective antagonists 2-methyl-6-(phenylethynyl)-pyridine (MPEP) did not reduce acute physiological pain responses but reduced heat hyperalgesia and allodynia in models of inflammatory and neuropathic pain (Walker, K. *et al*., 2001; Hudson, L. J. *et al*., 2002; Urban, M. O. *et al*., 2003).

Peripheral mGluR5 receptors have also been claimed to modulate pain (Jang, J. H. *et al*., 2004). Thus local administration of mGluR5 (MPEP, SIB1757) have been effective in reducing pain behavior (Dogrul, A. *et al*., 2000; Zhu, C. Z. *et al*., 2004) suggesting a potential for using peripheral mGlu5 antagonists in pain therapy.

Metabotropic group II receptors (mGluR2 and mGluR3) also modulate pain transmission. The mGluR2 is located in sensory neurons and presynaptic nerve terminals whereas mGluR3 is found all over the brain. MGluR3 can be selectively increased in the spinal dorsal horn neurons after peripheral ultraviolet injury (Boxall, S. J. *et al.*, 1998). mGluR2/3 receptor activation appears necessary to reduce nerve terminal excitability and modulate pain transmission since treatment with L-acetyl-carnitine reduced inflammatory hyperalgesia and mechanical allodynia and increased the expression of mGlur2/3. The effect of L-acetyl-carnitine were attenuated by LY379268, a mGlu2/3 antagonist (Chiechio, S. *et al.*, 2002).

5.53.12 Gamma-Aminobutyric Acid Receptors

Gamma-aminobutyric acid (GABA) receptors are emerging as important regulators of pain, particularly in the spinal cord as they are abundantly expressed both on spinal afferent nerve terminals and spinal neurons. Activation of both subtypes of GABA receptor by muscimol ($GABA_A$ agonist) or baclofen ($GABA_B$ agonist) reduced pain behavior. In contrast, $GABA_A$ (bicuculline) and $GABA_B$ (CGP35348) antagonists cause pain when injected into the spinal intrathecal space (Malan, T. P. *et al.*, 2002). Loss of GABA (Ibuki, T. *et al.*, 1997) and impaired GABA-mediated inhibition through loss of spinal interneurons has been demonstrated in models of neuropathic pain (Moor, A. K., *et al.*, 2002).

Improvement of GABA synthesis through promotion of its synthetic enzyme, glutamic acid decarboxylase (GAD), has been achieved by gene transfer of a GAD promoter (in herpes simplex virus vector) via peripheral injection. This was taken up into sensory neurons and transported to DRGs to reduce spinal excitability, as well as mechanical and thermal allodynia caused by nerve injury (Hao, S. *et al.*, 2005).

Other important changes in ionic regulation have been highlighted to occur in chronic pain which indirectly affects GABA- and glycine-mediated inhibition and excitability in the spinal cord. In particular changes in transmembrane ion transporters have been associated with modulation of primary afferent excitability and related to neuropathic pain disorders. Thus the chloride transporter NKCC1, localized in primary sensory neurons, is responsible for maintaining the high chloride ion gradient in afferent terminals. This allows the outflow of chloride ions associated with the primary afferent depolarization (PAD) and presynaptic inhibition, following $GABA_A$ receptor activation of afferent terminals. Deletion of the NKCC1 gene induced touch-evoked pain caused by light stroking. This was shown to be due to increased nerve terminal excitability caused by a reduced capability to generate presynaptic inhibition (Laird, J. M. A. *et al.*, 2004).

On the other hand increasing the expression of this cotransporter or increasing its efficacy through AMPA mediated Ca/CaM-kinase II phosphorylation has been postulated (Cervero, F. *et al.*, 2003) to increase PAD sufficient to reach the firing threshold of the nerve terminal. This mechanism may also contribute to spinal sensitization following nerve injury and may indeed generate antidromic action potentials triggering a dorsal root reflex or the ectopic discharges in sensory nerves which cause, or contribute to spontaneous pain.

Spinal sensitization that occurs following peripheral nerve injury may also arise by other mechanisms of spinal disinhibition. This has been hypothesized to involve the reduced expression of the potassium-chloride exporter KCC2, seen only in superficial spinal lamina 1 neurons after injury. In addition, knockdown of KCC2 with antisense or block of this transporter with ((dihydronindenyl)oxy) alkanoic acid (DIOA) causes a similar shift in the transmembrane ionic gradient in spinal lamina 1 neurons and a consequent behavioral hyperalgesia resembling that seen after nerve injury (Coull, J. A. M. *et al.*, 2003). In addition, normal spinal inhibitory currents, mediated by GABA and glycine interneurons, are reversed in the absence of KCC2, so that the effects of GABA become predominant excitatory, due to the outward, rather than inward, flow of chloride ions. The emerging view suggests that a variety of changes in ionic regulation occur during chronic pain. This adds complexity to the puzzle of pain but opportunity for intervention. It will be important to learn how these disinhibitory mechanisms contribute in different chronic pain conditions and whether they are critical for pain initiation as well as its maintenance.

5.53.13 Ion Channels

5.53.13.1 Ligand-Gated Channels

Transient receptor potential (TRP) channels form a large family of sensory transducers involved in cellular calcium regulation. Many are localized to

mammalian sensory nerves and are involved in the transduction of temperature and chemical signals that result in pain. The TRPV family has received considerable attention and is considered a good targeted for developing analgesics (Krause, J. E. *et al.*, 2005). TRPV1, originally called the vanilloid receptor because of its selective activation by capsaicin and pungent vanilloids, has the properties of a noxious heat transducer. The effects of capsaicin on sensory neurons are complex, involving activation through ligand-operated cation channels, and the extracellular influx as well as the intracellular increase in calcium ions. Calcium-induced stimulation of phosphatase such as cacineurin then reduces excitability via inactivation voltage-gated calcium (CaV) channels as well as rapid CaV2.2 internalization (Wu, Z. Z. *et al.*, 2005). This mechanism explains the transient and reversible analgesia effects of capsaicin either on peripheral or spinal afferent nerve terminals. TRP channel regulation of heat transduction is complex as animals with deleted *TRPV1* and *TRPV2* genes appear to have normal heat sensitivity (Woodbury, J. *et al.*, 2004) whereas gene deletion of *TRPV1* prevented inflammatory heat hyperalgesia (Caterina, M. J. *et al.*, 2000).

The TRPV1 receptor has assumed an increasingly prominent role in regulating sensory neuronal excitability in inflammatory pain. A variety of inflammatory agents including protons, bradykinin, adenosine triphosphate (ATP), PGE2, 12-lipoxygenase products, PAR2, anandamide, and nerve growth factor (NGF) indirectly sensitize TRPV1, or regulate its expression, to cause thermal hyperalgesia. A common mechanism appears to be GPCR-coupled stimulation of PLC, the formation of intermediates inositol triphosphate (IP3) and DAG and the activation and mobilization of PKC (Vellani, V. *et al.*, 2001) which can phosphorylate the TRPV1 receptor.

Earlier analgesia strategies, targeting TRPV1, were focused on capsaicin-like agonists that induced functional inactivation of sensory fibers by causing reversible subepidermal degeneration. This has been successfully translated into the clinic with the introduction of a number of topical capsaicin therapies for inflammatory pain. Currently there is a focus on TRPV1 channel blockers or selective antagonists against the TRPV1 receptor (Garcia-Martiez, C. *et al.*, 2002). Supporting these approaches, competitive (AMG-9810, personal communication) and noncompetitive vanilloid receptor-1 (VR1) antagonists (DD161515; Sachez-Baez, F. *et al.*, 2002) block chemical and thermal pain sensitivity, heralding the emergence of a novel therapy. Indeed recent clinical studies in human volunteers have shown that oral SB705498 attenuated capsaicin and ultraviolet C (UVC)-induced pain and hyperalgesia (Chizh, B. *et al.*, 2006).

Other TRP channels (TRPV3, TRPV4, TRPA1) have been suggested to be involved in transduction. Thus TRPA1 (ANKTM1) is colocalized with TRPV1, is activated by capsaicin and mustard oil but can also be sensitized by inflammatory mediators including bradykinin to produce cold-induced burning pain (Bandell, M. *et al.*, 2004). In addition TRPV1 can oligomerize with other TRP family members including TRPV3. TRPV3 is also a heat transducer that it sensitive in the physiological temperature range and responds to noxious heat, but is insensitive to capsaicin. This is found in keratinocytes and appears to be upregulated in inflammatory pain conditions. It is unclear how activity of TRPV3 leads to nociceptor activation. So far there are few chemical tools to help characterize the functions of these TRP receptors and support their value as analgesia targets.

5.53.14 Purinergic Receptors

5.53.14.1 P2X Receptors

The unique localization of the P2X3 receptor to small sensory fibers has highlighted its importance in pain. Large amounts of the endogenous ligand, ATP are released after tissue injury and during inflammatory injuries while both ATP and a stable analogue α,β-Me ATP, induce pain and are pronociceptive when administered intradermally in human volunteers.

In chronic inflammatory pain, P2X3-mediated excitability is enhanced while reduction of P2X3 receptors, by antisense oligonucleotide administrations, reduced inflammatory hyperalgesia as well as that evoked by α,β-Me ATP (Honore, P. *et al.*, 2002). In keeping with this a number of antagonists including 2′,3′-*O*-(2,4,6-trinitrophenyl) adenosine 5′-triphosphate (TNP-ATP), pyridoxal-phosphate-6-azophenyl-2′,4′-disulfonate (PPADS), and suramin, reduce pain behavior. More selective, and druglike, antagonists such as A-3174919 reduced pain in a number of acute and chronic pain models supporting the possibility for future analgesia therapy (Jarvis, M. F. *et al.*, 2002).

It should be noted that a number of other purinergic receptor subtypes, for example, P2X4 and P2X7, have also been suggested to modulate pain

through altered central excitability and the release of neuroglial-cell products. Thus activated microglial, astrocytes, and satellite cells release a variety of inflammatory mediators including IL-1β, TNF-α, prostanoids, and NO upon ATP stimulation. Indeed increased expression of P2X4 has been shown to occur in spinal microglial after peripheral nerve lesions and this was related to painful mechanical allodynia. This behavior was blocked by spinal administrations of the selective P2X4 antagonist TNP-ATP (Tsuda, M. *et al.*, 2003). Remarkably spinal administration of activated microglia reproduced TNP-ATP sensitive mechanical allodynia in naïve animals.

Increased P2X7 expression has been found in peripheral macrophages following inflammation but this receptor is also expression in spinal neurons and microglia following peripheral nerve injury (Deuchars, S. A. *et al.*, 2001). In keeping with an important role in chronic pain both microglia and P2X7 receptors are upregulated in human chronic pain patients while deletion of the P2X7 receptor gene produced a complete absence of mechanical and thermal pain in mice (Chessell, I. P. *et al.*, 2005).

It is worth noting that other nucleotide-gated ion channels have also been shown to be important for regulating peripheral excitability. Thus the sodium/potassium repolarizing pacemaker current, Ih, which is activated during membrane hyperpolarization is important for generation of rhythmic and spontaneous action potentials in sensory neurons following nerve injury. Ih currents are controlled by cyclic nucleotides (cAMP and cGMP) via a family (HCN1–4 channels) of ligand-gated ion channels that are constitutively expressed in sensory nerves and differentially distributed after crush or inflammatory nerve injuries (Chaplan, S. R. *et al.*, 2003; Yao, H. *et al.*, 2003). Nerve injury has been shown to enhance the Ih and this can be blocked with ZD7288 which also prevents repetitive firing in damaged sensory neurons and reverses touch hypersensitivity in neuropathic pain models (Chaplan, S. R. *et al.*, 2003). This approach clearly has great potential for addressing peripheral excitability in neuropathic pain disorders.

5.53.14.2 Acid-Sensing Channels

Proton production is increased in inflammation and is likely to be involved in inflammatory hyperalgesia and in the sensation of muscle aching and discomfort due to the hypoxia/anoxia of muscle exercise. Indeed direct activation of nociceptors accounts for the sharp stinging pain produced by intradermal injections of acidic solutions and low extracellular pH enhancing the effects of other inflammatory mediators (Krishtal, O., 2003; Mamet, J. *et al.*, 2003).

Exogenously administered acidic solutions produce a rapid but transient increase in membrane cation permeability as well as a more prolonged permeability increase in sensory neurons. This can give rise to sustained nerve activation as well as an enhanced mechanosensitivity. The mechanism of proton-induced activation of sensory neurons underlying pain has not been fully elucidated, but appears to be driven by a number of acid-sensing ion channel (ASICs) particularly ASIC1 and ASIC3 (also called DRASIC). ASIC3 has been shown to have a strong antinociceptive phenotype following deletion of this gene in KO mice (Sluka, K. A. *et al.*, 2003).

A novel blocker (A-317567) of peripheral ASIC1, ASIC2, and ASIC3 channels has been described (Dube, G. R. *et al.*, 2005). This produces antihyperalgesia in models of inflammatory and postoperative pain but there have been no reports of therapeutic advances with more selective inhibitors.

5.53.15 Sodium Channels

Voltage-gated sodium channels are characterized by their primary structure and sensitivity to tetrodotoxin (TTX). A variety of TTX sensitive (NaV1.1, Nav1.2, NaV1.6, and Nav1.7) and TTX insensitive (Nav1.8, NaV1.9) channels are involved in regulating sensory neural excitability (Matzner, O. and Devor, M., 1994; Eglen, R. M. *et al.*, 1999). Changes in the expression, trafficking, and redistribution of NaVs, following inflammation or nerve injury is considered to account for the abnormal firing (ectopic generators) of afferent nerves (Devor, M., 2005). However channel redistribution appears complex as most channels appear to be downregulated in DRGs after nerve injury whereas, for example, NaV1.8 is redistributed along small axons. It has also been important to recognize that channel expression and nerve excitability are changed dramatically in uninjured axons that are closely apposed to injury (Gold, M. S. *et al.*, 2003).

The TTX-R sodium channel, NaV1.8, is uniquely expressed in all sensory neurons (IB4 positive and NGF sensitive) and appears to be an important contributor in the generation of abnormal excitability in sensory axons. Thus knockdown of NaV1.8 produces a marked reduction in abnormal pain responsiveness in pain models (Lai, J. *et al.*, 2003).

Inflammation also causes the overexpression of NaV1.7 in several types of sensory neurons in models of inflammatory pain (Gould, H. J. *et al.*, 2004) and in inflamed human tooth pulp. Interestingly NaV1.7 overexpression can be prevented by pretreatment with COX-1 and COX-2 inhibitors (ibuprofen, NS-398).

The clinical utility of nonselective sodium channel blockade in pain treatment has been well established with the use of local anesthetics such as lidocaine. Clinical experience has confirmed that local block of abnormally active afferents reduces secondary pain in established neuropathic pain conditions (Gracely, R. *et al.*, 1992). Interestingly this can be achieved at lower concentrations than are required for block of conduction in quiescent fibers highlighting a potential therapeutic advantage for selective fiber block (Devor, M. *et al.*, 1992). The basis of this is due to the state-dependent increase in the affinity of channel blockers for ion channel proteins (Devor, M., 2005). An additional utility of lidocaine is that intravenous administration has been reported to produce long-lasting pain relief both in animal models (Araujo, M. C. *et al.*, 2003) and in intractable neuropathic pain (Kastrup, J. *et al.*, 1987). The major disadvantages of nonselective sodium channel blockers are cardiotoxicity and CNS sedation and confusion produced by NaV1.5 and NaV1.2 channel block, respectively. Thus great activity is currently focused on discovering novel but selective sodium channel blockers.

In this regard novel activity-dependent sodium channel blockers (e.g., NW-1029) have been shown to reduce excitability of peripheral nerves and cause antihyperalgesia in models of inflammatory and neuropathic pain (Veneroni, O. *et al.*, 2003). Overall however, channel blockers still appear insufficiently selective to avoid cardiac and CNS side effects.

An alternative approach to selectively regulate ion channels is to block the trafficking of channels to the nerve membrane. For example the functioning of NaV1.8 may be reduced by preventing its interaction with p-11, an annexin II-related protein that tethers the channel to the nerve membrane (Okuse, K. *et al.*, 2002). In addition, channel-associated cell surface glycoproteins such as contactin may be involved in concentrating specific channel subtypes, e.g., NaV1.8 and NaV1.9 (IB4 positive) but not NaV1.6 and NaV1.7 (IB4 negative) in DRG nerve membranes, with an associated increased in current density (Rush, A. M. *et al.*, 2005). Although these approaches are attractive it is unclear whether they will impact on nerve excitability associated with specific pain etiology.

NaV1.3 is another ion channel that is dramatically regulated after injury. This channel has been found abundantly in fetal but not in adult tissue. However NaV1.3 is dramatically upregulated in adult sensory neurons and spinal cord following peripheral and CNS injury (Hains, B. C. *et al.*, 2004). The expression of NaV1.3 has been suggested to make an important contribution to the sustained and high-frequency firing found in injured afferents related to neuropathic pain (Cummins, T. R. and Waxman, S. G., 1997; Kim, C. H. *et al.*, 2002). Further it has been proposed that NaV1.3 expression may not be directly related to neural injury as it was not correlated with activating transcription factor (ATF)-3 expression, a neuronal cell death marker (Lindia, J. A. *et al.*, 2005), but caused by a deficiency of growth factor. In this respect, GDNF administration reduced NaV1.3 expression and attenuated neuropathic pain behavior (Boucher, T. J. *et al.*, 2000). In contrast, antisense treatments that significantly reduced sensory neuronal NaV1.3 expression in the spared nerve injury (SNI) model of neuropathic pain did not attenuate nerve injury-induced allodynia (mechanical or cold; Lindia, J. A. *et al.*, 2005) whereas this was reduced by the nonselective channel blockers mexiletine and lamotrigine.

5.53.16 Calcium Channels

A variety of calcium channels (CaV) have been identified and characterized. Several have been shown to be prominently involved in pain regulation (Yaksh, T. L., 2006). The N-type calcium channel CaV2.2 is an important regulator of nerve terminal excitability and neurotransmitter release. It has been well established that there is complex chemical regulation of N-channels, particularly through GPCR signaling. For example, N-channel activity is attenuated by analgesic drugs such as opioids, with a resultant modulation of sensory transmitter release, e.g., substance P, CGRP, and glutamate, at both spinal and at peripheral sensory nerve terminals. N-channel trafficking may also be affected by GPCRs. For example, activation of the orphanin FQ receptor (ORL) by nociceptin causes channel internalization and downregulation of calcium entry (Altier, C. *et al.*, 2005).

Of additional importance is the fact that deletion of the N-channel gene reduces inflammatory and neuropathic pain (Kim, C. *et al.*, 2001; Saegusa, H. *et al.*, 2001). Moreover selective blockers such as ziconotide,

(a naturally occurring conopeptide) and verapamil have been used to characterize channel activity while ziconitide (SNX-111, Prialt) has been used experimentally and clinically by intrathecal administration, to show utility for pain relief (Xiao, W. H. and Bennett, G. J., 1995; Snutch, T. P., 2005). Building on this concept, small molecule CaV2.2 channel blockers with oral availability are now reported to have been developed, e.g., NMED-160, showing efficacy in chronic pain models (Snutch, T. P., 2005).

While it is believed that blockers of CaV2.2 exert their major analgesic effects via the spinal cord, peripheral actions are also possible. Thus N-channels expression also occurs in peripheral terminals and has been shown to increase following axotomy (Baccei, M. L. and Kocsis, J. D., 2000). This suggests that peripheral N-channels can be targeted for neuropathic pain treatments; thus avoiding potential CNS side effects such as sedation.

Low-voltage-activated T channels (CaV3.1, CaV3.2, and CaV3.3) also appear important for pain transmission and as targets for pain therapy. Thus they are expressed in superficial laminas of the spinal cord and in DRG neurons (for references see Altier, C. and Zamponi, G. W., 2004; Yaksh, T. L., 2006). T-channels appear unaffected in DRGs after axotomy (Baccei, M. L. and Kocsis, J. D., 2000) but may play a more prominent role in regulating spinal excitability and spinal sensitization following repetitive C-fiber stimulation (Ikeda, H. *et al.*, 2003). Moreover nerve injury-induced hyper-responsiveness was blocked by the T-channel blocker ethosuximide (Matthews, E. A. and Dickenson, A. H., 2001) which also attenuated mechanical allodynia in animal models of vincristine- and paclitaxel-induced neuropathic pain (Flatters, S. J. and Bennett, G. J., 2004).

Finally a strongly validated approach for neuropathic pain has targeted the $\alpha 2,\delta 1$ calcium channel subunit, the substrate for the antiallodynic drugs, gabapentin and pregabalin. This subunit is important for channel assembly, is expressed in small DRGs and in spinal neurons, and its overexpression has been associated with allodynia in a number of specific pain models (Luo, Z. D. *et al.*, 2002).

5.53.17 Neurotrophins and Their Receptors

The neurotrophins represent an important family of regulatory proteins essential for sensory nerve development, survival, and determination of chemical phenotype including excitability (Sah, D. W. H. *et al.*, 2003; Zweifel, L. S. *et al.*, 2005). Several neurotrophins have been identified including NGF, brain-derived growth factor (BDNF) and neurotrophins (NT) 3, neurotrophin 4/5. Each neurotrophin binds with high affinity to receptor tyrosine kinases (Trk): NGF to TrkA, BDNF and NT4/5 to TrkB, and NT3 to TrkC. NT3 also binds with TrkA and TrkB. Mature neurotrophins also bind to a structurally distinct receptor p75 which affects neuronal development through downstream signaling. Neurotrophins arise from proneurotrophin precursors following extracellular cleavage by metalloproteinases and plasmin. It should be observed that proneurotrophins also signal through the p75 receptor and may produce opposite effects from neurotrophins, e.g., apoptosis rather than cell survival (Lu, B. *et al.*, 2005).

NGF has been most studies with respect to inflammatory hyperalgesia as its production is unregulated by inflammation in macrophages, fibroblasts, and Schwann cells. NGF has emerged as a key regulator of sensory neuron excitability and as an important mediator of injury-induced nociceptive and neuropathic pain (Ro, L. S. *et al.*, 1999; Theodosiou, M. *et al.*, 1999; Hefti, F. F. *et al.*, 2005). NGF acts via TrkA and p75 to activate a number of kinase pathways (e.g., p38 kinase; Ji, R. R. *et al.*, 2002) leading to altered gene transcription and the increased synthesis of sensory neuropeptides (substance P, CGRP), ion channels (TRPV1, NaV1.8, ASIC3; Fjell, J. *et al.*, 1999; Ji, R. R. *et al.*, 2002; Mamet, J. *et al.*, 2003), membrane receptors such as bradykinin and P2X3 (Petersen, M. *et al.*, 1998; Ramer, M. S. *et al.*, 2001), and structural molecules including neurofilament and channel anchoring proteins such as the annexin light chain p11 (Okuse, K. *et al.*, 2002).

Increased expression and release of NGF have been demonstration in several painful conditions in animal models (e.g., ultraviolet injury, surgical injury; Oddiah, D. *et al.*, 1998; Miller, L. J. *et al.*, 2002) and in human conditions including arthritis, cystitis, prostitis, and headache (Aloe, L. *et al.*, 1992; Halliday, D. A. *et al.*, 1998; Sarchielli, P. *et al.*, 2001). Administration of exogenous NGF induces thermal and mechanical hyperalgesia in animals and humans (Andreev, N. *et al.*, 1995; Apfel, S. C., 2002), which is considered to be due in part to mast cell degranulation and by directly increasing sensory neuronal excitability (Sah, D. W. H. *et al.*, 2003).

Few small molecule NGF antagonists are available but ALE0540, which inhibits the binding of

NGF to TrkA and p75, and PD90780 which inhibits NGF binding to p75, have been proposed to have efficacy in chronic pain models (Owolabi, J. B. *et al.*, 1999; Colquhoun, A. *et al.*, 2004). In contrast, the use of TrkA-immunoglobulin G (IgG) and NGF monoclonal antisera have confirmed the importance of NGF in pain. Thus anti-NGF treatment have provided positive behavioral and biochemical readouts in several models of chronic nociceptive (including visceral) and neuropathic pain (Obata, K. *et al.*, 2004; Hefti, F. F. *et al.*, 2005; Sevcik, M. A. *et al.*, 2005; Shelton, D. L. *et al.*, 2005). These studies have also indicted a lack of effect on acute nociceptive processing or on sympathetic nerves whose phenotype is also regulated by NGF.

The importance of NGF has also received clinical confirmations since RN624, a humanized anti-NGF monoclonal antibody (mAb), has been reported to be efficacious in reducing pain and improved mobility in OA (Lane, N. *et al.*, 2005). Anti-NGF mAb therapy appears as an attractive therapeutic approach with the potential for long-lasting pain treatment, similar in efficacy to morphine, without necessarily compromising physiological nociception.

NGF also induces the synthesis of another neurotrophin, BDNF, from peptide-containing sensory neurons. BDNF also accumulates in sensory neurons following painful nerve injury (see Sah, D. W. H. *et al.*, 2003). Release of BDNF in the spinal dorsal horn increasing spinal excitability and pain sensitization via TrkB receptors. This initiates a variety of effects, including direct neural excitation, activation of a signaling cascade via the phosphorylation of NMDA receptors, and an altered regulation of the neural chloride transporter that contributes to pain hypersensitivity (Coull, J. A. M. *et al.*, 2005).

In keeping with these observations, spinal BDNF administration induces thermal and mechanical allodynia whereas anti-BNDF neutralization or TrkB IgG administration reduces inflammation or nerve injury-mediated hypersensitivity pain in a number of animal models (Kerr, B. J. *et al.*, 1999; Theodosiou, M. *et al.*, 1999; Deng, Y. S. *et al.*, 2000).

Finally glial cell-line-derived neurotrophic factor, GDNF represents an extensive family of ligands and membrane receptor complexes which have an important role in regulating peripheral and central neural phenotypes. GDNF-related ligands include neurturin and artemin, which act via the complex RET Trk receptor and co-receptors GFRα1, GFRα2, GFRα3, and GFRα4.

Although there appears not to be a specific role in inflammation, GDNF has been shown to have neuroprotective and restorative properties in a number of neurodegenerative and neuropathic pain states (Sah, D. W. H. *et al.*, 2003). Specifically GDNF treatment has been shown to restore peripheral sensory neuron function, including peptide and ion channel expression patterns, following painful peripheral nerve injury accompanied by an attenuation of pain behaviors. Unfortunately clinical observations using GDNF have shown unacceptable side effects such as weight loss and allodynia, which has discouraged therapeutic developments (Nutt, J. G. *et al.*, 2003).

5.53.18 Kinases

As mentioned earlier inflammatory mediators also activate a number of protein kinases in sensory neurons and in the spinal cord. These include PKA, PKC, and mitogen-activated protein kinases (MAPK) considered to be important downstream regulators of excitability through altering gene transcription and posttranslational modification of target proteins (Woolf, C. J. and Salter, M. W., 2000). There are several types of MAPKs including extracellular signal-regulated kinases (ERK), cJUN, N-terminal kinase (JNK), and p38 kinase that are considered as targets for inflammatory pain. For example, several inhibitors of p38 kinase (e.g., SB203580, CNI-14930) posses anti-inflammatory as well as antihyperalgesic properties in a variety of animal models (Schafers *et al.*, 2003b).

5.53.19 Botulinum Toxin

Another approach to pain modulation has been the use of botulinum toxins (BoTNs). This family of neurotoxins has been traditionally used as an experimental tool to study muscle nerve interactions. Recently BoTN-A has been approved for clinical use to induce muscle relaxation. The mechanism of action of BoTN is related to inhibition of transmitter release from motor fibers through proteolytic cleavage of a number of synaptosomal regulatory proteins (SNARE, syntaxin, SNAP-25, synaptobrevin). More recent studies also indicated potential for inhibition of neuropeptide transmitter release from small afferent neurons (Welch, M. J. *et al.*, 2000; Mense, S., 2004). In keeping with this BoTN has been shown to provide long-lasting pain relief following administration into human osteoarthritic

joints and improve bladder dysfunction in overactive bladder patients. This was correlated with loss of both P2X3 and VR1 receptors in the bladder (Apostolidis, A. *et al.*, 2005).

5.53.20 Nitric Oxide

NO induces a delayed burning pain upon intradermal injection (Holthusen, H. and Arndt, J. O., 1994) and NO donors have been postulated to activate cerebral sensory fibers directly, causing release of the sensory vasodilator CGRP (Wei, P. *et al.*, 1992). Indeed NO has been suggested to contribute to migraine and other types of head pain (Olesen, J. *et al.*, 1994) and there is an abundance of evidence linking NO in the etiology of a number of chronic pain conditions (Millan, M. J., 1999).

Peripheral nerve injury and inflammation increases the expression of NO in sensory neurons and causes the upregulation of the nitric oxide synthase (NOS) isozymes neuronal NOS (nNOS) and inducible NOS (iNOS) in the spinal cord (Gordh, T. *et al.*, 1998) as a result of axonal neurodegeneration, neuroglial cell activation and inflammation (Levy, D. *et al.*, 2001). In keeping with these observations, treatment with nonspecific NOS inhibitors such as L-N-nitro-L-arginine methyl ester (L-NAME) has been shown to prevent or reduce pain hypersensitivity (Meller, S. T. *et al.*, 1992; Hao, J. X. and Xu, X. J., 1996; Handy, R. L. and Moore, P. K., 1998). Indeed particular interest has been devoted to producing selective blockers of iNOS, to avoid side effects associated with nonspecific block of nNOS and endothelial NOS (eNOS). Recently GW27415, a selective iNOS inhibitor has been shown to partially reduce Freund's complete adjuvant (FCA)-induced inflammatory pain as well the hypersensitivity associated with the CCI neuropathy model. This action was most likely to have been caused via a peripheral mechanism as no iNOS expression was detectable in sensory ganglia or spinal cord (Alba, J. D. *et al.*, 2006).

5.53.21 Summary and Conclusions

Pharmacological understanding of pain is the foundation on which new and effective therapies for pain can emerge. Great advances have been made with greater availability of improved chemical and biological tools. This has fueled greater understanding of the mechanistic and molecular substrates of pain, derived for the most part from our studies of animal models (see Figure 1). The complexity and heterogeneity of chronic pain states will clearly remain an enormously challenging area for future research. There is still a great need for human data showing the regulated expression of pain molecules and clinical data that provides more rapid evaluation of emerging pharmacological concepts. This will allow the most valuable targets to be selected for analgesia development in the clinic.

Clearly the improvements in our pharmacological understand of pain has also provided an abundance of opportunities for developing analgesics. Among the most comprehensively studied molecules in chronic pain are inflammatory mediators and their key receptors. These include PGE2/EP1, bradykinin/BK1 and BK2, ATP/P2X3, cytokines/ IL-1β, chemokines/ CCr2 and neurotrophins/NGF/TrkA that sensitize and increase excitability in peripheral and central pain pathways. Many of these mediators act through GPCRs and there appears to be some convergence of mechanisms with changes in expression and regulation of ion channel. Key channels for pain are either ligand gated, for example, TRPV1, P2X3, P2X4, P2X7, or voltage gated, for example, NaV1.8, NaV1.7, NaV1.3, CaV2.2.

A variety of additional cellular process including protein phosphorylation of membrane receptors and channels via key kinases, for example, MAPK, as well as complex phenotype change regulated by neurotrophins require further understanding. In addition, the emerging importance of neuroglia and their pharmacology needs exploration and consolidation.

Finally despite the great advances in pain pharmacology, many pain molecules remain poorly validated as good targets for analgesia. Stronger clinical translation is highly likely with the progression of pharmacological opportunities into humans.

5.54.1 Introduction

The initial studies on the neurobiology of pain and the discovery and understanding of the endogenous opioid systems have been historically intrinsically linked. In the 1960s, early research by Liebeskind and coworkers (Mayer, D. J. *et al.*, 1971) demonstrated that the electrical stimulation of the ventral periaqueductal and periventricular gray produced profound analgesia, an effect that was independently observed by Reynolds D. V. (1969). During the same time, Tsou K. and Jang C. S. (1964) observed similar analgesic effects when morphine was microinjected into these locations. As a consequence, and before opioid receptors or their ligands had been isolated, Mayer D. J. *et al.* (1971) proposed that electrical stimulation induced analgesia by activating neural substrates that are involved in the blockage of pain and that were related to the analgesic action of morphine. These observations were followed by the subsequent use of electrical stimulation of the posterior aspect of the paraventricular nucleus of the thalamus for the treatment of pain (Richardson, D. E. and Akil, H., 1977a; 1977b). In 1973, Snyder and Pert published the first manuscript demonstrating the existence of opioid receptors (Pert, C. B. and Snyder, S. H., 1973), a development that was paralleled by the work of Eric Simon (Simon, E. J. *et al.*, 1973) and Lars Terenius (Terenius, L., 1973). These initial findings were followed by the identification of met- and leu-enkephalin (Hughes, J. *et al.*, 1975), β-endorphin (Li, C. H. *et al.*, 1976; Loh, H. H. *et al.*, 1976), and the dynorphin peptides (Goldstein, A. *et al.*, 1979). The 1990s saw the cloning of the opioid receptors delta (δ) (Evans, C. J. *et al.*, 1992; Kieffer, B. L. *et al.*, 1992), mu (μ) (Chen, Y. *et al.*, 1993; Thompson, R. C. *et al.*, 1993), and kappa (κ) (Li, S. *et al.*, 1993; Meng, F. *et al.*, 1993). These are seven transmembrane domain G-protein-coupled receptors inhibiting adenyl cyclase and modulating calcium and potassium conductance.

5.54.2 Endogenous Opioid Mechanisms in the Regulation of Pain

5.54.2.1 μ-Opioid-Receptor-Mediated Pain Processing

This chapter will cover the regulation of pain by supraspinal opioid systems. Investigation of these mechanisms has been most extensive for those pertaining to the μ-opioid receptor, as this is the site of action of opiate analgesics and the receptor most consistently associated with pain suppression. Knockout animals devoid of these receptors display shorter latencies in the tail flick and hot plate tests, thought to involve spinal and supraspinal mechanisms, respectively, as well as a lack of morphine effects (Sora, I. *et al.*, 1997). Its endogenous ligands include β-endorphin, derived from the peptide precursor proopiomelanocortin (POMC), the recently described endomorphins 1 and 2, and in some circuits, the enkephalins (cleaved from the larger preproenkephalin precursor). POMC-containing neurons are located in the arcuate nucleus of the hypothalamus and periarcuate regions of the medial-basal hypothalamus, with a smaller group localized in the nucleus of the tractus solitarius of the medulla. Projections are extensive to the periventricular thalamus, septum, and amygdala, dorsally descending to the periaqueductal gray (PAG), midline

raphe, and reticular formation, and laterally to the anterior and lateral hypothalamus. Lighter innervation is observed in the medial portion of the nucleus accumbens and olfactory cortex (Khachaturian, H. *et al.*, 1985). Animals devoid of a functioning POMC gene show a lack of naloxone-reversible analgesia induced by mild swim stress, but greater nonopioid (naloxone nonreversible) analgesic effects and normal effects of morphine. These data demonstrated the involvement of β-endorphin in stress-induced analgesic responses, while also highlighting the presence of alternate mechanisms not mediated by β-endorphin and μ-opioid receptors (Rubinstein, M. *et al.*, 1996).

In contrast to the narrow localization of POMC-containing cells, enkephalinergic cells and projections are widely distributed, forming both local circuits and long projections, with similar distributions for met- and leu-enkephalin, albeit with a higher level of met-enkephalin in all regions. The highest concentrations of terminals with these peptides are encountered in the globus pallidus and central and lateral amygdala nuclei. Globus pallidus and ventral pallidal projections form part of the enkephalinergic striatopallidal pathway, with cell bodies arising primarily in the nucleus accumbens and to a lesser extent in the ventromedial hypothalamus. Cell bodies containing preproenkephalin are also encountered in the olfactory bulb, septal nuclei, bed nucleus of the stria terminalis, throughout the basal ganglia and in the cortex. Terminal densities are moderate to dense in the cingulate, piriform, and entorhinal cortex, anterior and periventricular thalamus, and preoptic hypothalamus (the latter from both local projections and terminals arising from the amygdala and periamygdalar area). Both cell bodies and rich local projections are encountered in the PAG, raphe, locus coeruleus, nucleus ambiguus, and nucleus of the solitary tract (Petrusz, P. *et al.*, 1985). Enkephalin-deficient mice display large increases in the concentration of μ-opioid receptors in the globus pallidus, central nucleus of the amygdala, bed nucleus of the stria terminalis and substantia innominata, preoptic, medial and lateral hypothalamus, medial thalamus, PAG, raphe, nucleus ambiguus, and nucleus of the tractus solitarius, suggesting substantial enkephalinergic activity on μ-opioid receptors in these regions, with compensatory upregulation in the knockouts (Brady, L. S. *et al.*, 1999). Enkephalin-deficient mice display reductions in supraspinal analgesic responses as measured with the hot-plate test and rapid nocifensive responses in the formalin assay, but unaltered spinal analgesic responses (tail-flick test) and stress-induced analgesia (Konig, M. *et al.*, 1996).

Last, the most recently identified family of opioid peptides, the endomorphins 1 and 2, and in a manner similar to that for β-endorphin, is synthesized in the brain only in hypothalamic cells (periventricular, arcuate, and ventromedial and dorsomedial nuclei), and project to pain-processing regions of the brainstem and pons (trigeminal tract, parabrachial nucleus, nucleus of the tractus solitarious, PAG, and locus coeruleus) as well as to midline thalamic nuclei and the amygdala. Besides the hypothalamic cell bodies, the only other known areas containing endomorphin-positive cell bodies include the nucleus of the tractus solitarius and the dorsal root ganglia. Consistent with its actions at μ-opioid receptors, intracerebroventricular administration of endomorphins induces profound analgesia that may be dissociated from the rewarding properties associated with μ-opioid receptor agonists (Zadina, J. E., 2002).

Initial studies on the role of supraspinal μ-opioid-receptor-mediated antinociception focused on the role of the PAG and its connections with the rostroventral medulla (RVM). These are regions that, together with the dorsolateral pontine tegmentum, control nociceptive transmission via projections through the spinal cord dorsolateral funiculus to the dorsal horn laminae (Fields, H. L. and Basbaum, A. I., 1978). Much of the focus during the following decades was then dedicated to the understanding of the mechanisms underlying this modulation. Both pain facilitatory and inhibitory cells have been described at the level of the RVM (Moreau, J. L. and Fields, H. L., 1986; Heinricher, M. M. *et al.*, 1987; Urban, M. O. and Smith, D. J., 1994; Zhuo, M. and Gebhart, G. E., 1997). μ-Opioid receptors, through the activation of enkephalinergic neurotransmission and GABA interneurons in the PAG and RVM (al-Rodhan, N. *et al.*, 1990), increase the activity of inhibitory (off) cells reducing pain transmission. The administration of μ-opioid receptor agonists systemically, or directly into the PAG or RVM, increases the activity of these off cells, with blockade of the activation of these neurons preventing morphine's antinociceptive effects (Heinricher, M. M. *et al.*, 1999). Not surprisingly, in view of these results, the possible role of μ-opioid neurotransmission beyond the PAG, RVM, and descending pathways into the spinal cord (e.g., supraspinal mechanisms) was thought to be less critical and mostly regarded as secondary to the analgesia mediated primarily by brainstem and spinal cord regions.

Nevertheless, examination of the distribution of μ-opioid receptors, mRNA in the rodent (Mansour,

A. *et al.*, 1995) and *in vivo* μ-opioid receptor availability in the human brain (Frost, J. *et al.*, 1985) demonstrate a broad distribution of these sites in telencephalic areas. Administration of μ-opioid receptor agonists increases the blood flow of brain regions rich in μ-opioid receptors (cingulate, prefrontal, temporal and insular cortices, thalamus, hypothalamus, basal ganglia, amygdala, and brainstem) (Adler, L. J. *et al.*, 1997; Schlaepfer, T. *et al.*, 1998; Casey, K. *et al.*, 2000; Wagner, K. J. *et al.*, 2001), and reduces pain-induced activation in the thalamus (Casey, K. *et al.*, 2000). Some of these areas, such as thalamic and hypothalamic nuclei, the central nucleus of the amygdala, the agranular insular cortex and lateral orbitofrontal cortex, have been associated with the suppression of pain behavior in animal models (Mayer, D. J. and Liebeskind, J. C., 1974; Yaksh, T. L. and Rudy, T. A., 1978; Bodnar, R. J. *et al.*, 1980; Coffield, J. A. *et al.*, 1992; Burkey, A. R. *et al.*, 1996; Manning, B., 1998; Manning, B. and Franklin, K., 1998; Harte, S. *et al.*, 2000; Manning, B. H. *et al.*, 2001). However, the inhibition of pain signaling elicited by the activation of μ-opioid receptors in these supraspinal regions is thought to take place through their connections with the PAG, since inactivation of the PAG or the administration of opioid antagonists in this area abolishes the analgesic response. In turn, PAG-induced analgesia is blocked by μ-opioid receptor antagonists microinjected in the RVM, then reducing nociceptive transmission from the spinal cord (Kiefel, J. M. *et al.*, 1993; Roychowdhury, S. M. and Fields, H. L., 1996).

In view of the critical role of the PAG and RVM on μ-opioid-receptor-mediated antinociception, perhaps the question to be answered regarding the involvement of opioid systems in supraspinal nuclei is their respective role in the experience of pain as a complex phenomenon. Opioid neurotransmission is activated in humans during clinical pain, or experimental pain of some duration, as evidenced by enhancements in pain ratings after the administration of naloxone, a nonselective opioid receptor antagonist (Levine, J. *et al.*, 1978). Conversely, experimental pain of relatively short duration (e.g., <10 min) does not elicit an apparent activation of opioid neurotransmission, evidenced by a lack of increases in pain ratings after naloxone administration (Grevert, P., and Goldstein, A., 1977). These findings are similar to those observed in response to nonpainful stressors, whereby prolonged or unpredictable stimuli activate opioid neurotransmission, leading to the term stress-induced analgesia (Madden, J. T. *et al.*, 1977; Watkins, L. and Mayer, D., 1982). It is therefore possible that the progressive engagement of supraspinal μ-opioid mechanisms may be of greater importance for the control of noxious stimuli as it progresses from a relatively simple sensory experience to one that requires the assessment of its significance and an appropriate response by the organism.

Two studies have examined the activity of μ-receptor-mediated opioid neurotransmission in humans during the experience of pain. Both studies employed the μ-opioid-receptor-selective radiotracer [^{11}C]carfentanil and positron emission tomography. Bencherif B. *et al.* (2002) utilized the capsaicin model of experimental pain, while in Zubieta J. K. *et al.* (2001), jaw muscle pain was induced by the intramuscular infusion of hypertonic saline. The former, in a smaller sample, showed evidence of activation of μ-opioid-receptor-mediated neurotransmission in the thalamus. In the latter, engagement of this neurotransmitter system was observed in a number of brain areas, including the PAG, dorsal and rostral anterior cingulate, dorsolateral prefrontal cortex, anterior and posterior insular cortex, medial and lateral thalamus, hypothalamus, ventral basal ganglia, and amygdala. Invariably, the relationship between μ-opioid activation and subjective ratings of pain was in the negative direction (the larger the activation the lower the pain ratings), with sensory or pain affect elements being modulated by different regions. Some of these regions had been previously implicated in opioid-mediated suppression of nociceptive responses in animal models (e.g., PAG, thalamus, hypothalamus, amygdala, and to a lesser extent areas of the insular cortex), as noted above. Conversely, while pain-induced increases in synaptic activity of the prefrontal cortex (Baron, R. *et al.*, 1999; Lorenz, J. *et al.*, 2002) and dorsal anterior cingulate cortex (Rainville, P. *et al.*, 1997) had been described and associated with hyperalgesia and pain affect, respectively, the involvement of the endogenous opioid system on these processes had not been previously explored. Similarly, the ventral basal ganglia (nucleus accumbens, ventral pallidum) have been typically associated with either responses to natural rewards or drugs of abuse, stress, or, as is more recently postulated, with salient stimuli irrespective of its valence (Horvitz, J., 2000). These data then appear to indicate that, besides its traditional role in the modulation of descending inhibitory pathways into the PAG and RVM, supraspinal μ-opioid receptors are additionally involved in the local

processing of complex assessments of the pain experience. In this regard, μ-opioid receptors appear implicated in regulating emotional responses, as examined in knockout rodents devoid of these receptors. These animals display an enhancement of anxiety-like responses in the elevated arm maze (Filliol, D. *et al.*, 2000) and deficits in attachment behavior (Moles, A. *et al.*, 2004). Proenkephalin knockouts also show a lack of conditioned place aversion to naloxone (Skoubis, P. D. *et al.*, 2005), increased aggressive behavior to an intruder and anxiety-like behavior in the open arm maze, as well as alterations in supraspinal but not spinal pain processing (Konig, M. *et al.*, 1996), additionally involving this neurotransmitter system in emotional behavioral responses.

Work in humans has also shown that in the case of some of the brain regions in which μ-opioid systems become active during pain (e.g., rostral anterior cingulate, dorsolateral prefrontal cortex, nucleus accumbens, and insular cortex), cognitive expectations associated with the administration of a placebo with expected analgesic properties are also capable of activating this neurotransmitter system to mediate the placebo analgesic effect (Benedetti, F. *et al.*, 2005; Zubieta, J. K. *et al.*, 2005).

A relatively less explored area in the understanding of μ-opioid receptor modulation of pain is the additional influences of age and gonadal steroids (e.g., sex effects). In rodents, age-associated declines in μ-opioid receptor concentrations have been reported (Piva, F. *et al.*, 1987). However, humans demonstrate opposite effects, with increases in most brain regions shown in postmortem material (Gross-Isseroff, R. *et al.*, 1990; Gabilondo, A. *et al.*, 1995) and in neuroimaging studies (Zubieta, J. K. *et al.*, 1999), albeit the psychophysical correlates of these changes in receptor concentrations have not been determined. In human subjects, women further demonstrate declines in μ-opioid receptor levels after menopause (Zubieta, J. K. *et al.*, 1999). In this regard, trophic effects of estradiol have been shown at the level of μ-opioid receptor levels and their mRNA, POMC content, and β-endorphin release in animal models (Hammer, R. P. and Bridges, R. S., 1987; Dondi, D. *et al.*, 1992; Quinones-Jenab, V. *et al.*, 1997; Eckersell, C. *et al.*, 1998). The clinical implications of these effects have not been well developed, albeit sex differences have been observed in the effects of μ-opioid receptor agonists, including their side effects and cardiovascular parameters, which appear to be more prominently affected in women (Zacny, J. P., 2001; Fillingim, R. B. and Gear, R. W., 2004). A less prominent activation of μ-opioid-receptor-mediated neurotransmission, as measured with neuroimaging techniques, has been shown in women studied under conditions of low estradiol, low progesterone during an experimental pain challenge (Zubieta, J. K. *et al.*, 2002). This effect, observed in the thalamus, amygdala, and nucleus accumbens, was reversed after selectively increasing estradiol plasma levels, which also increased μ-opioid receptor concentrations in these regions (Smith, Y. R. *et al.*, 2006). These data then suggest an active regulation of μ-opioid-receptor-mediated mechanisms by gonadal steroids.

5.54.2.2 κ-Opioid-Receptor-Mediated Processing

The prodynorphin-derived peptides, which present the highest affinity and colocalization with κ-opioid receptors, consist of extended forms of leu-enkephalin coded by a different gene and mRNA. These peptides include dynorphin A, B, and neoendorphins α and β (Goldstein, A. *et al.*, 1979). Their involvement in pain regulatory mechanisms has been controversial, as both anti- and pronociceptive responses have been described in response to κ-agonists depending on the brain regions studied. Similarly to β-endorphin and endomorphin systems, there is a dense accumulation of dynorphin-containing cells in the multiple regions of the hypothalamus, forming both local circuits and longer projections, particularly to the amygdala and descending to brainstem, pontine, and medullary/spinal regions (e.g., PAG, but also substantia nigra). However, and closer to the distribution of the enkephalin peptides, cell bodies are also encountered in limbic areas of the cortex, such as the anterior cingulate, orbitofrontal, insular, periamygdaloid, and entorhinal cortex, in the basal ganglia (caudate, putamen, globus pallidus), nucleus accumbens, amygdala, particularly in its central nucleus, PAG, raphe nuclei, locus coeruleus, nucleus ambiguus, and nucleus of the solitary tract. Long pathways have been described from the striatum to the substantia nigra and ventral pallidum, as well as from the amygdala to brainstem and pons regions. Minimal innervation of the thalamus has been observed, which is confined to midline and intralaminar nuclei (Fallon, J. and Ciofi, P., 1990). Mice devoid of the dynorphin gene show an upregulation of κ-receptors in the nucleus accumbens shell and core, hypothalamus, amygdala, and substantia

nigra, consistent with their high level of dynorphin innervation, and suggesting an active role of this peptide in the modulation of the κ-receptors in these brain regions (Clarke, S. *et al.*, 2003).

Intrathecal administration of κ-opioid agonists or their microinjection in the RVM has been shown to result in antinociceptive responses in various rat models (Harada, Y. *et al.*, 1995; Ackley, M. A. *et al.*, 2001), albeit modest, and typically requiring high doses. These effects have also been demonstrated to be sex dimorphic, with female rats demonstrating a more profound analgesic effect than the males in the tail-flick test (Tershner, S. A. *et al.*, 2000). In κ-receptor knockout animals, female but not male rats demonstrate decreased withdrawal latencies in the tail-immersion test, compared to wild-type animals (Martin, M. *et al.*, 2003). Consistent with these findings, one study has shown a preferential antinociceptive effect of opiates with κ-opioid activity in women, with respect to men, after surgical extraction of the third molar (Gear, R. *et al.*, 1996).

κ-Opioid agonists, however, have also been shown to antagonize morphine analgesia, by the hyperpolarization of pain-inhibitory cells activated by μ-opioid receptors in the RVM (Pan, Z. Z. *et al.*, 1997; Meng, I. D. *et al.*, 2005). Therefore pronociceptive, antianalgesic effects of κ-opioids may exist simultaneously with antinociceptive activity, depending on the brain regions involved or the existing level of μ-opioid receptor activity. Opposing effects of μ- and κ-receptors have also been shown at the level of the medial thalamus, whereby microinjection of μ-agonists increased, and κ-agonists reduced, the thresholds for pain-induced vocalization and motor responses in male rodents (Carr, K. D. and Bak, T. H., 1988). Dynorphin also appears to be involved in the maintenance of hyperalgesia and persistent pain, with only spinal mechanisms having been investigated at this time (Wang, Z. *et al.*, 2001).

Dynorphin and κ-opioid agonists further antagonize dopamine release in the basal ganglia (Zhang, Y. *et al.*, 2004), whether induced by μ-opioid receptor agonists, psychostimulants, or stressors, by the inhibition of dopamine (DA) cells in the ventral tegmental area and substantia nigra or possibly indirectly through the regulation of DA reuptake at the level of the nucleus accumbens (Thompson, A. C. *et al.*, 2000; Margolis, E. B. *et al.*, 2003; McLaughlin, J. P. *et al.*, 2003; Narita, M. *et al.*, 2005). Dopaminergic mechanisms, typically associated with responses to drugs of abuse and more generally to salient stimuli regardless of its valence, have been found dysregulated in chronic pain patients, albeit the clinical consequences of these alterations are presently unknown (Hagelberg, N. *et al.*, 2004).

5.54.2.3 δ-Opioid-Receptor-Mediated Processing

The enkephalins are thought to be the endogenous ligand for the δ-opioid receptor, in addition to acting on μ-opioid receptors, as noted above. Their distribution was described in this chapter under Section 5.54.2.1. Knockout mice devoid of the enkephalin gene display increases in the regional concentration of μ- and δ-opioid receptors (Brady, L. S. *et al.*, 1999), suggesting an effect of this peptide in both receptor systems. In the case of the δ-receptor, these increases were observed in the caudate–putamen, nucleus accumbens core and shell, ventral pallidum, globus pallidus, the central nucleus of the amygdala, preoptic area, and lateral hypothalamus. Microinjection of δ-receptor agonists in the PAG and medullary reticular formation has been shown to induce antinociception (Jensen, T. S. and Yaksh, T. L., 1986). Their intracerebroventricular administration has also been shown to have antinociceptive properties in tests of spinal and supraspinal nociceptive mechanisms in wild-type and μ-opioid-receptor-deficient mice (Porreca, F. *et al.*, 1984; Vaught, J. L. *et al.*, 1988; Ossipov, M. H. *et al.*, 1995). Rodent, primate, and human δ-opioid receptors are uniformly distributed throughout the cortex, diffusely in the striatum, and moderately to densely in the nucleus accumbens, ventral pallidum, hippocampus, amygdala, medial thalamus, hypothalamus, PAG, and raphe nuclei. Low concentrations are observed in lateral thalamic nuclei and the cerebellum (Lewis, M. E. *et al.*, 1981; 1983; Moskowitz, A. S. and Goodman, R. R., 1985; Smith, J. S. *et al.*, 1999; Cahill, C. M. *et al.*, 2001b). This distribution, which emphasizes a limbic and paralimbic organization as well as its relationship with pain circuitry, has suggested the involvement of this receptor and neurotransmitter system in emotional and stress regulation in addition to antinociceptive mechanisms. Regarding the latter, δ-opioid-receptor-agonist-induced analgesia and respiratory depression has been shown either reduced (Matthes, H. W. *et al.*, 1998) or in some cases abolished (Scherrer, G. *et al.*, 2004), depending on the assays employed, in animals devoid of μ-opioid receptors. These results then suggested the presence of functional interactions between μ- and δ-opioid-receptor types. Conversely, δ-opioid

stress-induced analgesia after forced swim stress was found maintained in μ-opioid receptor knockout mice. These data supported a lack of interactions between μ- and δ-opioid receptors when endogenous opioid transmission was activated by a stressor, as opposed to exogenously administered agonists. However, and in the same studies, two phases of the stress-induced analgesia were observed, one early response mediated by δ-opioid receptors, and a later response that was abolished in the μ-opioid receptor knockouts and unaffected by δ-opioid receptor antagonists (LaBuda, C. J. *et al.*, 2000).

Utilizing single, double, and triple knockouts for μ-, κ-, and δ-opioid receptors Martin M. *et al.* (2003) have suggested that δ-opioid receptors, together with μ-opioid receptors, were involved in mechanical nociception and some, but not other phases of inflammatory pain. Besides their independent functions, interactions between μ- and δ-receptors have also been demonstrated at various levels. Treatment with μ-opioid agonists has been shown to increase the concentration of membrane-bound δ-receptors in the spinal cord by increasing their trafficking from intracellular sites, an effect that was abolished in μ-opioid receptor knockout animals (Cahill, C. M. *et al.*, 2001a; Morinville, A. *et al.*, 2003). Furthermore, interacting complexes of μ- and δ-receptors (heterodimers) have been demonstrated in spinal cord and neuroblastoma cell lines, as well as synergistic interactions in analgesic effects between the two receptor types (Gomes, I. *et al.*, 2004).

Regarding other possible effects of δ-opioid neurotransmission, stressors have been shown to decrease the concentration of δ-opioid receptors in limbic areas of the rat (Fadda, P. *et al.*, 1991) and increase that of enkephalin mRNA in the ventral medulla (Mansi, J. A. *et al.*, 2000) and hypothalamus (Helmreich, D. L. *et al.*, 1999; Dumont, E. C. *et al.*, 2000), confirming their involvement in the modulation of the stress response, albeit not in its neuroendocrine components, at least in primates (Williams, K. L. *et al.*, 2003). Antidepressant-like effects have also been demonstrated in animal models of depression, suggesting the participation of this system in complex behavioral functions (Jutkiewicz, E. M. *et al.*, 2003; Torregrossa, M. M. *et al.*, 2004).

5.54.2.4 Opioid Receptor-like (ORL-1, NOP Receptor)-Mediated Processing

The opioid receptor-like (ORL1) receptor (now denominated NOP) is the most recently identified opioid receptor, with high homology with other opioid receptors, but does not bind to traditional opioid peptides. It is present in high concentrations in the septum, diagonal band of Broca, hypothalamus (preoptic, arcuate, paraventricular, ventromedial), hippocampus, medial amygdala, substantia nigra, locus coeruleus, raphe nuclei, PAG, as well as in the dorsal and ventral horns of the spinal cord and in the trigeminal nucleus. It is also moderately concentrated in the thalamus, cortex (olfactory, cingulate, claustrum, and frontoparietal areas), the shell of the nucleus accumbens, and islets of Calleja. Low levels are observed in the caudate–putamen, core of the nucleus accumbens, and cerebellum (Mollereau, C. *et al.*, 1994). The 17-amino acid peptide orphanin FQ/nociceptin (OFQ/N), the endogenous ligand for this receptor, was subsequently isolated. It presented high homology with opioid peptide transmitters, particularly dynorphin (Meunier, J. C. *et al.*, 1995; Reinscheid, R. K. *et al.*, 1995). This peptide is synthesized as part of a larger precursor, preproOFQ/N, with a distribution largely overlapping with that of the NOP receptor in the rat brain (Mollereau, C. *et al.*, 1996; Darland, T. *et al.*, 1998). Like opioid agonists, OFQ/N inhibits adenylate cyclase and calcium channels, and induces an inhibitory effect on postsynaptic neurons by opening potassium channels and hyperpolarization (Hawes, B. E. *et al.*, 2000; Moran, T. D. *et al.*, 2000). This inhibitory effect has been invoked in explaining the often-times contradictory effects of generalized routes of OFQ/N peptide administration (e.g., intracerebroventricular) (Darland, T. *et al.*, 1998). For example, initial reports described increases in pain behavior (Meunier, J. C. *et al.*, 1995; Reinscheid, R. K. *et al.*, 1995), no effect on pain responses (Mogil, J. S. *et al.*, 1996a; 1996b; Tian, J. H. *et al.*, 1997), or even hyperalgesia (Rossi, G. C. *et al.*, 1996; 1997), and a reversal of the analgesic actions of morphine and endogenous opioid peptides (Mogil, J. S. *et al.*, 1996a; 1996b). It is thought that these effects depend on the populations of cells being inhibited, as OFQ/N can hyperpolarize neurons that both facilitate and inhibit pain signal transmission at the level of the RVM (Heinricher, M. M. *et al.*, 1997), as well as most of the neuronal populations rich in the NOP receptor (e.g., hypothalamus, medulla, hippocampus, amygdala, ventral tegmental area, locus coeruleus, and PAG) (see Heinricher, M. M., 2003 for a recent review). Using data acquired by the microinjection of OFQ/N in the RVM, Heinricher M. M. *et al.* (1997) proposed that the behavioral effects of this peptide depend on the state of activity of the output neurons affected by the peptide. Under conditions of stimulation (opioid withdrawal,

stress, and opioid agonist effects) the effects of OFQ/N would oppose the state of activation in the relevant circuits, inducing an opposing effect, with additional influencing variables, such as sex or genotype, also suggested to influence its effects (Mogil, J. S. and Pasternak, G. W., 2001; Flores, C. A. *et al*., 2003). On the other hand, and during basal states, OFQ/N effects would be minimal (Heinricher, M. M. *et al*., 1997). Consistent with these findings, OFQ/N enhanced stress-induced ACTH production at the level of the pituitary and plasma corticosterone, an effect that in this case was also observed to a lesser extent in nonstressed animals (Devine, D. P. *et al*., 2001). Knockout rodents devoid of either OFQ/N or NOP receptors do not appear to have significant changes in nociceptive responses or changes in opiate analgesia under nonstimulated conditions (Nishi, M. *et al*., 1997; Koster, A. *et al*., 1999; Kest, B. *et al*., 2001; Mamiya, T. *et al*., 2001). In a neuropathic pain model, NOP mRNA expression increased in pain regulatory circuitry (raphe magnus, PAG, and RVM), albeit the behavioral consequences of these increases have not been explored (Ma, F. *et al*., 2005).

5.55.1 Introduction

Neuropathic pain is defined by the International Association for the Study of Pain (IASP) as "pain initiated or caused by a primary lesion or dysfunction in the nervous system". Although this definition functions well as a guide for the clinical assessment of neuropathic pain, a definitive categorization of neuropathic pain is difficult because there are many descriptions of the pain syndrome. Neuropathic pain may arise from an actual injury to a peripheral nerve or it may arise in the absence of any obvious nerve damage (e.g., trigeminal neuralgia and complex regional pain syndrome (CRPS), type I). Disease processes, such as diabetic neuropathy, postherpetic neuralgia resulting from varicella zoster infection (shingles), and complications from AIDS also may cause neuropathic pain, as may alterations in peripheral nerve function induced by chemotherapeutic regimens. Neuropathic pain may include spontaneous, or stimulus-independent, pain that has been described as shooting, burning, lancinating, prickling, and electrical. Evoked, or stimulus-dependent, neuropathic pain includes allodynia, defined by IASP as "pain due to a stimulus which does not normally provoke pain." These stimuli may be nonnoxious heat, light touch, or even a puff of cool air. Moreover, mechanical allodynia may be static, as evoked by a light touch, or dynamic, as evoked by a light brush of the skin. Hyperalgesia is identified when a stimulus that normally produces a nociceptive responses produces an exaggerated responses. The different forms through which neuropathic pain manifests suggest that differing mechanisms are likely to mediate the different features of the condition. The numerous features of neuropathic pain can complicate an accurate clinical diagnosis. For this reason, efforts have emphasized the development of highly specific questionnaires emphasizing a unique set of symptoms that can aid clinical diagnosis with relatively little effort. Features that appear to be most often related to neuropathic pain include tingling

or numbness, pain evoked by heat or cold, and especially, a sensation of heat or a burning-like quality is associated with the neuropathic pain state (Krause, S. J. and Backonja, M. M., 2003; Backonja, M. M. and Stacey, B., 2004; Bennett, M. I. *et al.*, 2007). More recently, a questionnaire identified at DN4 was designed to assess the presence of pain combined with parasthesias or dysesthesias (Bouhassira, D. *et al.*, 2005).

5.55.2 Injury-Induced Sensitization of Peripheral Nerves and Neuropathic Pain

There are several factors common to the neuropathic pain state, regardless of the etiology that may initiate the condition. It has been repeatedly demonstrated that peripheral nerve injury is associated with a heightened sensitivity of nerves to sensory stimuli, a phenomenon that has been termed peripheral sensitization. Importantly, peripheral sensitization is not restricted to the injured nerve fibers, but also includes adjacent, uninjured (but abnormal) nerves. Injured nerves may form a tangled mass of connective tissue termed a neuroma with distally sprouting regenerating axons. Physical manipulation of the neuroma elicits sensations ranging from minor dysesthesias to intense pain. Electrophysiologic studies showed that both myelinated and unmyelinated fibers in neuromas show a basal spontaneous activity as well as enhanced discharges provoked by touch or movement, indicating that the neuroma may serve as an ectopic generator of action potentials. In addition, cell bodies of the dorsal root ganglia (DRG) may also generate ectopic discharges, thus producing spontaneous hyperesthesias and pain as well as enhanced sensitivity to stimuli. Traumatic injury of the rat sciatic nerve produced by loose ligatures, the chronic constriction injury or CCI model, resulted in spontaneous discharges generated from the DRG. In this study, discharges were recorded from 15% to 35% of myelinated and 3% of unmyelinated fibers (Kajander, K. C. *et al.*, 1992). Electrophysiological recordings performed on sciatic nerve bundles after CCI also demonstrated spontaneous and evoked ectopic discharges from the region of injury (Tal, M. and Bennett, G. J., 1994). Surprisingly, these spontaneous discharges of DRG neurons occurred from cells of both injured as well as intact nerves (Michaelis, M. *et al.*, 1996). Additionally, electrophysiologic studies showed spinal nerve transection enhanced the spontaneous activity of nerve fibers in adjacent, uninjured nerve roots and in peripheral nerves (Ali, Z. *et al.*, 1999; Wu, G., *et al.*, 2001). Such studies raised the question of relative contributions of enhanced excitability from injured and uninjured fibers in eliciting neuropathic pain. Yoon Y. W. *et al.* (1996) used a model of neuropathic pain in which the L5 spinal nerve was injured (the spinal nerve ligation or SNL model, Kim, S. H. and Chung, J. M., 1992) and showed that the behavioral signs of pain were abolished by dorsal rhizotomy or bupivacaine applied to the injured spinal nerves emphasizing the importance of afferent drive. Moreover, dorsal rhizotomy or bupivacaine at L4 and L5 also abolished behavioral signs of mechanical and cold allodynia, but not signs of ongoing pain (Yoon, Y. W. *et al.*, 1996). The contribution of uninjured nerves, or uninjured adjacent fibers, to neuropathic pain has been debated. In an insightful study, Belzberg and coworkers (Li, Y. *et al.*, 2000) used the SNL model and found that the behavioral signs of experimental neuropathic pain produced by ligation of the L5 spinal nerve were not abolished by rhizotomy at L5, but rather were abolished by rhizotomy at L4. These findings suggested a prominent role for uninjured but abnormal adjacent nerve fibers following nerve injury and were consistent with the suggested importance of uninjured, but abnormal, L4 afferents; these fibers show significant redistribution of sodium channels such as $Na_V1.8$ following L5 injury (Lai, J. *et al.*, 2002) and this may reflect a mechanism which drives neuropathic pain (see below). It has also been suggested that sensitization of uninjured peripheral nerves may result, in part, from ephaptic excitation caused by the close proximity of injured and noninjured nerves within the nerve trunks or in the DRG (Devor, M. and Wall, P. D., 1990; Attal, N. and Bouhassira, D., 1999). Sensitization of peripheral nerves may mediate SNL-induced thermal hyperalgesia, but may not mediate tactile allodynia. Unlike tactile allodynia, thermal hyperalgesia was abolished by the intravenous infusion of the quaternary lidocaine analogs QX-314 and QX-222, which do not cross the blood–brain barrier (Chen, Q. *et al.*, 2004). In contrast, both tactile and thermal parameters of enhanced pain were abolished by systemic lidocaine, or microinjection of lidocaine or QX-222 into the rostralventromedial medulla (RVM) (Chen, Q. *et al.*, 2004). These observations emphasize the contribution of a central mechanism (addressed below) which may act in addition to peripheral mechanisms to elicit neuropathic pain states.

5.55.2.1 Role of Peripheral Nerve Degeneration in Neuropathic Pain

Degeneration of peripheral nerves provokes the release of proinflammatory cytokines such as interleukins and tumor necrosis factor (TNF), and neurotrophic factors in the region of the target tissue. The initial reaction is followed by macrophage infiltration that further mediate proinflammatory signals. This accumulation of proinflammatory substances may sensitize adjacent nerve terminals of uninjured fibers. Myelinated peripheral nerve fibers undergoing Wallerian degeneration elicit the release of several pronociceptive factors in the target tissue and cytokines along the peripheral nerve, thereby sensitizing the adjacent nerve endings of uninjured nerve fibers, and exciting and potentially producing an ectopic focus in the uninjured adjacent C fibers (Li, Y. *et al.*, 2000). Wallerian degeneration of the injured, spontaneously active myelinated fibers may excite unmyelinated fibers through the comingling of injured and uninjured nerves that occurs within the Remak bundles of the sciatic nerve trunk (Wu, G. *et al.*, 2001; 2002). Furthermore, Wallerian degeneration associated with injured nerves causes alterations in the Schwann cells that provoke them to release proinflammatory mediators, including glutamate as well as nerve growth factor (NGF) (Shamash, S. *et al.*, 2002; MacInnis, B. L. and Campenot, R. B., 2005). Within the nerve trunk, these substances may diffuse to adjacent uninjured nerve fibers and enhance sensitivity such that an ectopic locus may develop. Release of proinflammatory mediators including NGF in the peripheral terminal fields that include uninjured neurons may sensitize these fibers to ensuing stimulation, thus producing peripheral sensitization. It has been shown that nerve injury causes significant elevations in NGF and its mRNA in Schwann cells, macrophages, and fibroblasts at the site of injury (Shamash, S. *et al.*, 2002; MacInnis, B. L. and Campenot, R. B., 2005). Treatment of cultured fibroblasts or keratinocytes with inflammatory mediators, including histamine and interleukin-1 also provoke upregulation of NGF (Kanda, N. and Watanabe, S., 2003). Moreover, NGF promotes degranulation of mast cells, which release inflammatory mediators and thereby promotes peripheral sensitization of nociceptors as well as further release of NGF (Lewin, G. R. *et al.*, 1994; Stempelj, M. and Ferjan, I., 2005). Denervation of the skin due to degeneration of peripheral nerves produce regions that are insensate surrounded by regions of increased sensitivity to noxious stimuli perhaps as a consequence of upregulation of NGF by keratinocytes (Taherzadeh, O. *et al.*, 2003). Increased NGF production promotes sprouting of peripheral nerve terminals into the region into the boundary between the denervated region and that with normal innervation (Rajan, B. *et al.*, 2003). Collateral sprouting of peripheral axons together with the pronociceptive actions of peripheral NGF can promote nociceptive hypersensitivity in the region immediately surrounding the zone of denervation (Griffin, J. W., 2006).

Other growth factors, such as those in the glial-cell-line-derived neutrotropic factor (GDNF) family including GDNF and artemin, may play a significant role in expression of neuropathic pain. NGF and GDNF family members may act at peripheral nociceptive primary afferents, leading to enhancement of sensitivity to noxious inputs (Zwick, M. *et al.*, 2002; Elitt, C. M. *et al.*, 2006; Griffin, J. W., 2006; Malin, S. A. *et al.*, 2006). Injury-induced upregulation of growth factors such as NGF results in a situation where intact, uninjured nociceptive C fibers expressing the trkA receptor are exposed to a surplus of NGF and may become overtrophed in response to nerve injury (Griffin, J. W., 2006). In these fibers, NGF would promote nociceptive transmission through phosphorylation of TRPV1 ion channels, as well as posttranslational mechanisms that include upregulation of ion channels, redistribution of $Na_V1.8$ and increased synthesis of substance P and CGRP (Boucher, T. J. *et al.*, 2000; Boucher, T. J. and McMahon, S. B., 2001; Griffin, J. W., 2006). In contrast, the axons of the injured peripheral fibers, which include C fiber nociceptors as well as some myelinated sensory fibers, are not able to traffic target-derived growth factors to the cell body. These peripheral nerves may be considered to be undertrophed (Griffin, J. W., 2006) and can demonstrate increased expression of tetrodotoxin (TTX)-sensitive (TTX-S) sodium channels and enhanced spontaneous activity, adaptations which may underlie such painful conditions as postamputation pain and neuropathic pain associated with mastectomy and thoracotomy scars (Griffin, J. W., 2006). This hypothesis was tested by providing support with exogenous trophic factors including GDNF and artemin. Administration of exogenous GDNF normalized expression of sodium channels and the reversed the behavioral signs of neuropathic pain (Boucher, T. J. *et al.*, 2000; Boucher, T. J. and McMahon, S. B., 2001; Wang, R. *et al.*, 2003). In addition, exogenous GDNF delivered by the intrathecal route also abolished electrophysiologic

signs of enhanced firing, ectopic discharges, and normalized sodium channel currents in injured peripheral nerves (Boucher, T. J. *et al.*, 2000; Boucher, T. J. and McMahon, S. B., 2001) as well as multiple biochemical markers in the DRG (Wang, R. *et al.*, 2003). Systemic treatment with artemin to rats with SNL also normalized the expression of biochemical markers of neuropathy, including the expression and redistribution of $Na_V1.8$ and abolished signs of neuropathic pain (Gardell *et al.*, 2003b). The pronociceptive role of neurotrophic factors is discussed below.

5.55.2.2 Role of Nerve Growth Factor in Immediate Pronociceptive Function

NGF binds preferentially to the high-affinity tyrosine kinase receptor subtype trkA and to the low-affinity, nonselective neurotrophin receptor p75 (Sah, D. W. *et al.*, 2005a; 2005b). The neuronal distribution of the trkA receptor indicates a substantial role of NGF in nociceptive processes, since trkA is found almost exclusively on small-diameter unmyelinated peptidergic DRG neurons (Sah, D. W. *et al.*, 2003). Double-labeling studies indicate that 92% of trkA-expressing DRG neurons also express CGRP and substance P, whereas it is present on about 20% of myelinated DRG neurons (Bennett, D. L. *et al.*, 2000; Averill, S. *et al.*, 2004). Investigations performed with a skin–nerve preparation showed that NGF increased mechanical hyperalgesia mediated by thin myelinated fibers and thermal hyperalgesia mediated by unmyelinated nociceptors (Stucky, C. L. *et al.*, 2002). Electrophysiologic studies revealed that endogenous NGF regulates the sensitivity of unmyelinated nociceptors to chemical and thermal stimuli (Bennett, D. L. *et al.*, 1998). Sensitization to heat stimulus or to capsaicin application is induced rapidly by NGF (Shu, X. and Mendell, L. M., 2001). Within 10 min of exposure to NGF, there is a rapid potentiation of capsaicin-evoked ion currents in cultured DRG neurons gated by TRPV1 (Shu, X. and Mendell, L. M., 2001). Activation of the trkA receptor by NGF leads to, among other events, phosphorylation of TRPV1, in part through the signaling cascades associated with PKA, PKC, MEK, and the MAP kinases (Shu, X. and Mendell, L. M., 1999; 2001). Moreover, NGF increases nociceptor activity by a rapid facilitation of sodium currents and suppression of an outward potassium current. Behavioral hyperalgesia is evoked by NGF administered systemically or into the endoneurium of a peripheral nerve (Ruiz, G. *et al.*, 2004; Ruiz, G. and Banos, J. E., 2005). Clinical studies also showed that exogenous NGF produced long-lasting mechanical allodynia and hyperalgesia and mild-to-moderate myalgia (Apfel, S. C., 2000; Svensson, P. *et al.*, 2003). Conversely, manipulations that block NGF activity alleviate signs of hyperalgesia. Blockade of NGF activity with the trkA–IgG fusion protein, that antagonist ALE-540 or with antiserum to NGF abolished mechanical and thermal hyperalgesia in animal models of inflammation, incision, or nerve injury (Owolabi J. B. *et al.*, 1999; Banik, R. K. *et al.*, 2005). More recently, intrathecal injection of antibody to NGF blocked behavioral signs of cold allodynia after nerve ligation (Obata, K. *et al.*, 2005). In addition, anti-NGF given by intrathecal injection or local application onto the L4 spinal nerve abolished signs of thermal and mechanical hyperalgesia in rats with peripheral nerve injury (Obata, K. *et al.*, 2004; 2006). The prominent role of NGF in the expression of chronic pain states has led a number of pharmaceutical companies, including Pfizer/Rinat, Amgen, and PainCeptor Pharma to initiate drug discovery and development efforts targeting NGF or trkA (Shelton, D. L. *et al.*, 2005; Hefti, F. F. *et al.*, 2006). Drug development approaches include sequestering or binding NGF so that it does not interact with the trkA receptor, trkA receptor antagonists, or disruption of the signaling pathways linked to trkA receptor activation (Hefti, F. F. *et al.*, 2006).

5.55.2.3 Nerve Growth Factor May Mediate Posttranslational Pronociceptive Functions

In addition to its immediate actions in the periphery, NGF can also initiate long-lasting posttranscriptional changes in peripheral nerves to promote and sustain an enhanced pain state. When NGF binds to the trkA receptor at the peripheral terminal, it is rapidly internalized and the phosphorylated trkA–NGF complex is accumulated in signaling endosomes that are transported to the DRG, where it triggers the activation of several intracellular signaling cascades, including expression of the MAP kinases, ERK, and p38 (Ji, R. R. *et al.*, 2002; McMahon, S. B. and Cafferty, W. B., 2004). Inflammation or exogenous NGF administered spinally causes phosphorylation of p38 in nociceptors in the DRG, but not the dorsal horn, along with a substantial upregulation of TRPV1 in the DRG (Ji, R. R. *et al.*, 2002; McMahon, S. B. and Cafferty, W. B., 2004; Malik-Hall, M. *et al.*, 2005). Moreover, there is evidence that the TRPV1 receptor is preferentially trafficked to the peripheral terminals of the nociceptors, where it can contribute to

peripheral sensitization and hyperalgesia (Ji, R. R. *et al.*, 2002). Furthermore, hyperalgesia may also be maintained by the increased expression of peptidic neurotransmitters specific to primary afferent nociceptors. The exposure of DRG cultures to NGF produced 15- to 60-fold increases in mRNA for substance P and CGRP in trkA-expressing cells, and increased capsaicin-evoked release of CGRP or substance P from cultured trigeminal neurons and from central terminals of primary afferent nociceptors in spinal cord sections (McMahon, S. B. and Cafferty, W. B., 2004; Puntambekar, P. *et al.*, 2005). Animals with diabetic or chemotherapy-induced neuropathy treated with NGF showed abnormally elevated levels of substance P and CGRP protein and mRNA (Tomlinson, D. R. *et al.*, 1997). These functional consequences of NGF expression, including stimulation of BDNF production, may enable transition from peripheral to central sensitization after injury, resulting in chronic pain (Sah, D. W. *et al.*, 2003; McMahon, S. B., *et al.*, 2005; Sah, D. W. *et al.*, 2005a; 2005b). Moreover, retrogradely transported NGF promotes the upregulation of ion channels that promote activation of peripheral nerves and enhances nociceptive transmission. For example, hyperalgesia is also maintained by NGF-mediated upregulation of ASIC3 and upregulation and redistribution of $Na_V1.8$ on primary afferent nociceptors (McMahon, S. B. and Jones, N. G., 2004). Importantly, it was shown that peripheral nerve injury is associated with enhanced retrograde transport of NGF to the cell bodies of spared, or uninjured adjacent, peripheral nerves, thus promoting pronociceptive transcriptional changes in these nerves as well. For example, ligation of the L5 spinal nerve increased the expression of p75NTR in the DRG that was abolished by spinal administration of anti-NGF (Obata, K. *et al.*, 2006). Moreover, the application of anti-NGF onto the L4 spinal nerve after ligation of the L5 spinal nerve blocked the injury-induced upregulation of p75NTR (Obata, K. *et al.*, 2006). The spinal injection of the NGF/TrkA antagonist K252a blocked injury-induced thermal and cold hyperalgesia and the upregulation of phosphorylated trkA, p38, and of TRPV1 and TRPA1 in L4 DRG (Obata, K. *et al.*, 2006).

5.55.2.4 Sodium Channels and Enhanced Peripheral Nerve Activity

Because of their critical role in the generation of action potentials and neuronal excitation, the increased abnormal spontaneous and ectopic discharges of injured peripheral nerves are related to increased activity of voltage-gated sodium channels (VGSCs) (Lai, J. *et al.*, 2002; 2003). The VGSCs have been linked to excitability of primary afferent nociceptors and may mediate sensitized pain states (Lai, J. *et al.*, 2003). Peripheral nerve injury is also associated with changes in the expression and distribution of isoforms of the VGSCs (Novakovic, S. D. *et al.*, 2001). Three sodium channels merit special consideration.

The TTX-S sodium channel $Na_V1.3$ is fast-activating channel normally present in brain tissue but scarce in the DRG. However, peripheral nerve injury results in a substantial expression this channel in peripheral nerves, and it is believed that this novel expression may be partly responsible for the enhanced excitability of the primary afferents (Waxman, S. G. *et al.*, 1999; Lai, J. *et al.*, 2003). However, although its biophysical properties favor generation of spontaneous discharges, a causal relationship between expression of $Na_V1.3$ in the DRG and neuronal discharges has not been established. It had been hypothesized that upregulation of $Na_V1.3$ in peripheral nerves might mediate neuropathic pain as intrathecal treatment with GDNF abolished behavioral signs of enhanced pain, injury-induced enhanced peripheral neuronal excitability, and the upregulation of $Na_V1.3$ (Boucher, T. J. *et al.*, 2000). Other studies, however, showed that intrathecal GDNF normalized many changes observed in the DRG following peripheral nerve injury (Wang, R. *et al.*, 2003) making specific conclusions about $Na_V1.3$ difficult. Observations that knockdown of $Na_V1.3$ by antisense treatment abolished both the enhanced neuronal activity and behavioral signs of neuropathic pain in nerve-injured rats seemed to support this hypothesis (Hains, B. C. *et al.*, 2004). However, more recent evidence has clearly shown that this channel may not be relevant to enhanced pain after nerve injury. Studies employing two different conditional mutant mice lines, one with knockout of $Na_V1.3$ in nociceptors and another with global knockout of $Na_V1.3$ throughout the nervous system, showed that behavioral signs of neuropathic pain developed normally in both mutant lines after peripheral nerve injury (Nassar, M. A. *et al.*, 2006). Knockout of $Na_V1.3$ also did not alter responses to acute nociceptive stimuli or to inflammation (Nassar, M. A. *et al.*, 2006). Accordingly, it is believed that the $Na_V1.3$ channel is neither sufficient nor necessary for the expression of neuropathic pain (Nassar, M. A. *et al.*, 2006).

The TTX-insensitive sodium channel $Na_V1.8$ exhibits properties consistent with a role in neuropathic pain (Sangameswaran, L. *et al.*, 1997; Lai, J. *et al.*, 2002). It is expressed primarily in small-diameter,

unmyelinated peripheral nerve fibers (C fibers) and in other cells in the DRG, and is not found in other peripheral or central neurons or nonneuronal tissue (Sangameswaran, L. *et al.*, 1997; Akopian, A. N. *et al.*, 1999). Studies employing mutant mice lacking the $Na_V1.8$ channel or antisense knockdown techniques have shown that this channel is not essential for resting membrane potentials, neuronal excitation thresholds, or basal nociceptive thresholds (Akopian, A. N. *et al.*, 1999; Renganathan, M., *et al.*, 2001; Lai, J. *et al.*, 2003). In contrast, knockdown of $Na_V1.8$ in rats with SNL reversed behavioral signs of neuropathic pain (Porreca, F. *et al.*, 2000; Lai, J. *et al.*, 2003), which is consistent with the ability of $Na_V1.8$ to enable DRG neurons to fire repetitively after stimulation (Akopian, A. N. *et al.*, 1999; Renganathan, M., *et al.*, 2001). There is evidence that suggests that behavioral neuropathic pain may be partly mediated through an abnormal redistribution of $Na_V1.8$ after nerve injury (Lai, J. *et al.*, 2003). Recent investigations found that the μO-conotoxin MrVIB produced a selective block of the $Na_V1.8$ current (Ekberg, J. *et al.*, 2006). Intrathecal injections of MrVIB produced dose-dependent attenuation of tactile allodynia and thermal hyperalgesia in rats with peripheral nerve injury, leading to the conclusion that blockade of $Na_V1.8$ may provide one therapeutic avenue for the alleviation of neuropathic pain (Ekberg, J. *et al.*, 2006).

Interestingly, immunological and electrophysiological studies showed that SNL resulted in a downregulation of $Na_V1.8$ protein or conductance in the DRG of injured neurons but upregulation in adjacent, uninjured unmyelinated, and myelinated DRG neurons (Porreca, F. *et al.*, 1998; Gold, M. S. *et al.*, 2003). This redistribution of $Na_V1.8$ after SNL was blocked by antisense knockdown techniques (Gold, M. S. *et al.*, 2003; Lai, J. *et al.*, 2003). The injury-induced changes in immunoreactivity of $Na_V1.8$ was correlated with an increase in tetrodotoxin-resistant (TTX-R) compound action potential at C fiber conduction velocity along with a minor contribution at A fiber conduction velocity, suggesting a functional reorganization of $Na_V1.8$ along unmyelinated fibers and in some myelinated fibers (Gold, M. S. *et al.*, 2003). Antisense-mediated knockdown of $Na_V1.8$ immunoreactivity and TTX-R current in these uninjured axons correlates with the reversal of both mechanical and thermal hypersensitivity, suggesting that this reorganization of $Na_V1.8$ activity along the uninjured axons may be necessary for expression of neuropathic pain in the injured rat (Gold, M. S. *et al.*, 2003; Lai, J. *et al.*, 2003). A redistribution of $Na_V1.8$ along the injured sciatic nerve has been also observed in the chronic constriction injury model of neuropathic pain, and $Na_V1.8$ immunoreactivity is evident in peripheral nerve tissues from patients with chronic neuropathic pain (Novakovic, S. D. *et al.*, 1998; Coward, K. *et al.*, 2000). Immunohistochemical studies of human tooth pulp obtained from painful and nonpainful teeth demonstrated that fine unmyelinated nerve fibers expressed $Na_V1.8$ (Renton, T. *et al.*, 2005). In addition, there was an increased expression of $Na_V1.8$ in nerve fibers obtained from painful teeth (Renton, T. *et al.*, 2005).

$Na_V1.7$, a TTX-S VGSC is found predominantly in small-diameter sensory DRG neurons and in sympathetic nerves and plays a prominent role in enhanced pain states (Wood, J. N. *et al.*, 2004b). Recent investigations confirm that this channel mediates the intense burning pain associated with familial erythermalgia. Primary erythermalgia is a rare, autosomal-dominant condition that manifests itself by intermittent bouts of swelling of the feet or hands, intense burning pain, and erythemia (Yang, Y. *et al.*, 2004). The syndrome may be provoked by warmth or exercise and is refractory to therapeutic interventions (Yang, Y. *et al.*, 2004). It was found that individuals afflicted with erythromelalgia expressed a T to A transversion mutation in the gene *SCN9A*, which codes the alpha-subunit of the $Na_V1.7$ sodium channel (Yang, Y. *et al.*, 2004). These mutations of the $Na_V1.7$ sodium channel were found to promote abnormal activity of small-diameter nociceptors, which would be consistent with a small-fiber neuropathy (Drenth, J. P. *et al.*, 2005). Electrophysiologic studies demonstrated that the mutated channel produced a hyperpolarizing shift in activation, slowed deactivation of the channel and markedly increased the ramp current, with the net effect being a marked hyperexcitation of the cells (Dib-Hajj, S. D. *et al.*, 2005). The $Na_V1.7$ sodium channel is upregulated after carrageenan-induced inflammation, and genetically modified mice with knockdown of the $Na_V1.7$ channel of sensory neurons showed an attenuated inflammation-induced hyperalgesia (Wood, J. N. *et al.*, 2004a). More recently, voltage clamp studies performed on transfected mouse DRG cells showed that the human mutations lowered the thresholds for generation of action potentials and repetitive firing, thus provoking high-frequency firing of nociceptive small-diameter sensory neurons in the DRG (Dib-Hajj, S. D. *et al.*, 2005). It is now believed that enhanced sensitivity of this sodium channel may exacerbate activation of the TRPV1 channels, thus driving nociceptor hyperexcitability.

More recent studies were undertaken with patients with the autosomal dominant spontaneous pain condition, paroxysmal extreme pain disorder (PEPD), which manifests as paroxysmal episodes of burning pain in ocular, mandibular, and rectal regions. Mutational analysis of SCN9A obtained from individuals with PEPD and unafflicted family members revealed that the mutation was associated with enhanced $Na_V1.7$ current activity (Fertleman, C. R. *et al.*, 2006). Although primary erythermalgia and PEPD are due to mutations of *SCN9A*, these familial disorders are considered allelic variants that are clinically and mechanistically distinct, related to the specific effects of the mutations on the sodium channel activity (Fertleman, C. R. *et al.*, 2006). On the other side of the spectrum, individuals with one of three distinct nonsense mutations of *SCN9A* show a loss of function of the $Na_V1.7$ channel activity show a marked insensitivity to pain (Cox, J. J. *et al.*, 2006). This sodium channel appears to be critical to nociceptive processing, both acutely and in chronic pain states (Cox, J. J. *et al.*, 2006; Fertleman, C. R. *et al.*, 2006). In spite of the evidence pointing to a prominent role of voltage-gated sodium channels in nociception and enhanced pain due to nerve injury, therapeutic interventions based on blockade of the sodium channels have, to this point, been disappointing. A large multicenter clinical investigation that was recently concluded showed that lamotrigine, which is a nonselective sodium channel blocker, failed to produce changes that were different from placebo in patients with diabetic neuropathy (Vinik, A. I. *et al.*, 2007). A multicenter clinical investigation with oxcarbazepine for diabetic neuropathy suggested that this nonselective sodium channel blocker produced a moderate effect that may be clinically meaningful (Dogra, S. *et al.*, 2005). Though currently unclear, one conclusion is that sodium channel blockers may not be suitable for routine use against neuropathic pain, but may be appropriate for responsive subgroups of neuropathic pain patients (Sindrup, S. H. and Jensen, T. S., 2007). One such example may be patients with postherpetic neuralgia mediated by irritable nociceptors (Sindrup, S. H. and Jensen, T. S., 2007).

5.55.2.5 Role of Calcium Channels

Calcium channels also are critical elements that modulate neuronal excitation (Snutch, T. P. *et al.*, 2001). The N-type calcium channel, which is blocked by omega-conotoxin, has been identified in DRG neurons (Nowycky, M. C. *et al.*, 1985; McCleskey, E. W. *et al.*, 1987). This channel is predominant on nerve terminals of primary afferent terminals in the superficial lamina of the spinal dorsal horn and participates in nociceptive transmission since it is critical to depolarization-coupled release of neurotransmitters, including substance P, CGRP, and glutamate, from these terminals (Santicioli, P. *et al.*, 1992). It was suggested that nerve injury results in either increased frequency of opening of the N-type calcium channel, or an increase in the population (see Snutch, T. P. *et al.*, 2001; Snutch T. P., 2005, for reviews). Blocking the activity of the N-type calcium channel with the omega-conotoxin–GVIA abolished enhanced electrically evoked responses of dorsal horn neurons as well as windup and post-discharge phenomena in nerve-injured rats, which is consistent with inhibition of signs of enhanced pain (Matthews, E. A. and Dickenson, A. H., 2001b). The spinal administration of a novel N-type calcium channel blocker ziconitide produced antinociception in uninjured rats and abolished tactile and thermal hyperesthesias in those with peripheral nerve injuries (Scott, D. A. *et al.*, 2002; Wang, Y. X. *et al.*, 2000a; 2000b). Recent clinical trials with ziconotide (PRIALT) provide strong evidence that blockade of the N-type calcium channel may provide a significant clinical benefit in the management of severe, refractory pain, such as deafferentation pain or pain due to cancer or neuropathies associated with HIV/AIDS and postherpetic neuralgia (Wang, Y. X., *et al.*, 2000a; 2000b; Miljanich, G. P., 2004; Prommer, E. E., 2005).

The T-type calcium channel is present in DRG neurons and on second-order neurons of the dorsal horn of the spinal cord (Talley, E. M. *et al.*, 1999; see Hildebrand, M. E. and Snutch, T. P., 2006, for a review). Activation of the NK1 receptor and of the T-type voltage-gated calcium channels (VGCCs) acts synergistically with activation of the NMDA/calcium channel complex to facilitate firing of the NK1-expressing cells of lamina I, thus promoting central sensitization (Ikeda, H. *et al.*, 2003). This observation is consistent with observations that blockade of the T-type VGCC produced dose-dependent reversal of behavioral signs of neuropathic pain in rats with peripheral nerve injury (Dogrul, A. *et al.*, 2003). Moreover, pharmacologic blockade of T-type VGCCs also diminished electrophysiologic signs of postsynaptic sensitization indicated by windup and after-discharges in nerve-injured rats (Matthews, E. A. and Dickenson, A. H., 2001a). The role of this VGCC in pain modulation makes the T-type calcium channel an attractive target for drug development. Although several compounds are

under preclinical investigation as T-type channel blockers, no clinical data exist with which to gauge their clinical utility against neuropathic pain (Hildebrand, M. E. and Snutch, T. P., 2006).

5.55.3 Enhanced Afferent Discharges Lead to Central Sensitization in the Spinal Cord

The pronociceptive changes that occur in peripheral afferent fibers after nerve injury promote enhanced activity of these fibers, and this afferent drive is thought to result in hyperalgesia and allodynia (Amir, R. *et al.*, 2002). However, although although onset of neuropathic pain is consistent with the initiation of the increased afferent discharges, the enhanced activity of peripheral fibers diminishes fairly rapidly, whereas the behavioral signs of enhanced pain persist long after the initial insult, indicating that mechanisms which sustain neuropathic pain may differ from those which initiate such pain (Liu, C. N. *et al.*, 2001; Ossipov, M. H. *et al.*, 2005; Sun, Q. *et al.*, 2005). There is general agreement that these behavioral manifestations of enhanced pain are mediated in large part by an enhanced responsiveness of the spinal cord to sensory inputs, or central sensitization, which may be both initiated, and in part, sustained by the primary afferent barrage. Sensitization of second-order neurons of the spinal dorsal horn has been illustrated experimentally by the phenomena of windup. Windup is characterized by progressively increasing responses of spinal dorsal horn neurons in response to repetitive electrical stimulation of C fibers (Mendell, L. M., 1966; Woolf, C. J., 1996). Windup is relatively short term in duration and occurs only in response to stimulation of C fibers, and, in the uninjured state, not of A-beta fibers, and is nociceptive specific (Woolf, C. J., 1996; Ji, R. R. *et al.*, 2003; Ji, R. R. and Strichartz, G., 2004). Conditioning stimuli in the form of electrically evoked trains of C fiber activity has been found to produce long-term responsiveness of dorsal horn units to additional stimuli, a profile that appears similar to long-term potentiation (LTP) (Woolf, C. J., 1996; Ji, R. R. *et al.*, 2003; Ji, R. R. and Strichartz, G., 2004). Although these dorsal horn neurons are unreactive to A-beta fiber inputs in the resting state, they become sensitized through repetitive C fiber stimulation which can render them excitable by A-beta fiber inputs, and this may represent a mechanism which contributes to touch-evoked allodynia (Woolf, C. J., 1996; Ji, R. R. *et al.*, 2003; Ji, R. R. and Strichartz, G., 2004).

The state of central sensitization is generally characterized by electrophysiologic parameters that include a reduction in sensory thresholds, increased responsiveness of second-order neurons to afferent inputs along with after-discharges, and expansion of the receptive field along with recruitment of afferent fibers that are not normally nociceptive (Cook, A. J. *et al.*, 1987). Behaviorally, a reduction in sensory threshold is demonstrated by the significantly reduced withdrawal latencies to noxious thermal stimuli or reduced thresholds to noxious mechanical stimuli (Woolf, C. J. and Thompson, S. W., 1991; Hedo, G. *et al.*, 1999). In addition, light tactile stimuli that do not elicit behavioral responses in normal animals produce nocifensive behaviors in the sensitized state (Woolf, C. J. and Thompson, S. W., 1991; Hedo, G. *et al.*, 1999; Ossipov, M. H. and Porreca, F., 2005). For example, sensitization induced by the intradermal injection of capsaicin reduced pain thresholds to noxious heat and elicited allodynia to light brush in human volunteers (Simone, D. A. *et al.*, 1989). Similarly, intradermal injection of capsaicin reduced the stimulus threshold required to elicit responses of the spinothalamic tract (STT) neurons to light brush and also increased the response intensity of these second-order neurons (Simone, D. A. *et al.*, 1991). Peripheral nerve injury was shown to increase the spontaneous activity of dorsal horn neurons and to enhance the responses of these neurons to noxious heat or light touch applied to the injured hindpaw (Suzuki, R. and Dickenson, A., 2005a; 2005b). Moreover, nerve injury also provoked pronounced after-discharges and significantly enlarged the receptive field of dorsal horn neurons in response to noxious heat or pinch (Suzuki, R. *et al.*, 2004a; Suzuki, R. and Dickenson, A., 2005a; 2005b). Peripheral nerve injury also caused a shift to the left of the stimulus–response function of wide dynamic range (WDR) neurons in response to tactile, but not thermal, stimuli (Kauppila, T. *et al.*, 1998; Pertovaara, A. *et al.*, 2001).

In addition to electrophysiologic means, immunohistochemical detection of the proto-oncogene product FOS in the spinal cord has been widely employed as an indicator for neurons that are activated by noxious inputs, and its enhanced expression in the spinal dorsal horn is suggestive of sensitization (Hunt, S. P. *et al.*, 1987; Shortland, P. and Molander, C., 1998). Peripheral nerve injury produced significant increases in noxious and touch-evoked FOS expression in the superficial and intermediate laminae of the spinal dorsal horn (Catheline, G. *et al.*, 1999; Vera-Portocarrero, L. P. *et al.*, 2006; Zhang, E. T. *et al.*, 2007). Electrical stimulation at A-beta fiber intensity or application of light

touch evoked FOS expression, but only after nerve injury or inflammation (Ma, Q. P. and Woolf, C. J., 1996; Shortland, P. and Molander, C., 1998; Nomura, H. *et al.*, 2002). Recently, gentle stroking of the hindpaw, which did not evoke FOS expression in normal rats, but caused significant increases in FOS expression after nerve injury (Catheline, G. *et al.*, 1999; Zhang, E. T. *et al.*, 2007). The enhanced expression of FOS was found in the superficial and deep laminae of the spinal dorsal horn (Zhang, E. T. *et al.*, 2007). Together, these studies indicate that peripheral nerve injury can promote a state of sensitization of spinal dorsal horn neurons.

5.55.4 Excitatory Transmitters Promote Central Sensitization

Sensitization of the spinal cord elicited by enhanced peripheral afferent inputs results in part from the recruitment of subthreshold stimuli to evoke a neuronal response that is related to increased release of excitatory neurotransmitters form the primary afferent terminals (Li, Q. J. and Lu, G. W., 1989; Li, J. *et al.*, 1999). Microdialysis studies demonstrated the release of glutamate and aspartate from primary afferents in response to the capsaicin injected intradermally in the plantar aspect of the hindpaw of the rat or electrical stimulation of the sciatic nerve at C fiber intensity (Paleckova, V. *et al.*, 1992; Sluka, K. A. and Willis, W. D., 1998). Similarly, behavioral hypersensitivity and central sensitization due to peripheral nerve injury or inflammation are associated with increased evoked release of glutamate and aspartate from primary afferent terminals (Paleckova, V. *et al.*, 1992; Kawamata, M. and Omote, K., 1996; Sluka, K. A. and Willis, W. D., 1998; Kawamata, M. and Omote, K., 1999). Spontaneous and stimulus-evoked release of substance P and CGRP from primary afferent terminals is increased after peripheral nerve injury (Paleckova, V. *et al.*, 1992; Sluka, K. A. and Willis, W. D., 1998; Wallin, J. and Schott, E., 2002; Gardell, L. R. *et al.*, 2003a; 2003b). Increased release of excitatory neurotransmitters, including glutamate, substance P, and CGRP is believed to contribute to central sensitization and to hyperalgesia. For example, CGRP release after intradermal capsaicin increased WDR activity in the dorsal horn in response to brush or pinch (Sun, R. Q. *et al.*, 2003; Sun, R. Q. *et al.*, 2004).

The existence of excitatory NMDA autoreceptors on central terminals of primary afferents has been described (Liu, H. *et al.*, 1997). Nociception and release of substance P and glutamate from primary afferent terminals evoked by spinal NMDA was abolished by capsaicin, indicating that presynaptic NMDA receptors provoke further release of excitatory transmitters (Liu, H. *et al.*, 1997). Glutamate may also act at presynaptic metabotropic receptors to promote sensitization (Ohishi, H. *et al.*, 1995). Prostacyclin and PGE2 enhanced capsaicin-evoked release of substance P and CGRP through presynaptic excitation (Southall, M. D. *et al.*, 1998; Southall, M. D. and Vasko, M. R., 2001; Southall, M. D. *et al.*, 2002). These observations are consistent with the fact that central sensitization elicited by C fiber stimulation or inflammation was blocked by NMDA antagonists (Woolf, C. J. and Salter, M. W., 2000).

A measure indicative of the level of primary afferent drive into the spinal dorsal horn is the determination of internalization of the NK1 receptor on second-order neurons that are activated by substance P released from primary afferent nociceptors (Allen, B. J. *et al.*, 1999; Honore, P. *et al.*, 1999). Under nonsensitized conditions, noxious stimulation, such as electrical stimulation at C fiber intensity, subcutaneous capsaicin or noxious heat or pinch, will evoke rapid internalization of the NK1 receptor almost exclusively in the outer lamina of the spinal cord (Allen, B. J. *et al.*, 1999; Honore, P. *et al.*, 1999). Moreover, nonnoxious stimulation does not evoke internalization of NK1. However, when sensitization occurs due to inflammation or peripheral nerve injury, there is a marked enhancement of noxious-induced NK1 internalization, and NK1 internalization is found in the deeper laminae of the spinal cord as well (Allen, B. J. *et al.*, 1999; Honore, P. *et al.*, 1999). In addition, nonnoxious stimuli such as light brush also evoke NK1 internalization in the intermediate and deep laminae of the spinal dorsal horn (Allen, B. J. *et al.*, 1999; Honore, P. *et al.*, 1999; Khasabov, S. G. *et al.*, 2002). Critically, electrical stimulation at A-beta fiber intensity does not elicit NK1 internalization after nerve injury, indicating that the effect produced by light brush is not a direct result of large-diameter fiber stimulation, but is likely to be secondary to other mechanisms driving sensitization (Allen, B. J. *et al.*, 1999; Khasabov, S. G. *et al.*, 2002). NK1 internalization observed in the deeper laminae may be due in part to diffusion of substance P to NK1 receptors on sensitized deep lamina neurons, or partly due to the small number of direct synaptic contacts between C fibers and deep lamina neurons (Allen, B. J. *et al.*, 1999; Khasabov, S. G. *et al.*, 2002).

Recent studies demonstrated that the postsynaptic second-order neurons of the spinal dorsal horn

express message for the bradykinin B2 receptor (Wang, H. B. *et al.*, 2005). Patch-clamp studies showed that activation of the B2 receptor produces a dose-dependent potentiation of AMPA and NMDA currents in dorsal horn neurons. Excitation of the B2 receptor mediates increased frequency and amplitude of AMPA-mediated excitatory postsynaptic potentials, whereas B2 antagonists abolished electrophysiologic signs of central sensitization in dorsal horn neurons (Wang, H. B. *et al.*, 2005). These studies suggest that spinal bradykinin B2 receptors represent an important postsynaptic mechanism in promoting central sensitization and enhanced pain through the potentiation of glutaminergic synaptic transmission (Wang, H. B. *et al.*, 2005). While the importance of bradykinin receptors in enhancing pain, including chronic neuropathic pain (see below) seem clear, the mechanism by which the receptors are activated is not known.

5.55.5 Descending Facilitation Promotes Enhanced Pain

The existence of a pronociceptive pain facilitatory system projecting from the RVM has been well established (see Porreca, F. *et al.*, 2002; Heinricher, M. M. *et al.*, 2003; Ossipov, M. H. and Porreca, F., 2005 for reviews). It has been demonstrated that the microinjection of lidocaine into the RVM abolished behavioral signs of enhanced pain after nerve injury or inflammation, and abolished the sensitization of spinal WDR neurons to mustard oil induced inflammation (Mansikka, H. and Pertovaara, A., 1997; Burgess, S. E. *et al.*, 2002; Pertovaara, A. and Almeida, A., 2006). Lesions of the descending projections from the RVM in the dorsolateral funiculus also abolished behavioral hypersensitivity after inflammation or nerve injury (Wei, F. *et al.*, 1998; 1999; Ossipov, M. H. *et al.*, 2000; Burgess, S. E. *et al.*, 2002). Finally, it was found that selective ablation of RVM neurons that express the mu-opioid receptor, and which may label cells which contribute to descending facilitation, also abolished behavioral signs of sensitization and the enhanced capsaicin-evoked release of CGRP (Burgess, S. E. *et al.*, 2002; Gardell, L. R. *et al.*, 2003a; 2003b; Porreca, F. *et al.*, 2002). Importantly, disruption of descending facilitation abolished behavioral hypersensitization during later, but not initial, phases after nerve injury, indicating that it is essential to the maintenance of a sensitized state (Burgess, S. E. *et al.*, 2002; Porreca, F. *et al.*, 2002; Gardell, L. R. *et al.*, 2003a; 2003b). Most recently, it was shown that activation of descending facilitation from the RVM was subsequent to stimulation of NK1-expressing lamina I postsynaptic cells and increased the neuronal responses of WDR neurons of the deeper laminae of the dorsal horn after nerve injury or inflammation (Suzuki, R. *et al.*, 2002; 2004a; Rahman, W. *et al.*, 2004; 2006). Spinal ondansetron blocked the sensitization of these WDR neurons, which is consistent with a descending serotonergic facilitatory pathway from the RVM (Suzuki, R. *et al.*, 2002; Rahman, W. *et al.*, 2004; Suzuki, R. *et al.*, 2004a; Rahman, W. *et al.*, 2006).

5.55.5.1 Role of the Rostralventromedial Medulla in Descending Facilitation of Pain

The RVM and surrounding tissue has long been recognized as a region critical to nociceptive processing and receives inputs from ascending nociceptive pathways as well as from descending pain modulatory sites. The RVM is considered to be the final common relay for descending inhibition of nociceptive inputs. More recently, this region has also been demonstrated to mediate a significant descending pain facilitatory system as well (Fields, H. L. and Basbaum, A. I., 1999; Porreca, F. *et al.*, 2002; Heinricher, M. M. *et al.*, 2003; Ossipov, M. H. and Porreca, F., 2005). Stimulation of this region, either through electrical stimulating electrodes or through the microinjection of glutamate or neurotensin, resulted in biphasic effects on behavioral and electrophysiologic responses to noxious stimuli (Zhuo, M. and Gebhart, G. F., 1997; Fields, H. L. and Basbaum, A. I., 1999). Whereas high levels of stimulation inhibited nociceptive responses, lower levels of stimulation facilitated the same responses (Zhuo, M. and Gebhart, G. F., 1997; Urban, M. O. *et al.*, 1999). Similarly, microinjection of the neurotensin antagonist SR48692 into the RVM also produced a biphasic effect on nociceptive responses. Taken together, these observations indicate that the RVM is capable of mediating both pain inhibitory functions, which are likely to predominate under basal conditions, and facilitation of pain, which would predominate under conditions of enhanced pain (Ossipov, M. H. *et al.*, 2001). Pharmacologic manipulations that attenuate RVM activity also block enhanced nociception. For example, thermal hyperalgesia induced by naloxone-precipitated withdrawal or by previous prolonged exposure to a nociceptive stimulus can be blocked by the

microinjection of lidocaine into the RVM (Kaplan, H. and Fields, H. L., 1991; Morgan, M. M. and Heinricher, M. M., 1992). It is likely that activation of these pronociceptive circuits in the RVM in response to persistent or prolonged noxious inputs leads to a facilitation of more pain (Porreca, F. *et al.*, 2002). Tail withdrawal responses to noxious thermal or mechanical stimuli can be facilitated by the subcutaneous injection of formalin into a hindpaw, and this effect can be reversed by local infusion of the hydrophilic lidocaine derivative QX-314 injected at the site of formalin (Calejesan, A. A. *et al.*, 1998). It is currently understood that descending pain facilitatory systems arising from the RVM are likely mediated through spinopetal serotonergic projections that enhance nociceptive inputs at the level of the spinal cord. The relationship among noxious inputs, the RVM, and descending serotonergic projections to chronic pain states is described in greater detail below.

5.55.5.2 The ON Cells of the Rostralventromedial Medulla Promote Pain Through Descending Facilitation

Neuronal populations within the RVM have been described as ON cells, OFF cells and neutral cells based upon electrophysiologic responses to noxious heat applied to the tail of lightly anesthetized rats (Fields, H. L., 2000; Ossipov, M. H. *et al.*, 2001; Neubert, M. J. *et al.*, 2004). By definition, the OFF cells are tonically active and pause in firing immediately before a withdrawal response from a noxious thermal stimulus, whereas the ON cells accelerate firing immediately before the nociceptive reflex occurs (Fields, H. L. and Heinricher, M. M., 1985; Neubert, M. J. *et al.*, 2004). As the name implies, the activity of the neutral cells does not correlate with nociceptive inputs. Characterization of the neurons of the RVM were initially determined in lightly anesthetized rat preparations, and it was found that tail flick latency was longer during periods of increased OFF cell activity and shorter when the ON cells were active. The considerable body of evidence collected subsequent to these studies confirmed the role of these neurons in the modulation of nociception and extended the findings to other models of acute and enhanced pain. It is now generally accepted that the activity of OFF cells correlates with inhibition of nociceptive inputs and of behavioral nocifensive responses to nociception. In the presence of opioids, OFF cells continue firing after a noxious stimulus is applied and inhibit electrophysiologic and behavioral parameters of nociception through descending inhibition from the RVM (Fields, H. L. and Heinricher, M. M., 1985; Neubert, M. J. *et al.*, 2004). In contrast, the electrophysiologically determined response characteristics of the ON cells are consistent with a pronociceptive function, and it is believed that these neurons serve as the source of descending facilitation from the RVM (Fields, H. L. and Heinricher, M. M., 1985; Heinricher, M. M. *et al.*, 2003; Neubert, M. J. *et al.*, 2004). Accordingly, manipulations that promote nociceptive responsiveness also increase ON cell activity, which is consistent with pain facilitation.

The enhanced behavioral responses to noxious stimuli elicited during naloxone-precipitated withdrawal from morphine correlates with increased spontaneous activity of the RVM ON cells, and both behavioral hyperalgesia and enhanced on cell activity are abolished by lidocaine microinjected into the RVM (Bederson, J. B. *et al.*, 1990; Kaplan, H. and Fields, H. L., 1991). Prolonged application of a noxious thermal stimulus increased ON cell activity and facilitated behavioral nociceptive responses, and both the electrophysiologic and behavioral responses were abolished by microinjection of lidocaine into the RVM (Kaplan, H. and Fields, H. L., 1991; Morgan, M. M. and Fields, H. L., 1994). Electrophysiologic monitoring of RVM neurons demonstrated that the microinjection of either cholecystokinin (CCK) or neurotensin at doses that selectively activated on cells produced facilitated behavioral responses to nociceptive stimuli in lightly anesthetized rats (Heinricher, M. M. and Neubert, M. J., 2004; Neubert, M. J. *et al.*, 2004). Application of mustard oil to the skin of the rat produced increased firing of ON cells and thermal hyperalgesia that were both blocked by NMDA antagonist application into the RVM (Kincaid, W. *et al.*, 2006; Xu, M. *et al.*, 2007). It was also shown that inflammation induces an upregulation of NMDA receptors on the ON cells, along with increased phosphorylation of AMPA receptors, thus enhancing ON cell activity and facilitating nociceptive responses (Guan, Y. *et al.*, 2003; 2004). Finally, recent studies showed that inflammation results in upregulation of BDNF, which facilitates ON cell firing through an NMDA-dependent mechanism (Guo, W. *et al.*, 2006). Most recently, it was discovered that capsaicin injected into a hindpaw or iontophoretic application of Sar^{9},$Met(O_2)^{11}$-substance P into the RVM enhanced ON cell activity and potentiated the responses of ON cells to iontophoretic NMDA (Budai, D. *et al.*, 2007). Conversely,

iontophoretic administration of an NK1 antagonist into the RVM abolished the enhanced responses of ON cells (Budai, D. *et al.*, 2007). Taken together, these studies indicate that ON cells promote nociception, and that enhanced ON cell activity underlies hyperalgesia associated with chronic pain states. In addition, it is suggested that substance P in the RVM may modulate enhanced ON cell activity, and consequently, enhanced pain states.

In light of these observations, it has been proposed that neuropathic pain due to peripheral nerve injury may be initially mediated through enhanced afferent activity, but that the enhanced discharges lead to a sensitized spinal cord and neuroplastic changes culminating in an enhancement of descending facilitation mediated through ON cells of the RVM (Heinricher, M. M. *et al.*, 2003; Ossipov, M. H. *et al.*, 2005; Ossipov, M. H. and Porreca, F., 2006). Considerable electrophysiologic evidence exists to indicate that the population of RVM neurons that express the mu-opioid receptor, or a subset of these cells, are likely to drive descending facilitation (Heinricher, M. M. *et al.*, 1994; Neubert, M. J. *et al.*, 2004). Based on this evidence, presumptive pain facilitatory neurons of the RVM were selectively ablated by using the mu-opioid receptor as a portal of entry into these cells for dermorphin conjugated with the cytotoxin saporin (Porreca, F. *et al.*, 2001; Burgess, S. E. *et al.*, 2002; Vera-Portocarrero, L. P. *et al.*, 2006). With this technique, when the agonist binds to the receptor, internalization occurs, bringing the conjugated agonist and saporin complex into the cell body, where saporin is released and leads to inhibition of ribosome activity, thus causing cell death within 2–3 weeks (Mantyh, P. W. *et al.*, 1997). Selective ablation of pain facilitatory neurons of the RVM by microinjection of the dermorphin–saporin conjugate either 7 days prior to SNL or once tactile and thermal hyperesthesias were well established, respectively, prevented and reversed the behavioral signs of neuropathic pain (Porreca, F. *et al.*, 2001; Burgess, S. E. *et al.*, 2002). Importantly, these behavioral signs of neuropathic pain were abolished 1 week after SNL, and not earlier. Similarly, physical disruption of descending facilitatory tracts from the RVM or microinjection of lidocaine at different time points after SNL produced similar results (Porreca, F. *et al.*, 2001; Burgess, S. E. *et al.*, 2002). Enhanced expression of FOS in the spinal cord is indicative of sensitization. Recently, it was shown that SNL enhanced both the intensity and laminar distribution of FOS evoked by noxious stimuli to include the intermediate laminae of the dorsal horn and promoted novel expression of FOS in response to light brush (Vera-Portocarrero, L. P. *et al.*, 2006; Zhang, E. T. *et al.*, 2007). Microinjection of dermorphin–saporin conjugate into the RVM abolished enhanced FOS expression due to SNL (Vera-Portocarrero, L. P. *et al.*, 2006). These observations indicate that the maintenance phase of the neuropathic pain state is dependent on the certain neuroplastic changes that result in activation of a tonic descending pain facilitation from the RVM, whereas the earlier initiation phase is independent of descending systems.

5.55.5.3 Cholecystokinin in the Rostralventromedial Medulla May Mediate Pain Facilitation

It was recently shown that CCK opposes the antinociceptive activity of morphine by attenuating the morphine-induced activation of OFF cells, which constitute part of the descending inhibition of nociceptive inputs (Heinricher, M. M. *et al.*, 2001; Heinricher, M. M. and Neubert, M. J., 2004). The microinjection of CCK into the RVM produces enhancement of responses to light tactile or noxious thermal stimuli similar to that observed after SNL (Kovelowski, C. J. *et al.*, 2000; Xie, J. Y. *et al.*, 2005). Moreover, the microinjection of CCK2 antagonists into the RVM attenuated behavioral signs of neuropathic pain in rats with SNL (Kovelowski, C. J. *et al.*, 2000; Xie, J. Y. *et al.*, 2005). The behavioral hyperesthesias and hyperalgesia elicited by RVM CCK were abolished by dorsolateral funiculus (DLF) lesions or microinjection of L365,260 (Kovelowski, C. J. *et al.*, 2000; Xie, J. Y. *et al.*, 2005). In addition to its activities in inhibiting morphine-induced activation of OFF cells, it was also recently demonstrated that CCK provokes a direct and selective activation of ON cells of the RVM and that this activation is directly related to the production of hyperalgesia (Heinricher, M. M. and Neubert, M. J., 2004).

5.55.6 Second-Order Projection Neurons Expressing NK1 Receptors May Result in Activation of Descending Pain Facilitation

Converging evidence strongly indicates that central sensitization and hypersensitivity to sensory stimuli is dependent predominantly on the long-term sensitization of the lamina I cells that express the NK1

receptor (Ikeda, H. *et al.*, 2003). Electrophysiologic studies have revealed that approximately 75% of the neurons of lamina I are nociceptive specific, and the remainder are either WDR neurons or polymodal nociceptors that also respond to noxious cold (Suzuki, R. and Dickenson, A. H., 2005a; 2005b). Approximately one-half of the lamina I neurons express the NK1 receptor and project to supraspinal sites that process nociception, including the parabrachial region and the thalamus (Suzuki, R. and Dickenson, A. H., 2005a; 2005b). Recent studies showed that selective ablation of lamina I neurons that express the NK1 receptor abolish behavioral signs of neuropathic pain in rats with SNL (Nichols, M. L. *et al.*, 1999; Honore, P. *et al.*, 1999; Suzuki, R. *et al.*, 2002). In these studies, ablation was performed by spinal injection of substance P conjugated to saporin. Internalization of the NK1 receptor stimulated by substance P introduced the conjugate into the cell body, where saporin interfered with protein synthesis, causing eventual death of the cell (Honore, P. *et al.*, 1999; Nichols, M. L. *et al.*, 1999). Electrophysiologic studies indicated that signs of spinal sensitization induced by intraplantar capsaicin or peripheral inflammation were abolished by selective ablation of the NK1-expressing neurons of lamina I (Khasabov, S. G. *et al.*, 2002; 2005). Additional electrophysiologic studies demonstrated that SNL-induced enhancement of neuronal responses to noxious thermal stimuli or light brush, neuronal after-discharge, and enlargement of the receptive field were abolished in rats with SNL and in which NK1-expressing spinal neurons were selectively ablated with spinal injections of substance P conjugated to saporin (Suzuki, R. *et al.*, 2004a; 2004b; Suzuki, R. and Dickenson, A. H., 2005a; 2005b). Moreover, evoked expression of FOS in the RVM and in neurons in the deep laminae of the spinal cord was also abolished by selective ablation of NK1-expressing neurons of lamina I (Suzuki, R. *et al.*, 2002; Suzuki, R. and Dickenson, A. H., 2005a; 2005b). Based on these observations, especially the critical finding that the projection neurons of the superficial lamina of the spinal cord appear to promote sensitization of dorsal horn neurons in the deep lamina through an indirect mechanism, led to the hypothesis that injury-induced enhanced noxious inputs are transmitted to supraspinal sites, leading to the activation of a pronociceptive descending pain facilitatory system that maintains the state of spinal sensitization and maintains the neuropathic pain state.

5.55.7 Descending Facilitation Maintains a Sensitized Spinal Cord: Upregulation of Spinal Dynorphin and Enhanced Release of Primary Afferent Transmitters

The enhancement of descending facilitation from the RVM is believed to lead to neuroplastic changes in the spinal cord that favor a sensitized state and enhanced nociceptive inputs. A number of studies have demonstrated that enhanced descending facilitation elicited by peripheral nerve injury is associated with an upregulation of spinal dynorphin content and enhanced release of excitatory neurotransmitters from primary afferent neurons. Based on these observations, we formulated the hypothesis that neuropathic pain is initially driven by enhanced primary afferent the ectopic discharge but is then maintained in large part through descending facilitation and upregulation of spinal dynorphin (Lai, J. *et al.*, 2001; Porreca, F. *et al.*, 2002; Ossipov, M. H. and Porreca, F., 2006). Dynorphin upregulation occurs in the same postsynaptic lamina I cells that also express FOS in response to sensitization (Ji, R. R., 2004; Kawasaki, Y. *et al.*, 2004). Elevated levels of spinal dynorphin enhance capsaicin-evoked release of CGRP and substance P from primary afferent terminals and of PGE2, presumably from postsynaptic cells, which further enhances the release of excitatory amino acids from afferent terminals (Gardell, L. R. *et al.*, 2003a; 2003b; Koetzner, L. *et al.*, 2004). Sequestration of dynorphin with antiserum or surgical and neurochemical manipulations that blocked the upregulation of spinal dynorphin also abolished enhanced transmitter release and behavioral neuropathic pain (Burgess, S. E. *et al.*, 2002; Porreca, F. *et al.*, 2002; Gardell, L. R. *et al.*, 2003a; 2003b).

It is well established that elevated levels of spinal dynorphin and its fragments have a prominent pronociceptive role in chronic pain states (Lai, J. *et al.*, 2001). The spinal injection of antiserum to dynorphin did not abolish behavioral signs of neuropathic pain in mice with SNL when administered 2 days after the injury, but was effective 10 days after SNL (Wang, Z. *et al.*, 2001; Gardell, L. R. *et al.*, 2004). Moreover, knockout mice that do not express dynorphin still develop behavioral signs of neuropathic pain after SNL, but these signs resolve within 1 week (Wang, Z. *et al.*, 2001; Gardell, L. R. *et al.*, 2004). The dynorphin-dependent maintenance phase is dependent on descending

facilitation form the RVM. Surgical and pharmacologic manipulations that disrupt descending facilitation abolish both dynorphin upregulation and the maintenance, but not the initiation, of behavioral signs of neuropathic pain. Rats with SNL and either lesions of the DLF or selective ablation of facilitatory RVM neurons after microinjection of the dermorphin–saporin conjugate did not show an upregulation of spinal dynorphin levels and the behavioral signs of neuropathic pain resolved over the time course during which dynorphin upregulation would be expected after SNL (Burgess, S. E. *et al.*, 2002; Gardell, L. R. *et al.*, 2003a). Thus, in the absence of elevated spinal dynorphin, neuropathic pain is not maintained.

Elevated levels of spinal dynorphin promote the release of transmitters from primary afferent terminals, thereby enhancing nociceptive input. The time course and profile of the effect of spinal dynorphin on capsaicin-evoked release of CGRP from primary afferent terminals correlates closely with the behavioral studies. Addition of antiserum to dynorphin abolishes the enhanced capsaicin-evoked release of CGRP 10 days after SNL, but not 2 days after SNL (Burgess, S. E. *et al.*, 2002; Gardell, L. R. *et al.*, 2003a). Disruption of descending facilitation by microinjection of dermorphin–saporin conjugate into the RVM or by lesioning the DLF also abolishes SNL-induced enhancement of capsaicin-evoked release of CGRP (Burgess, S. E. *et al.*, 2002; Gardell, L. R. *et al.*, 2003a). The significance of this line of investigation requires additional examination, however.

5.55.7.1 Descending Facilitation Maintains a Sensitized Spinal Cord: Upregulation of Spinal Dynorphin and Enhanced Release of Primary Afferent Transmitters

The mechanism through which dynorphin may exert a pronociceptive function in the spinal cord is not fully understood. It was once suggested that dynorphin may act at the glycine coagonist site to potentiate the effect of glutamate at the NMDA receptor (Zhang, L. *et al.*, 1997). However, other studies provided evidence that dynorphin could inhibit opening of ion channels mediated by the NMDA receptor (Chen, L. and Huang, L. Y., 1998). Bakalkin and coworkers suggested that dynorphin could promote the formation of pores through the cell membrane, allowing the leakage of sodium and calcium ions, thus sensitizing neurons in this fashion, but this mechanism was not explicitly demonstrated (Hugonin, L. *et al.*, 2006). The mechanism by which dynorphin may promote nociception has recently been suggested to be mediated through bradykinin receptors (Lai, J. *et al.*, 2006). Bradykinin B1 and B2 receptors are present on nerve terminals of primary afferent fibers (Botticelli, L. J. *et al.*, 1981; Cloutier, F. *et al.*, 2002), and are in close proximity to interneurons that express dynorphin (Botticelli, L. J. *et al.*, 1981). Moreover, the B1 and B2 receptors are upregulated after SNL (Lai, J. *et al.*, 2006). A pronociceptive role of these receptors is indicated since intrathecal administration of bradykinin produced behavioral signs of hyperalgesia (Wang, H. B. *et al.*, 2005). Behavioral signs of enhanced pain after nerve injury were attenuated in B1 or B2 knockout mice (Ferreira, J. *et al.*, 2002; Wang, H. B. *et al.*, 2005). Curiously, although the bradykinin receptors are present in the spinal cord, there is little evidence of bradykinin synthesis within the spinal cord, suggesting the either bradykinin must diffuse from the circulatory system to act at the receptors, or there may be another endogenous ligand (Lai, J. *et al.*, 2006). It was shown that dynorphin induced a transient increase in calcium conductance in embryonic DRG cells that was blocked by B2 antagonists (Lai, J. *et al.*, 2006). Dynorphin-induced calcium currents were also blocked by B1 or B2 antagonists in transfected cells expressing these receptors (Lai, J. *et al.*, 2006). In the same study, it was shown that dynorphin demonstrated specific binding to the B1 and B2 receptors (Lai, J. *et al.*, 2006). Finally, antagonists of the B1 or B2 receptors given intrathecally produced dose-dependent attenuation of behavioral parameters indicative of neuropathic pain in rats with SNL, but only at the time points when spinal dynorphin was elevated (Lai, J. *et al.*, 2006). The antagonists were without effect during the dynorphin-independent early phase of nerve injury. Taken together, these studies indicate that dynorphin may mediate its pronociceptive enhancement of neuropathic pain through actions at the bradykinin receptors. The activity of dynorphin at bradykinin receptors could underlie the sensitization of dorsal horn neurons as described above (Wang, H. B. *et al.*, 2005).

5.55.7.2 Descending Facilitation Maintains a Sensitized Spinal Cord: Serotonergic Contributions

More recent studies suggest that descending serotonergic projections from the RVM may promote spinal sensitization through an action at the 5-HT_3 receptor. The 5-HT_3 receptor facilitates release or transmitter from nerve terminals through a ligand-gated Ca^{2+} channel (Miquel, M. C. *et al.*,

2002; Zeitz, K. P. *et al.*, 2002). This receptor is predominant in the superficial laminae of the spinal dorsal horn (Doucet, E. *et al.*, 2000; Miquel, M. C. *et al.*, 2002). Of this population, the major portion, approximately 85%, are found on primary afferent nerve terminals and the remainder at postsynaptic sites (Doucet, E. *et al.*, 2000; Miquel, M. C. *et al.*, 2002). Electrophysiologic studies indicated that primary afferent nerves that express the 5-HT_3 receptor on their terminals include C fiber nociceptors and myelinated A-delta nociceptors sensitive to mechanical stimuli (Zeitz, K. P. *et al.*, 2002). This distribution is consistent with the modulation of mechanical-evoked nociceptive signals, and the 5-HT_3 receptor has been shown to facilitate nociceptive transmission at the level of the spinal cord (Zeitz, K. P. *et al.*, 2002). Double-labeling studies in the nucleus raphe magnus (NRM) detected a population of serotonergic neurons that express FOS in response to noxious stimulation, suggesting the existence of a pronociceptive serotonergic projection from the RVM (Suzuki, R. *et al.*, 2002). Moreover, it was found that serotonergic terminals from the RVM are juxtaposed with cell bodies in the intermediate laminae of the dorsal horn, some of which also express the NK1 receptor (Todd, A. J. *et al.*, 2000; Todd, A. J., 2002). Antagonists of the 5-HT_3 receptor or depletion of serotonin from the spinal cord abolished the enhanced responses of dorsal horn neurons to mechanical stimulation in rats with SNL (Rahman, W. *et al.*, 2006). The 5-HT_3 antagonist ondansetron abolished behavioral signs of neuropathic pain and electrophysiologic parameters indicative of sensitization of superficial and deep dorsal horn neurons in rats with SNL (Suzuki, R. *et al.*, 2004a; 2004b). The effects of ondansetron were blocked by disrupting enhanced RVM activity through the ablation of NK1-expressing dorsal horn neurons with substance P–saporin conjugate, indicating that the 5-HT_3 receptors were activated by a descending serotonergic pain facilitatory system from the RVM (Suzuki, R.*et al.*, 2004a; 2004b).

Collectively, these observations paint a picture suggesting that neuropathic pain states are maintained, at least in part, by increased sensitivity of primary afferent neurons to noxious stimuli. In addition, it is hypothesized that persistent nociceptive inputs elicits supraspinal neuroplastic changes that results in the activation of a tonic descending facilitation of nociceptive inputs, which is mediated by an upregulation of spinal dynorphin content. Thus, increased spinal dynorphin serves to promote excitatory transmitter release, which in turn promotes the maintenance of the tonic descending facilitatory system, thus perpetuating a chronic pain state. The existence of a pronociceptive spinal–supraspinal loop that maintains a sensitized spinal cord may also provide a mechanism through which tactile hyperesthesia might be mediated.

5.55.8 Summary

Tremendous progress in our understanding of mechanisms that initiate and maintain neuropathic pain has been made over the past two decades. Importantly, such increased understanding has led to programs aimed at the development of novel therapeutics for neuropathic pain. It has been well appreciated that peripheral nerve injury produces increased activity of the injured and adjacent uninjured peripheral nerve fibers. This enhanced activity, or peripheral sensitization, is maintained in part by increased or relocation of ion channels that promote axonal firing. Programs are in place in the pharmaceutical industry to develop subtype selective sodium channel blockers that may diminish enhance activities of injured or adjacent nerves. Increase in pronociceptive mediators, including cytokines, chemokines, and growth factors have been noted in multiple experimental models of neuropathic pain. The enhanced primary afferent activity leads to a state of sensitization of the spinal cord neurons, such that they are more responsive to sensory inputs. Approaches aimed at decreasing sensitization of nociceptors through anti-NGF strategies, or through the administration of exogenous growth factors of the GDNF family, are either in development or under consideration by the pharmaceutical industry. Enhanced activity of sensitized nociceptors can increase ascending sensory inputs to supraspinal centers and neuroplastic changes that help maintain a sensitized state. One prominent change is increased availability of CCK in the RVM and enhanced descending facilitation of pain from this region. The enhanced pain facilitation leads to further changes in the spinal cord, notably upregulation of spinal dynorphin to pathological levels. Dynorphin, along with pronociceptive transmitters such as PGEs and glutamate, enhance the release of excitatory transmitters from primary afferent terminals. The result is a net increase in nociceptive inputs that help perpetuate this pronociceptive spinal/supraspinal/spinal pain facilitatory loop. Such knowledge underlies efforts to development of N-type calcium channel

blockers. Understanding the changes that occur at each of these nodes in this cycle could lead to means through which this self-perpetuating chain of events may be broken, thus abolishing the mechanisms that perpetuate chronic pain. The accelerating understanding of pain regulatory systems advanced by the discovery of underlying mechanisms driving enhanced abnormal pain will be continuously validated by clinical trials of drugs with novel mechanisms of action. Critically, new mechanisms of action will be tested clinically with the expectation that improved therapy can be provided to patients.

Glossary

allodynia Pain due to a stimulus which does not normally provoke pain.

autotomy Self amputation by animal that severs its own appendages (usually distal phalanges).

hyperalgesia An increased response to a stimulus which is normally painful.

neuropathic pain Pain initiated or caused by a primary lesion or dysfunction in the nervous system.

neuropathy A disturbance of function or pathological change in a nerve.

spontaneous pain Pain without an evident stimulus.

stimulus-evoked pain pain evoked by a mechanical/thermal/chemical stimulus.

Wallerian degeneration The degeneration of a nerve fiber induces by injury or disease, characterized by segmentation of the myelin and resulting in atrophy and destruction of the axon.

5.56.1 Introduction

Animal models in pain research offer great promise for both the identification of pain mechanisms, and the investigation of possible therapeutic applications. Our understanding of neuropathic pain (NP) has progressed during last few decades and although animal models have provided important information, in humans a clear pattern of the mechanisms responsible for its generation and maintenance is still unclear. Therefore, it is essential to put forward advanced animal models based, on the investigation of specific mechanisms, as well as refining the way in which the data is interpreted. Moreover, it is clear that the quest of a unique and universal animal model of all symptoms in patients ignores the complexity of the mechanisms involved. Therefore, it is important to select the best model for each specific research interest or a combination of appropriate but distinct models. In this chapter we will argue for the most frequently used animal models of NP, compare their advantages and disadvantages, and summarize the behavioral characterization.

5.56.2 Animal Models of Neuropathic Pain

At present, animal models of NP cover various etiologies and are related to symptoms leading to an extensive picture of clinical NP manifestations. The majority of animal models of NP involve traumatic

injuries to peripheral nerves, nerve roots, or spinal cord by transection, ligation, or compression (Figure 1). Other experimental models are related to direct or indirect nerve inflammation, ischemia, drug toxicity, or systemic metabolic disorders. Each animal model has been characterized by precise behavioral-based evaluations using different modalities of sensory stimulus. Many temporal and spatial profiles of molecular, physiological, and structural changes occurring during the development of NP have been investigated and most of the rodent models are compatible with actual electrophysiological measurements, functional imaging techniques, as well as genomic and proteomic screenings.

5.56.2.1 Models of Central Neuropathic Pain: Spinal Cord Injuries

Partial or complete spinal cord injuries result in loss of function in varying degrees below the level of injury, and are often associated with central NP pain syndromes (Christensen, M. D. and Hulsebosch, C. E., 1997a; Siddall, P. J. and Loeser, J. D., 2001). This type of injury involves functional and structural changes, partial loss of normal descending pathway, and hyperexcitability of dorsal horn neurons (Woolf, C. J., 1983; Woolf, C. J. and Fitzgerald, M., 1983; Hulsebosch, C. E., 2002). Spinal cord transection, contusion, compression, and chemical toxicity induce all at-level or below-level signs of pain hypersensitivity (Vierck, C. J. *et al.*, 1999; Sjolund, B. H., 2002; Rosenzweig, E. S. and McDonald, J. W., 2004). In the hemisection model (Christensen, M. D. *et al.*, 1996), a lateral spinal hemisection is performed at T13 level. After a period of motor dysfunction, ipsilateral to the injury, rats display persistent stimulus-evoked hypersensitivity of the four limbs associated with vocalization. This model was successfully used to observe molecular and structural reorganization of the spinal cord in NP (Christensen, M. D. and Hulsebosch, C. E., 1997b; Bennett, A. D. *et al.*, 2000; Hains, B. C. *et al.*, 2003b). The anterolateral cordotomy model (Vierck, C. J. and Light, A. R., 1999) consists in an unilateral injury of the anterolateral column at the T9–T11 spinal segments. The injury is associated with overgrooming and signs of allodynia/hyperalgesia. The model has been adapted

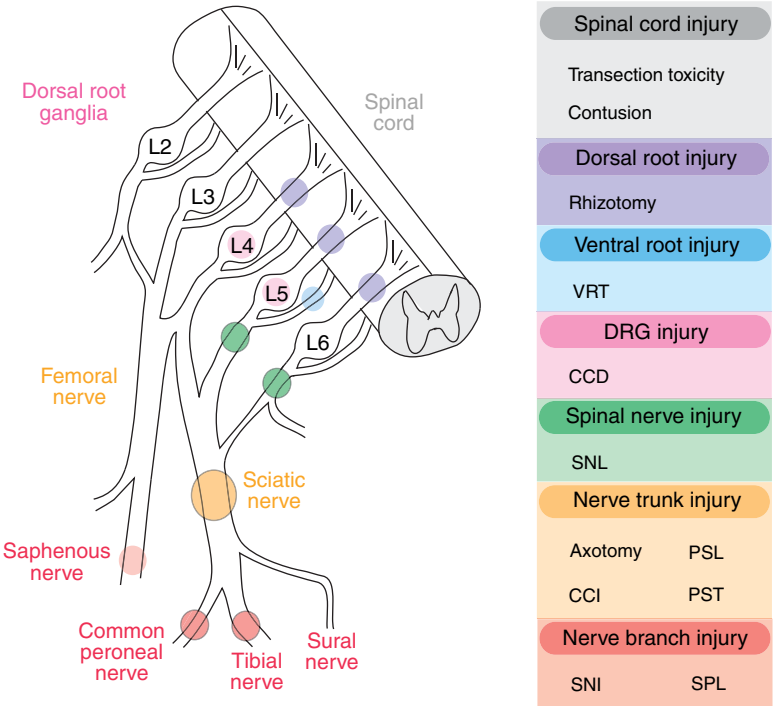

Figure 1 Anatomy of the rat lumbar plexus and the location of the different injuries used to create the different neuropathic pain models. VRT, ventral root transection; CCD, chronic compression of dorsal root ganglia; SNL, spinal nerve ligation; CCI, chronic constriction injury; PSL, partial sciatic ligation; PST, partial sciatic nerve transection; SNI, spared nerve injury (tibial and c. peroneal nerves are injured, sural nerve is intact); SPL, saphenous nerve partial ligation (30–50% of the saphenous is transected).

to primates and much information has been acquired on thalamus circuitry in NP (Weng, H.-R. *et al.*, 2000). The model of spinal cord contusion (Gruner, J. A., 1992; Siddall, P. *et al.*, 1995) is produced by an impact injury on the spinal cord at the level of T12/L1 using a weight dropped with a standard impact device (MASCIS, Multi-Center Animal Spinal Cord Injury Study). The incidence of pain hypersensitivity is correlated to the extent of the injury (Hulsebosch, C. E. *et al.*, 2000; Mills, C. D. *et al.*, 2001; Gwak, Y. S. *et al.*, 2004) and evidence of hyperexcitability of dorsal horn neurons and regulation of voltage-gated sodium channels have been shown (Hains, B. C. *et al.*, 2003a). Squeezing the spinal cord is the basis of the compression injury model (Fehlings, M. G. and Nashmi, R., 1995). A 35- or 50-g clip compression is placed on the dura mater at the juncture of T12 and T13 spinal segments and leads to microvasculature disruption, ischemia, and progressive axonal injury associated with the development of tactile allodynia (Bruce, J. C. *et al.*, 2002). Other central models of NP use toxic substances. The photochemically induced lesion of the spinal cord (Hao, J. X. *et al.*, 1991) is produced by the intravenous injection of erythrosine B (a photosensitizing dye) immediately followed by irradiation with an argon laser beam at T13 level. This procedure results in an ischemic lesion of thoracic spinal cord by occlusion of spinal cord vessels and produces a particularly severe mechanical and cold allodynia-like behavior in skin territories innervated by the rostral border of the injury (Hao, J. X. *et al.*, 1991; 1992). Excitotoxic spinal cord injury (ESCI) is directly mediated by the intraspinal injection at levels ranging from T10 to L4 of quisqualic acid (QUIS), an α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) metabotropic receptor agonist (Yezierski, R. P. *et al.*, 1993; 1998). This model offers the considerable advantage of avoiding surgical laminectomy, and although less representative of a clinical pathology, it induces sustained NP-like symptoms related to a precise mechanism. The QUIS model leads to a gradual and specific loss of neurons associated to NP-like behaviors and the extension of the injury and the intensity of changes are dependent on the depth and volume of the QUIS injections.

5.56.2.2 Models of Peripheral Neuropathic Pain: Injury to Roots, Dorsal Root Ganglia, and Spinal Nerves

Surgical procedures on selective root, dorsal root ganglia, and spinal nerves allows direct access to sensory and motor fibers and a clear segmental location of injured and noninjured primary afferents. Spontaneous and stimulus-evoked pain are sustained by different mechanisms such as deafferentation, ectopic activities in dorsal root ganglion (DRG), and spinal cord neurons, Wallerian degeneration of the peripheral axons and central reorganization (Eschenfelder, S. *et al.*, 2000; Li, Y. *et al.*, 2000). For dorsal and ventral root rhizotomies, typically at L5 level, the root is ligated and transected 3–4 mm proximal to the DRG (Colburn, R. W. *et al.*, 1999; Li, L. *et al.*, 2002). The ventral root transection model provides an additional feature to investigate NP, in the sense that lesion of a motor nerve induces alteration of pain sensitivity (Li, L. *et al.*, 2002; Sheth, R. N. *et al.*, 2002). Robust mechanical and cold allodynia-like behaviors have been documented (Sheen, K. and Chung, J. M., 1993), whereas loose ligation of L4–L6 dorsal roots produces only mechanical allodynia (Tabo, E. *et al.*, 1999). The chronic compression of dorsal root ganglia (CCD), proposed as a model of lower back pain/disc herniation, consists of the placement of a fine stainless-steel rod into the L5/L4 intervertebral foramen (Hu, S. J. and Xing, J. L., 1998). Heat hyperalgesia and a tactile allodynia are the resulting behaviors encountered in this model (Zhang, J. M. *et al.*, 1999; Ma, C. and LaMotte, R. H., 2005). The widely used spinal nerve ligation (SNL), where L5/L6 spinal nerve are tightly ligated (Kim, S. H. and Chung, J. M., 1992), produces robust and consistent sympathetic-dependent NP-related behaviors including indirect signs of spontaneous pain, heat hyperalgesia, mechanical allodynia/hyperalgesia, and cold allodynia (Choi, Y. *et al.*, 1994). This type of damage has also been applied successfully to mice and primates (Choi, Y. *et al.*, 1994; Ali, Z. *et al.*, 1999; Mogil, J. S. *et al.*, 1999). The additional and considerable advantage of SNL is the possibility to distinguish injured (L5/L6) and noninjured (L4) DRG and spinal segments.

5.56.2.3 Models of Peripheral Neuropathic Pain: Injury to Peripheral Nerves

The first models of NP used complete transection of major peripheral nerve. Wall and co-workers produce an entire denervation of the distal hindlimb, damaging the sciatic and saphenous nerves, to model anesthesia dolorosa, a type of NP referred to denervated zone without any sensory input from that area. Nerves were transected at midthigh level and the proximal stump was either tightly ligated or encapsulated into a

polyethylene tube (Wall, P. D. *et al.*, 1979a; 1979b). The total sciatic transection prevents stimulus-evoked assessment of the hindlimb but self-mutilation (autotomy) was the major feature of the experimental anesthesia dolorosa mode. Degrees of autotomy have been defined according to the extension of self-mutilation in the hindpaw and are used to evaluate the progression of the neuropathy. The subsequent chronic constriction injury (CCI) model, four catgut ligations loosely placed around the sciatic nerve (Bennett, G. J. and Xie, Y. K., 1988) or the partial sciatic ligation (PSL) model, ligation of one-third to one-half of the sciatic nerve in rats (Seltzer, Z. *et al.*, 1990) or mice (Malmberg, A. B. and Basbaum, A. I., 1998), allow sensory testing in the hindpaw (Figure 2). Moderate autotomy, guarding, and excessive grooming of the injured limb were noticed as well as thermal/mechanical hyperalgesia- and allodynia-like behavior were recorded (Bennett, G. J., 1993). Alternative to the CCI models include application of fixed-diameter polyethylene cuffs around the sciatic nerve, favoring a standardization of the loose, but constrictive ligatures in CCI (Mosconi, T. and Kruger, L., 1996). Another valuable alternative is the partial sciatic nerve transection (PST) model where half of the diameter of the sciatic nerve is only transected, avoiding inflammation caused by suture material with PSL. Chronic constriction of the trigeminal nerve (infraorbital nerve CCI, ION–CCI) was designed by Vos B. P. *et al.* (1994) as a model of trigeminal pain. ION–CCI model elicits excessive grooming of the face, mechanical allodynia, and thermal hyperalgesia (Imamura, Y. *et al.*, 1997). Sensory assessment of the animal face is difficult; however, the recent introduction of an automated thermal behavioral assay should provide valuable characterizations of orofacial pain models (Neubert, J. K. *et al.*, 2005).

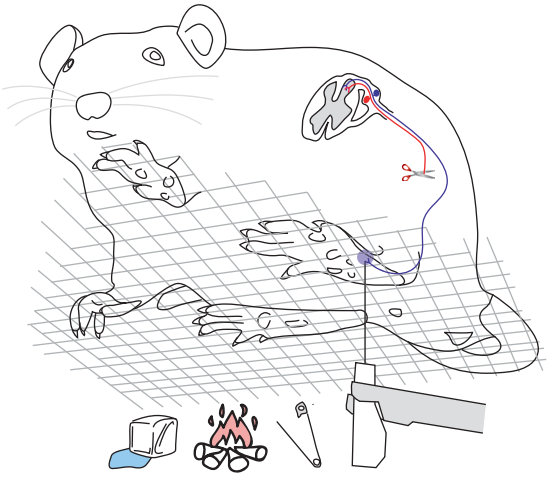

Figure 2 In many experimental models of neuropathic pain (NP), stimulus-evoked pain sensitivity is assessed in the plantar side of the hindpaw with various stimuli, usually in the territory of spared or regenerated afferents.

5.56.2.4 Models of Peripheral Neuropathic Pain: Distal Nerve Branch Injuries

Injuries to distal nerves branches offer the advantage that they can be anatomically defined, helping the standardization of surgical procedures. The spared nerve injury (SNI) in rats and mice is based on the ligation and transection of the tibial and common peroneal nerves leaving the sural nerve intact (Decosterd, I. and Woolf, C. J., 2000; Bourquin, A. F. *et al.*, 2006). This model results in early, robust, and intense mechanical allodynia/hyperalgesia and cold allodynia in the territory of the sural nerve (Figure 3). It offers the advantage of sparing an almost sensory nerve in combination with a clear separation of injured and noninjured axons distal to the injury. SNI has also been adapted to neonatal animals (Howard, R. F. *et al.*, 2005) and variants of the model have been described in rats and mice (Lee, B. H. *et al.*, 2000; Shields, S. D. *et al.*, 2003). Recently, the saphenous nerve partial ligation (SPL) model (30–50% of the saphenous nerve, a branch of the femoral nerve that innervates the medial part of the paw, is tightly ligated) leads to the development of NP-related symptoms (Walczak, J. S. *et al.*, 2005). The relevance in this model is that the injury of an exclusively sensory nerve is easily transferable for investigations with skin–nerve preparations (Reeh, P. W., 1986). Injury to peripheral branches has also been

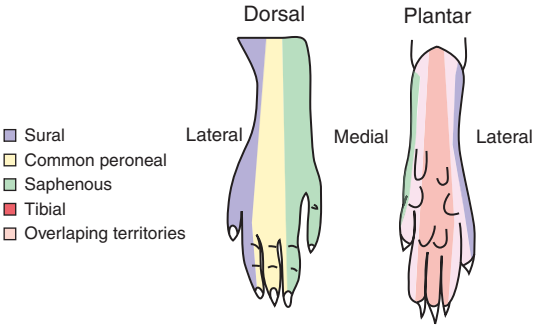

Figure 3 Areas of the dorsal and plantar paw innervated by the sciatic and femoral nerves in the rat. Some overlap between territories may occur (pink).

applied to the trigeminal nerve to study orofacial pain and similar to the SNI model, transection of a branch of the trigeminal nerve (infra-alveolar nerve) leads to hypersensitivity in the whisker pad area, which is innervated by a spared nerve (ION) (Tsuboi, Y. *et al.*, 2004).

5.56.2.5 Nontraumatic Models of Neuropathic Pain

Vincristine, taxol, and cisplatin may lead to peripheral neuropathy and NP in cancer patients. Models based on these substances have been created with different features of NP-related symptoms, usually in a dose-dependent manner (de Koning, P. *et al.*, 1987; Cavaletti, G. *et al.*, 1995; Aley, K. O. *et al.*, 1996; Authier, N. *et al.*, 2000; Mimura, Y. *et al.*, 2000; Nozaki-Taguchi, N. *et al.*, 2001). Diabetes is a major cause of painful neuropathy in humans. The diabetic model was induced by intraperitoneal injections of streptozotocin (STZ), which leads to pancreatic islet destruction and chronic hyperglycemia (Courteix, C. *et al.*, 1993; 1994). NP symptoms such as hyperalgesia- and allodynia-like behavior appear 2 weeks after. STZ produces functional, biochemical, and structural abnormalities in the sciatic nerve similar to those seen in human diabetic neuropathy (Sima, A. A. and Sugimoto, K., 1999). Prolonged ischemia of the hindpaw was proposed as a surrogate to complex regional pain syndrome (CRPS) type I (Coderre, T. J. *et al.*, 2004). After 8 h and lasting for 4 weeks, mechanical hyperalgesia and bilateral mechanical/thermal allodynia was observed along with excessive shaking and licking of hindpaws (Coderre, T. J. *et al.*, 2004). Axonal damage is combined with inflammation and nerve inflammatory models, without direct nerve injury were developed by wrapping the sciatic nerve with cellulose-containing inflammatory reagents such as carrageenan or complete Freund's adjuvant (CFA) (Eliav, E. *et al.*, 1999). In these cases, the course of pain hypersensitivity is very short (2–5 days only).

5.56.3 Behavioral Assessment of Neuropathic Pain in Animal Models: Spontaneous Pain, Stimulus-Evoked Pain, and Stimulus-Induced Pain

Tests based on pain sensitivity consider the type of injury, the remaining capacity of withdrawal reflexes (e.g., when neuromuscular defect is caused by the nerve injury), plus the localization, the intensity, and the time course of symptoms. NP in humans is characterized by modification of basal pain sensitivity with ongoing/spontaneous pain, and stimulus-evoked hyper- or hyposensitivity (Woolf, C. J. and Decosterd, I., 1999). Spontaneous pain appears independently of any external stimulus and cannot be assessed directly in animals. Only indirect physiological or behavioral surrogates of spontaneous pain are measurable: spontaneous discharges in sensory neurons, autotomy, posture (e.g., guarding behavior) movements (e.g., brisk paw flinches), or changes in general behavior (e.g., grooming, sleep patterns, vocalization, exploratory behavior) (Mogil, J. S. and Crager, S. E., 2004). All raised substantial issues that have meant laboratories favoring the recording of stimulus-evoked pain.

Stimulus-evoked pain is elicited by distinct stimuli like touch, pinprick, or temperature (heat or cold). Change in the threshold of response and/or quality of response are generally used as outcomes of allodynia/hyperalgesia-like behavior.

Mechanical allodynia-like behavior is usually measured by using a series of calibrated monofilaments of logarithmic incremental force (von Frey hairs) (Bennett, G. J., 2001). Monofilaments are applied in various territories of the animal's body, and positive responses are recorded when the application induces a withdrawal, movement, or vocalization. The evaluation of nociceptive threshold in sensible regions is the result of different procedures, such as the up–down method of Dixon (Chaplan, S. R. *et al.*, 1994). Cold allodynia-like behavior is assessed by placing an acetone drop on the area of interest, the acetone drop quickly evaporates eliciting a cold sensation (Choi, Y. *et al.*, 1994). Frequency of response to multiple applications as well as the type and duration of response have been used to score cold allodynia. Another method for measuring response to cold is the use of a cooled metal floor, usually at noxious low temperatures, thus evaluating cold hyperalgesia (Bennett, G. J. and Xie, Y. K., 1988; Choi, Y. *et al.*, 1994). Thermal hyperalgesia-like behavior is typically evaluated by measuring the latency and duration of reaction toward a heat noxious stimulus induced by a radial infrared beam (Hargreaves, K. *et al.*, 1988). Mechanical hyperalgesia-like behavior is evoked by a pinprick test, using a safety pin stimulus that provokes, in a normal animal, a small brisk withdrawal reflex, while abnormal responses are evoked in experimental NP rats. A large duration of withdrawal

and paw guarding/shaking/licking follows the stimulus (Tal, M. and Bennett, G. J., 1994).

Stimulus-induced pain refers to the capacity of external stimuli not only to directly evoke pain, but also to alter sensory processing such as to generate a state of pain hypersensitivity that outlast the primary stimuli. In animals, stimulus-evoked pain after capsaicin, inflammation, or nerve crush (Bennett, G. J. and Xie, Y. K., 1988; Choi, Y. *et al.*, 1994; Ma, Q. P. and Woolf, C. J., 1996; Kim, H. T. *et al.*, 2001; Decosterd, I. *et al.*, 2002) has been investigated after repeated low-threshold mechanical stimuli and further measurement of mechanical sensitivity is carried out using von Frey hairs. In this case, stimulus-induced pain has therefore been termed progressive tactile hypersensitivity.

Internal and external factors influence behavioral outcomes. These include: experimenter, genetic background, and gender of the animals, food, sawdust, noise, transportation, and so on (Chesler, E. J. *et al.*, 2002). Harmonized environments, as well as studies conducted by an investigator unaware of the treatment applied, facilitate this standardization of behavioral assessment.

5.56.4 Conclusions

Many factors need to be considered in any particular model such as the location, form, extension and evolution of the injury. At present, animal models of NP display unique and indispensable features and they are:

1. representative of a clinical entity or a fundamental mechanism;
2. ease in performance and reproducibility from investigator to investigator and laboratory to laboratory;
3. related to a development of symptoms consistent with clinical NP;
4. allowing well-characterized measure of pain sensitivity by behavioral assessments;
5. presenting robust alterations of nociceptive thresholds; and
6. compatible with reproducible pharmacological response.

Future challenges remain open for the development of new animal models as well as methods of measurement that include for instance measuring devices independent of the experimenter (Neubert, J. K. *et al.*, 2005). Pain symptoms are not equivalent to pain mechanisms, but they may reflect them. Similarly, all outcome measures in experimental models are not equivalent. A sophisticated approach using multiple models (Decosterd, I. *et al.*, 2004) is then required in order to correlate information obtained in experimental models with clinical syndromes of NP. Although all models of NP have weak points in modeling only partially human NP and the impossibility to have direct behavioral measurement of spontaneous pain, we believe that current and future models of NP will strengthen our knowledge of the underlying mechanisms and favor the development of new treatment strategies for this currently intractable form of pain.

5.57.1 Definition of Neuropathic Pain

The current NeuPSIG (Neuropathic pain special interest group of the International Association for the Study of Pain) taxonomy of chronic pain, defines neuropathic pain as a "Pain arising as a direct consequence of a lesion or disease affecting the somatosensory system." The term 'disease' refers to identifiable disease processes such as inflammatory, autoimmune conditions, or channelopathies, while lesions refer to macro- or microscopically identifiable damage. The restriction to the somatosensory system is necessary, because diseases and lesions of other parts of the nervous system may cause nociceptive pain. For example, lesions or diseases of the motor system may lead to spasticity or rigidity, and thus may indirectly cause muscle pain. The latter pain conditions are now explicitly excluded from the condition neuropathic pain. Where possible, neuropathic pain should be qualified as being of peripheral or central origin in terms of the location of the lesion or disease process. This distinction is important, as lesions or diseases of the central nervous system (CNS) and peripheral nervous system (PNS) are distinct in terms of clinical manifestations and underlying pathophysiology.

5.57.2 Epidemiology of Neuropathic Pain

Chronic neuropathic pain is common in clinical practice, greatly impairs the quality of life of patients and is a major economical health problem. Estimates of point prevalence for neuropathic pain in the general population are as high as 5% (Daousi, C. *et al.*, 2004), a quarter of them suffering from severe intensity (McDermott, A. M. *et al.*, 2006). Moreover, a recent prospective cross-sectional survey in more than 12 000 chronic pain patients with both nociceptive and neuropathic pain types who were referred to pain specialists in Germany (Freynhagen, R. *et al.*, 2005/2006) revealed that already 13% of these patients suffer from the two classical neuropathic disorders, postherpetic neuralgia (PHN) and painful diabetic neuropathy and 40% of all patients at least have a neuropathic component to their discomfort (especially patients with chronic back pain and radiculopathy). In neuropathic patients pain therapy was already performed for 2–4 years, one-third of the patients mentioned three or more doctor visits for pain therapy in the past month and 8–20% already applied for pension (Table 1).

Comorbidities such as poor sleep, depressed mood, and anxiety are common in neuropathic pain and have a significant impact on the global pain experience. The German survey revealed that about 60% of neuropathic patients were moderate or severely depressed compared with 25% in the nociceptive patient group. Optimal sleep quality was only scored by 27% of the neuropathic patients and in 49% of the nociceptive pain patients, respectively.

5.57.3 Classification

5.57.3.1 Disease/Anatomy-Based Classification

It is common clinical practice to classify neuropathic pain according to the underlying etiology of the disorder and the anatomical location of the specific lesion (Jensen, T. S. and Baron, R., 2003). The majority of patients fall into four broad classes (Table 2): painful peripheral neuropathies (focal, multifocal, or generalized, e.g., traumatic, ischemic, inflammatory, toxic, metabolic, and hereditary), central pain syndromes (e.g., stroke, multiple sclerosis (MS), and spinal cord injury (SCI)), complex painful neuropathic disorders (complex regional pain syndromes, CRPSs) and mixed pain syndromes (combination of

Table 1 Sociodemographic and clinical characteristics in patients with postherpetic neuralgia (PHN) and diabetic painful neuropathy (DPN) (%)

	PHN	*DPN*
Number of patients	498	1144
Male	199 (40.0)	596 (52.1)
Female	299 (60.0)	548 (47.9)
Age (years)		
Mean	60.6	61.7
SD ±	15.4	13.2
Duration of pain treatment (months)		
Mean	24	52
SD ±	41	63
No. of doctor visits for pain during the past 4 weeks		
One visit	188 (37.8)	348 (30.4)
Two visits	135 (27.1)	339 (29.6)
Three or more	132 (26.5)	348 (30.4)
Ongoing psychotherapy	8 (1.6)	34 (3.0)

nociceptive and neuropathic pain, e.g., chronic low back pain with radiculopathy).

The anatomical distribution pattern of the affected nerves provides valuable differential diagnostic clues as to possible underlying causes. Therefore, painful peripheral neuropathies are grouped into symmetrical generalized polyneuropathies, disease affecting many nerves simultaneously and into asymmetrical neuropathies with a focal or multifocal distribution or processes affecting the brachial or lumbosacral plexuses.

One important subgroup of painful polyneuropathies is characterized by a predominant or in some cases even isolated affection of small afferent fibers, i.e., unmyelinated C fibers and small myelinated Aδ fibers. In many cases, autonomic efferent small fiber systems are also affected. Several different etiologies may lead to small-fiber polyneuropathies (see below), up to 20% of cases, however, are of unknown cause. It is important to realize that conventional electrophysiological techniques like nerve conduction study (NCS), sensory-evoked potential (SEP), etc., only assess the function of myelinated peripheral axonal systems, the affection of small fibers are missed. Therefore, especially in small-fiber neuropathies alternative diagnostic procedures have to be used (see below).

5.57.3.1.1 Painful peripheral (focal, multifocal, generalized) neuropathies

Although most of the different neuropathic pain syndromes are common and well known to the pain specialists, there are certain entity-specific features that should be mentioned in detail (See also Table 3):

5.57.3.1.1.(i) Diabetic neuropathy

- High prevalence
- Several types of polyneuropathies, most prevalent symmetrical distally, sensory predominant neuropathy
- Numbness and paresthesias (sometimes burning quality) are common
- Sometimes spontaneous, deep, aching pain, and lightning pain
- Severe sensory neuropathy in diabetes may lead to painless perforating foot ulcers often associated with autonomic neuropathy
- Patients without pain tend to have areflexia with distal sensory loss particularly involving joint position sense
- Patients with severe burning pain and hyperesthesia tend to have sensory loss with a relative preservation of position sense and intact reflexes and often have accompanying autonomic neuropathy

Table 2 Disease-/anatomy-based classification of painful peripheral neuropathies

Painful peripheral neuropathies
- Focal, multifocal
  - Phantom pain, stump pain, nerve transection pain (partial or complete)
  - Neuroma (posttraumatic or postoperative)
  - Posttraumatic neuralgia
  - Entrapment syndromes
  - Mastectomy
  - Postthoracotomy
  - Morton's neuralgia
  - Painful scars
  - Herpes zoster and postherpetic neuralgia
  - Diabetic mononeuropathy, diabetic amyotrophy
  - Ischemic neuropathy
  - Borreliosis
  - Connective tissue disease (vasculitis)
  - Neuralgic amyotrophy
  - Peripheral nerve tumors
  - Radiation plexopathy
  - Plexus neuritis (idiopathic or hereditary)
  - Trigeminal or glossopharyngeal neuralgia
  - Vascular compression syndromes

Generalized (polyneuropathies)
- Metabolic or nutritional
  - Diabetic, often 'Burning feet syndrome'
  - Alcoholic
  - Amyloid
  - Hypothyroidism
  - Beri beri, pellagra
- Drugs
  - Antiretrovirals, cisplatin, disulfiram, ethambutol, isoniazid, nitrofurantoin, thalidomid, thiouracil, vincristine, chloramphenicol, metronidazole, taxoids, gold
- Toxins
  - Acrylamide, arsenic, clioquinol, dinitrophenol, ethylene oxide, pentachlorophenol, thallium
- Hereditary
  - Amyloid neuropathy
  - Fabry's disease
  - Charcot–Marie–Tooth disease type 5, type 2B
  - Hereditary sensory and autonomic neuropathy (HSAN) type 1, type 1B
- Malignant
  - Carcinomatous (paraneoplastic), myeloma
- Infective or postinfective, immune
  - Acute or inflammatory polyradiculoneuropathy (Guillain–Barré syndrome), borreliosis, HIV
- Other polyneuropathies
  - Erythromelalgia
  - Idiopathic small-fiber neuropathy
  - Trench foot (cold injury)

Central pain syndromes
- Vascular lesions in the brain (especially brainstem and thalamus) and spinal cord
  - Infarct
  - Hemorrhage
  - Vascular malformation
- Multiple sclerosis
- Traumatic spinal cord injury including iatrogenic cordotomy
- Traumatic brain injury
- Syringomyelia and syringobulbia
- Tumors
- Abscesses
- Inflammatory diseases other than multiple sclerosis; myelitis caused by viruses, syphilis
- Epilepsy
- Parkinson's disease

(*Continued*)

Table 2 (Continued)

Complex painful neuropathic disorders
Complex regional pain syndromes type I and II (reflex sympathetic dystrophy, causalgia)
Mixed pain syndromes
Chronic low back pain with radiculopathy
Cancer pain with malignant plexus invasion
Complex regional pain syndromes

Table 3 Special clinical features that are relevant for specific diagnoses

Special feature	*Possible diagnosis*
Cold allodynia	Traumatic nerve injury
	Trench foot syndrome
	Complex regional pain syndrome
	Oxaliplatin-induced polyneuropathy
	Central poststroke pain
Deep somatic allodynia	Complex regional pain syndrome
SMP	Complex regional pain syndrome, acute herpes
Isolated small-fiber affection	Diabetic polyneuropathy
	Amyloid polyneuropathy
	Fabry's disease
	Hereditary polyneuropathy
	Idiopathic small-fiber polyneuropathy
Painful polyneuropathy in several family members	Amyloid polyneuropathy,
	Fabry's disease
	Charcot–Marie–Tooth disease type 5, type 2B
	Hereditary sensory, autonomic polyneuropathy (HSAN) type 1, 1B

SMP, sympathetically maintained pain.

- Small sensory and autonomic fibers are involved early in diabetic neuropathy as well as in impaired glucose tolerance (IGT)
- Abnormal epidermal C fiber density is highly correlated with warm detection threshold (QST)
- Regeneration capacity of cutaneous C fibers (experimental challenge with topical capsaicin) is reduced
- Hyperglycemia in diabetic patients may itself be an important factor for acute exacerbations of pain
- Up 40% of patients with a so-called burning feet syndrome have a small-fiber neuropathy and many already demonstrate an IGT indicative of early diabetes

5.57.3.1.1.(ii) Alcoholic neuropathy

- Incidence of neuropathy in chronic alcoholism about 10%
- Paresthesias, burning pain, and tenderness of the feet
- Painful symptoms not related to the severity of somatosensory deficit
- Sensorimotor small- and large-fiber neuropathy
- Sometimes early small-fiber deficit

5.57.3.1.1.(iii) Amyloid neuropathy

- Predominant painful small fiber neuropathy in both inherited and sporadic forms
- Predominant distal sensory loss of pain and thermal sensations, often autonomic involvement
- Severe pain usually of a deep aching quality, sometimes shooting pains

5.57.3.1.1.(iv) Fabry's disease (angiokeratoma corporis diffusum)

- Lipid (glycosphingolipid) storage disorder, sex-linked recessive
- Heterozygous carrier females occasionally develop symptoms later in life
- Deficiency of α-galactosidase A lead to accumulation of glycosphingolipid (globotriaosylceramide) in tissues

- Painful small-fiber neuropathy early and presenting clinical feature
- Boys or young men present with tenderness of the feet and severe spontaneous burning pain in the legs
- Stroke in young adults due endothelial vasculopathy, about 5% of young male patients with cryptogenic stroke have Fabry's disease
- Extraneural manifestations: cutaneous telangiectasia, cardiac, renal, pulmonary failure
- Patients with preserved renal function involves exclusively small myelinated and unmyelinated fibers
- Normal results of nerve conduction studies
- Normal results of large-fiber quantitation by sural nerve biopsy

5.57.3.1.1.(v) Idiopathic small-fiber neuropathy

- Predominant or isolated loss of small fibers involving somatic and autonomic neurons
- Often elderly patients
- 40% of patients with a so-called burning feet syndrome have a small-fiber neuropathy suffering from burning sensation, dysesthesia and paresthesias in the feet, lancinating pains, and minimal or no distal weakness
- Abnormalities of epidermal skin innervation (skin biopsies)
- Normal results of nerve conduction studies
- Normal results of large-fiber quantitation by sural nerve biopsy

5.57.3.1.1.(vi) Human immunodeficiency virus- and highly active antiretroviral therapy–associated neuropathy

- Incidence about 15–30% in the human immunodeficiency virus (HIV) population
- Painful sensory polyneuropathy
- Distal painful paresthesias, spontaneous pain, evoked shock-like pain, and mechanical allodynia with symmetric stocking-like distribution associated with autonomic neuropathy
- Neuropathy is due to a combination of the virus itself and antiretroviral drugs (nucleoside analogue reverse transcriptase inhibitors, highly active antiretroviral therapy (HAART))
- Clinically, these two neuropathies are indistinguishable
- Nerve pathology in the painful sensory polyneuropathy includes axonal atrophy and endoneurial capillary thickening

5.57.3.1.1.(vii) Erythromelalgia (erythermalgia)

- Rare condition characterized by painful, red, hot extremities
- Acquired form sometimes associated with polycythemia rubra vera
- Rare hereditary form caused by a genetic defect of the sodium channel $Na_v1.7$
- Symptoms are aggravated by heat
- Immediate pain relief by cooling the affected limb
- Feet affected in more than 80%, hands in 25%
- Underlying small fiber neuropathy in some cases

5.57.3.1.1.(viii) Acute herpes zoster and postherpetic neuralgia

- Acute zoster: neurocutaneous disease with unilateral efflorescences within one or few dermatomes
- Reactivation of varicella zoster virus, which resides in latent form in sensory trigeminal and dorsal root ganglia following primary infection as varicella
- Preherpetic neuralgia (pain before cutaneous symptoms of acute zoster) of some days
- Every dermatome may be affected, thoracic 54%, especially Th5–10 (15%), trigeminal 20%, especially first branch (13%)
- PHN: chronic pain syndrome for more than 3 months after healing of acute zoster lesions
- Incidence of pain 9–15% after 1 month, 2–5% of all age groups after 1 year
- Main risk factor for PHN is age
- Spontaneous burning pain, stimulus-evoked pain, and shooting pains possible

5.57.3.1.1.(ix) Phantom limb pain

- Phantom limb: amputation of an extremity or other body part or transection of a peripheral nerve leads almost in all cases to a sensation of the missing or denervated limb
- Phantom limb pain: pain in the missing body part, up to 80% of patients, mainly after extremity amputation, cramp-like severe pain in distal phantom, sometime painful phantom movements
- Stump pain: the amputation stump itself shows mechanical allodynia especially close to the skin flap scar or near tender neuromas
- Telescoping: seemingly shrinking phantom
- Aggravation of both painful and nonpainful phantom sensations by external stimuli (noxious or

innocuous mechanical stimuli at the stump, sometimes at face or remote ipsilateral body parts)

- Aggravation of both painful and nonpainful phantom sensation by internal stimuli (micturition, yawning) or emotional stimuli
- Main reasons for amputations in times of peace: peripheral vascular disease (60%), half of the patients also suffer from additional diabetes mellitus, accidents (20%), rare causes like tumor, arterial thrombosis, and osteomyelitis (20%)
- Pathophysiological mechanisms: it seems obvious that the phantom limb image with its complex perceptual, emotional and cognitive qualities involves interaction of some cerebral structures. This, however, may not preclude the notion that neuronal mechanisms at a much lower level of the CNS or even within the severed peripheral nerves may furnish the brain with the information necessary for creating the phantom.

5.57.3.1.2 Central pain syndromes

Central pain is defined as chronic pain following a lesion or disease of the CNS. The cause of pain is a primary process within the CNS. All lesions that cause central pain affect the somatosensory pathways. They may be located at any level of the neuraxis. Thus lesions at the first synapse in the dorsal horn of the spinal cord or trigeminal nuclei, along the ascending pathways through the spinal cord (Figure 1) and brainstem, in the thalamus, in the subcortical white matter, and in the cerebral cortex have all been reported (Leijon, G. *et al.*, 1989).

The most common are cerebrovascular lesions, MS, and traumatic spinal cord injuries (SCIs). In these diseases the incidences are around 8%, 28%, and 40%, respectively (Siddall, P. J. *et al.*, 2003). In stroke, there is a particularly high prevalence among patients with brainstem and thalamic lesions, whereas there is no difference in the prevalence after ischemic and hemorrhagic events. In patients with thalamic infarction only patients with lesions that includes the ventroposterior region, which receives a particularly dense spinothalamic projection develop central pain. In MS it has not been possible to determine the location of the lesions that cause central pain, but clinical observations indicate that many of them are located in the spinal cord.

In stroke the pain is most frequently a hemipain (75%). In MS it affects one or both sides more often in the legs (87%) than in the upper extremities (31%). Trigeminal neuralgia, caused by a lesion in the brain stem, occurs in 5% of all MS patients. In all conditions, there is a large variation in the quality of central pain.

Often central pain develops with a latency of weeks or month after the inciting event. The most frequent clinical characteristics are spontaneous burning pain, shooting pain and evoked pain within the affected body part. Allodynia to touch or light pressure as well as to heat or cold are common. Many internal and external events influence central pain,

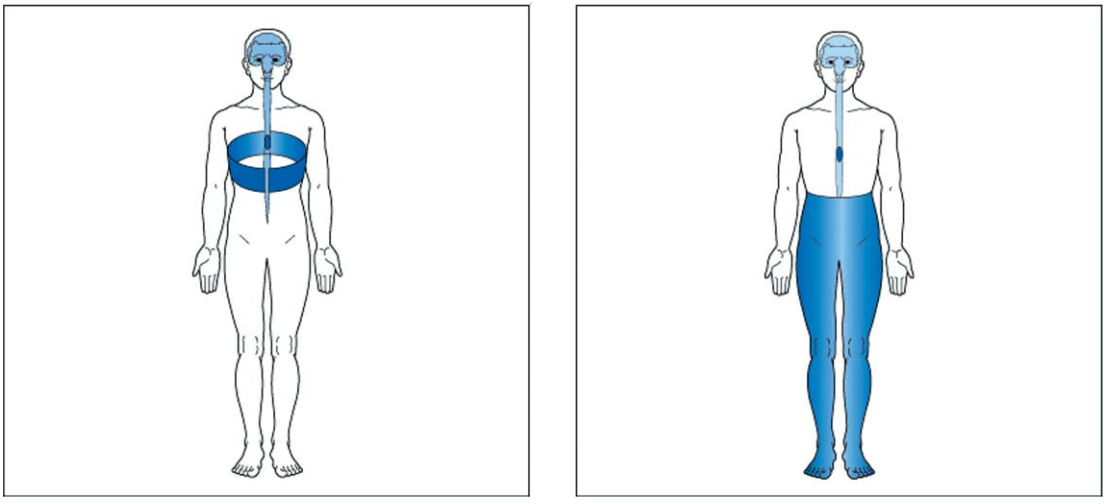

Figure 1 Different pains in spinal cord injury patients. (a) Typical pattern of below-level neuropathic pain following spinal cord injury (SCI) at T7. The dark shading represents the distribution of pain. (b) Typical pattern of at-level neuropathic pain following SCI at T7. The dark shading represents the distribution of pain. Adapted from Siddall, P. 2006. Pain Following Spinal Gord Injury. In: Walland Melzack's Textbook of Pain, 5th edn. (*eds.* McMahan, S. B. and Koltzenburg, M.), pp. 1043–1056. Elsevier.

such as cutaneous stimuli, body movements, visceral stimuli, emotions, and changes in mood.

In order to diagnose central pain it is necessary to ensure that the patient has a CNS disorder by a detailed history and a neurological examination, computed tomography (CT), magnetic resonance imaging (MRI), cerebrospinal fluid analysis, or electrophysiological techniques (in particular QST to assess spinothalamic function). It is necessary to exclude painful peripheral neuropathy as a cause. Polyneuropathy is not uncommon in, for instance stroke patients, a group with a high incidence of diabetes.

The pathophysiological mechanisms of central pain are unclear. An affection of the spinothalamocortical pathways seems to be crucial for the development of central pain, whereas isolated lesions of the lemniscal system are never associated with pain. Thus, the pain is always correlated with sensory disturbances, dominated by abnormalities in the sensibility to temperature and pain. Decreased sensibility to touch, vibration, and joint movements may be present, but is often less pronounced. It is hypothesized that central pain occurs only in patients who have lesions of the spinothalamocortical pathways. Lesioning of the spinothalamic tract leads to a loss of input to normal pain-modulating systems in particular in thalamic neurons. This loss may creates neuronal signs of hyperexcitability. Furthermore, infarction of the dorsolateral thalamus may lead to neuronal disinhibition in medial thalamic nuclei. Incomplete SCI may be associated with sensitization of spinal dorsal horn neurons.

5.57.3.1.2.(i) Spinal cord injury pain

- Prevalence of pain about 65% (Siddall, P. J. *et al.*, 2003)
- Four types of pain (Figure 1):

1. Nociceptive pain (musculoskeletal, spastic, visceral)
2. Neuropathic pain above level (secondary to nerve lesions: compressive mononeuropathies, CRPS)
3. Neuropathic pain at level (segmental, circumferential band-like distribution: nerve root compression, syringomyelia, spinal cord trauma, or ischemia)
4. Neuropathic pain below level (below the level of the spinal cord lesion perceived diffusely in anesthetic regions: spinal cord trauma, or ischemia)

- Musculoskeletal nociceptive pain is the most common (58%)
- At-level neuropathic pain 42%, sharp, shooting, electric, burning, and stabbing pain located in a region of sensory disturbance
- Below-level neuropathic pain 34%, develops months and even years following initial injury, spontaneous and/or evoked pain diffusely caudal to the level of SCI, burning, aching, stabbing, or electric shocks, often with hyperalgesia
- Fluctuation with mood, activity, infections
- Triggered by sudden noises, jarring movements
- Both complete and partial injuries may be associated with the diffuse, burning pain
- Incomplete injuries often show allodynia due to sparing of lemniscal tracts conveying touch sensations
- Mainly not painful phantom sensation present in 90%

5.57.3.1.3 Complex painful neuropathic disorders

In addition to the classical neuropathic syndromes like painful diabetic neuropathy, PHN, or phantom limb pain there are certain chronic painful conditions that share many clinical characteristics. These syndromes were formerly called reflex sympathetic dystrophy, M. Sudeck or causalgia and are now classified under the umbrella term CRPSs. CRPS are painful disorders that may develop as a disproportionate consequence of trauma typically affecting the limbs (Janig, W. and Baron, R., 2003; Baron, R. and Janig, W., 2004). CRPS type I usually develops after minor trauma with a small or no obvious nerve lesion at an extremity (e.g., bone fracture, sprains, bruises or skin lesions, surgeries). CRPS type II develops after trauma with a mostly large nerve lesion. The patients often report a burning spontaneous pain felt in the distal part of the affected extremity. Stimulus-evoked pains are a striking clinical feature; they include mechanical and thermal allodynia and/or hyperalgesia. These sensory abnormalities are most pronounced distally, and have no consistent spatial relationship to individual nerve territories or to the site of the inciting lesion. Typically, pain can be elicited by movement of and pressure on the joints (deep somatic allodynia), even if these are not directly affected by the inciting lesion.

Unlike other classical neuropathic pain syndromes CRPS show additional nonsensory features like signs of autonomic dysfunction (abnormal

regulation of blood flow and sweating), edema of skin and subcutaneous tissues, active and passive movement disorders, and trophic changes of skin, appendages of skin and subcutaneous tissues. Especially for the acute phase, there is accumulating evidence that inflammatory processes might be involved. Thus, it is likely that nociceptive as well as neuropathic mechanisms are responsible for pain generation in CRPS, which would then fit into the classification if a mixed pain syndrome (see below).

5.57.3.1.4 *Mixed pain syndromes*

There is agreement that both nociceptive and neuropathic processes contribute to many chronic pain syndromes and that these different mechanisms may explain the qualitatively different symptoms and signs that patients experience. In particular, patients with chronic low back pain, cancer pain, and CRPS seem to fit into this theoretical construct (Baron, R. and Binder, A., 2004).

In chronic low back pain, the nociceptive component stems from activation of intact nociceptors that innervate ligaments, small joints, muscle, and tendons. The neuropathic pain component is caused by mechanical compression of the nerve root or by action of inflammatory mediators originating from the degenerative disc on the nerve root. Cytokines and chemokines have been implicated in the chemical pathomechanism of radicular pain. Increased levels of tumor necrosis factor alpha (TNF-α), interleukin (IL)-1, IL-6, and granulocyte-macrophage colony stimulating factor (GM-CSF) have been detected in herniated disc tissue compared with normal, nondegenerated disc tissue. TNF-α applied to nerve roots reproduces the pathologic changes observed with nerve root exposure to nucleus pulposus extracts. Finally, in an animal model of radiculopathy induced by intervertebral disc material, inhibitors of TNF-α reversed the radicular pathology. So far it is unclear whether these mediators are capable of activating intact nerve root fibers even without any mechanical compression or if the combination of mechanical nerve damage and cytokine attack is the important prerequisite.

5.57.3.2 Mechanism-Based Classification

As described above neuropathic pain represents heterogeneous conditions, which neither can be explained by one single etiology or disease nor by a specific anatomical lesion, i.e., a disease- and anatomy-based classification is often insufficient. First, despite obvious differences in etiology, many of these conditions share common clinical phenomena; for example, touch-evoked pain in PHN and painful diabetic neuropathy. Conversely, different signs and symptoms can be present in the same disease; for example, pain paroxysms and stimulus-evoked abnormalities in PHN. Second, classification on the basis of anatomical location also has its shortcomings, as neuroplastic changes following nervous system lesions often give rise to sensory and pain distributions that do not respect nerve, root, segmental or cortical territories. Third, and most importantly, decades of rather discouraging systematic research on chronic pain therapy have revealed that a disease based strategy is of no or little help to these patients and their pain.

These observations have raised the question of whether an entirely different strategy, in which pain is analyzed on the basis of underlying mechanisms (Jensen, T. S. and Baron, R., 2003), could provide an alternative approach for examining and classifying patients, with the ultimate aim of obtaining a better treatment outcome (Woolf, C. W. *et al.*, 1998; Dworkin, R. H. *et al.*, 2003). Our increasing understanding of the mechanisms that underlie chronic pain, together with the discovery of new molecular therapy targets, has strengthened the demand for alternative concepts.

One theoretical possibility to identify pain mechanisms in patients is to assess differences in the somatosensory phenotype as precisely as possible. These specific patterns of signs and symptoms could be compared with the knowledge derived from animal experiments where the association of signs and symptoms and underlying mechanisms has been elucidated. This concept has led to the development of a symptom-oriented diagnostic approach to neuropathic pain conditions that supplements the etiology-based classification scheme, which recognizes the fact that neuropathic pains are usually a composite of several pain symptoms. A symptom-oriented approach does not negate the fact that distinct neuropathies present differently clinically, and that some neuropathic disease states may predispose to certain constellations of pain symptoms (e.g., touch-evoked pain in PHN). The rationale of this approach recognizes several principles:

- Clinically distinct pain symptoms such as ongoing stimulus-independent pain may be caused by similar, if not identical, neural mechanisms, even if the underlying neuropathies differ. For example,

nociceptive afferents that develop ongoing activity after axon injury could mediate ongoing pain regardless of the precipitating or sustaining neuropathic cause.

- More than one pain mechanism is usually present in an individual patient.
- Some symptoms, such as mechanical hypersensitivity, can be explained by several distinct neural mechanisms that may even coexist in an individual patient.

As said, a symptom-based approach to painful neuropathies can be useful for dissecting the underlying neural mechanisms, and this knowledge may eventually be harnessed for the development of novel analgesic drugs that differentially target these mechanisms. A very promising but still hypothetical approach is summarized in Table 5.

5.57.4 Signs and Symptoms in Neuropathic Pain

Pain associated with nerve injury has several clinical characteristics (Baron, R., 2006) (Tables 4 and 6). If a mixed peripheral nerve with a cutaneous branch or a central somatosensory pathway are involved, there is almost always an area of abnormal sensation and the patient's maximum pain is coextensive with or within an area of sensory deficit. This is a key diagnostic feature for neuropathic pain. The sensory deficit is usually to noxious and thermal stimuli, indicating damage to small-diameter afferent fibers.

Beside these negative somatosensory signs (deficit in function), which are bothering but not painful also positive signs are characteristic for neuropathic conditions. Paresthesias (ant crawling, tingling) are not painful. Painful positive signs are spontaneous (not stimulus-induced) ongoing pain and spontaneous shooting, electric schock-like sensations. Many patients with peripheral neuropathic pain also have evoked types of pain (stimulus-induced pain, hypersensitivity), which are characterized by several sensory abnormalities. They may be adjacent to or intermingled with skin areas of sensory deficit. Most often, patients report mechanical hypersensitivity followed by hypersensitivity to heat and cold. Two types of hypersensitivity can be distinguished. First, allodynia is defined as pain in response to a nonnociceptive stimulus. In case of mechanical allodynia even gentle mechanical stimuli such that even slight bending of hairs may evoke severe pain. Second, hyperalgesia is defined as an increased pain sensitivity to a nociceptive stimulus. Another evoked feature is summation, which is the progressive worsening of pain evoked by slow repetitive stimulation with mildly noxious stimuli, for example, pinprick. A small percentage of patients with peripheral nerve injury have a nearly pure hypersensitive syndrome in which no sensory deficit is demonstrable.

The quality of the reported sensation may also be a clue; neuropathic pain commonly has a burning and/or shooting quality with unusual tingling, crawling or electrical sensations (dysesthesiae).

Although all these characteristics are neither universally present in, nor absolutely diagnostic of

Table 4 Symptoms and signs of neuropathic pain

	Peripheral neuropathic pain	*Postherpetic neuralgia*	*Complex regional pain syndrome*
Ongoing pain	100%	100%	100%
Brush-evoked pain (dynamic mechanical allodynia)	36%	60%	60%
Pinprick hyperalgesia	38%	37%	Present
Static allodynia	35%	52%	Present
Deep somatic allodynia	None	None	90%

neuropathic pain, when they are present the diagnosis of neuropathic pain is likely (Table 4).

5.57.5 Pathophysiological Mechanisms in Neuropathic Pain

Most of the present pathophysiological ideas are derived from experimental work with animal models for neuropathic pain (Figure 2). This work has delineated a series of partially independent pathophysiological mechanisms presumed to be responsible for different types of neuropathic pain and different somatosensory abnormalities (Baron, R., 2006).

5.57.5.1 Peripheral Sensitization of Primary Afferent Nociceptors

Pain sensations are normally elicited by activity in unmyelinated (C) and thinly myelinated (Aδ) primary afferent neurons. After peripheral nerve lesion these neurons acquire an abnormal sensitization, i.e., an increased responsiveness of primary nociceptors to stimulation of their receptive field. The characteristic features of sensitized nociceptors are: pathological spontaneous discharge, a lowered activation threshold for thermal and mechanical stimuli, and an enhanced discharge to suprathreshold stimulation (hyperalgesia).

A large number of dramatic molecular and cellular changes at the level of the primary afferent nociceptor that are triggered by the nerve lesion underlie these pathological changes.

Nerve injury is matched by increased expression of messenger RNA for voltage gated sodium channels in primary afferent neurons. Two voltage-gated sodium channel genes ($Na_v1.8$ and $Na_v1.9$) are expressed selectively in nociceptive primary afferent neurons and an embryonic channel ($Na_v1.3$) is also upregulated in damaged peripheral nerves and associated with increased electrical excitability and spontaneous activity in neuropathic pain states. The accumulation of sodium channels at sites of ectopic impulse generation (sodium channel clusters) may be responsible for lowering of action potential threshold (Omana-Zapata, I. *et al.*, 1997). There is evidence that small primary afferent fibers may acquire a unique sodium channel expression profile after nerve lesion (e.g., a specific relation of up- and downregulation of channel proteins), which makes them an interesting target (Wood, J. N. *et al.*, 2004).

After peripheral nerve damage the accumulation of sodium channel clusters does not only occur at the site of the nerve lesion but also far proximally within the intact dorsal root ganglion (DRG). In the DRG a reciprocation between a phasically activating voltage-dependent, tetrodotoxin (TTX)-sensitive sodium conductance and a passive, voltage-independent potassium leak generates characteristic membrane potential oscillations. Ectopic firing is triggered when the amplitude of oscillation sinusoids reaches threshold (Amir, R. *et al.*, 2002). Pathological membrane properties within the DRG that occur after nerve lesion are of particular therapeutic interest as the DRG is spared of the blood brain barrier and might be easily accessible for systemic therapies (Jacobs, J. M. *et al.*, 1976). In addition to sodium currents, impaired potassium conductances in myelinated fibers were demonstrated in experimental diabetes and may underlie hyperexcitability in these fibers.

Damage to peripheral primary nociceptors also induces upregulation of a variety of receptor

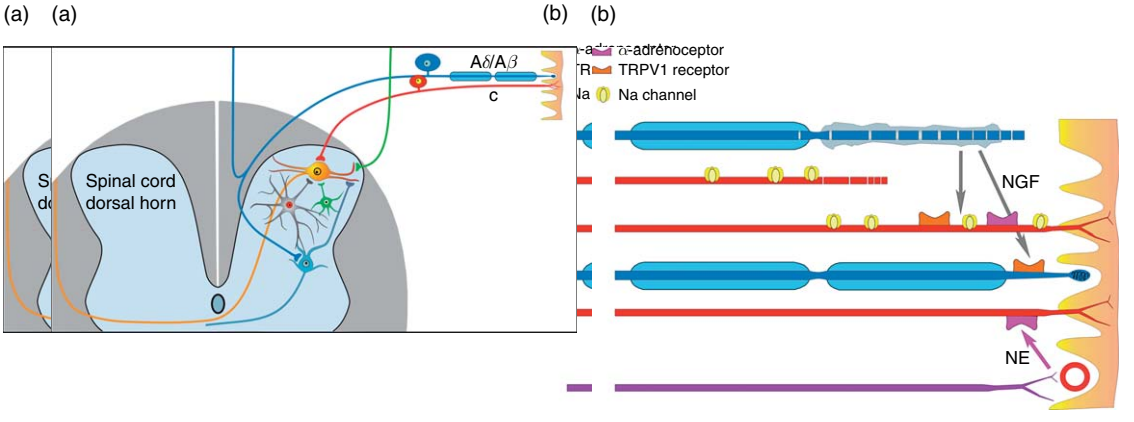

Figure 2 (continued)

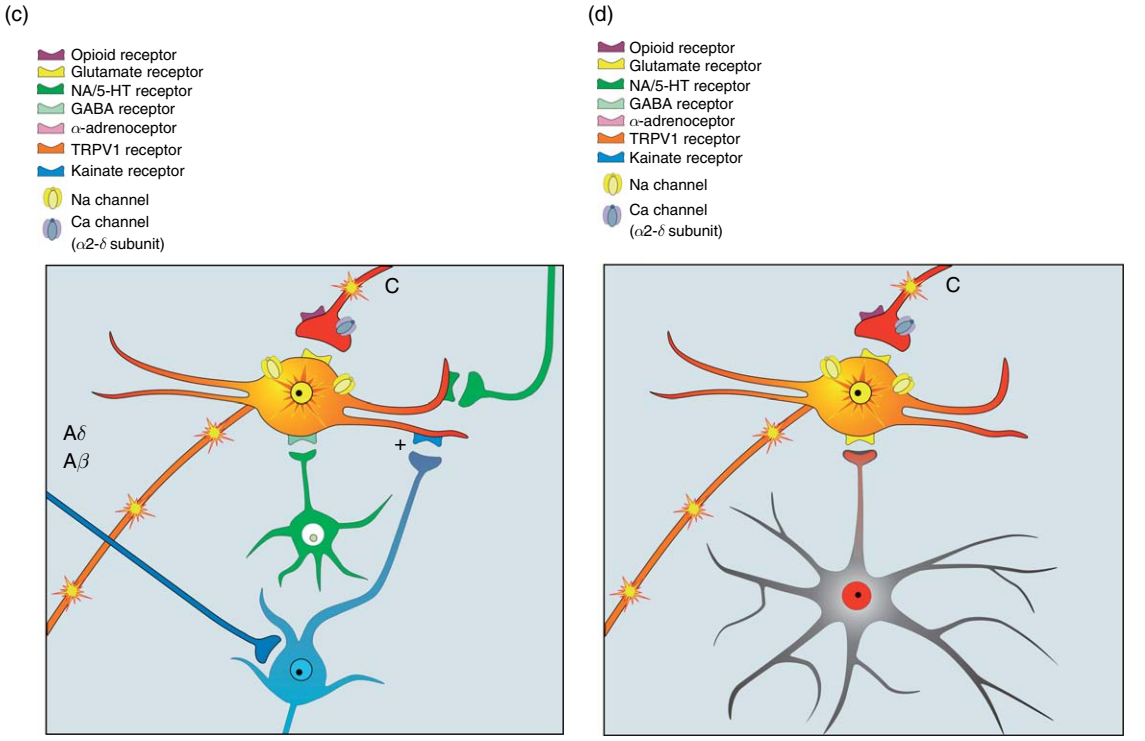

Figure 2 Mechanisms of peripheral sensitization and central sensitization in neuropathic pain. (a) Primary afferent pathways and their connections in the spinal cord dorsal horn. Nociceptive C fibers (red) terminate at spinothalamic projection neurons in upper laminae (orange neuron) whereas nonnociceptive myelinated A fibers project to deeper laminae. The second-order projection neuron is of wide dynamic range (WDR) type, that is, it receives direct synaptic input from nociceptive terminals and also multisynaptic input from myelinated A fibers (nonnoxions information, blue neuron system). γ-aminobutyric acid (GABA)-releasing interneurons (green neuron) normally exert inhibitory synaptic input on the WDR neuron. Furthermore, descending modulatory systems synapse at the WDR neuron (green descending terminal). Spinal cord glia cells (gray cell) also communicate with WDR neuron. (b) Peripheral changes at primary afferent neurons after partial nerve lesion leading to peripheral sensitization. Some axons are damaged and degenerate (upper two axons), whereas others (lower two axons) are still intact and connected with the peripheral end organ (skin). The lesion triggers the expression of sodium channels on damaged neurons. Furthermore, products such as nerve growth factor, which are associated with Wallerian degeneration, are released in the vicinity of spared fibers (arrows), triggering channel and receptor expression (sodium channels, TRPV1 receptors, adrenoceptors) on uninjured fibers. (c) Spontaneous activity in C nociceptors induces secondary changes in the central sensory processing, leading to spinal cord hyperexcitability (central sensitization of second-order WDR neurons indicated by star in orange neuron). This causes input from mechanoreceptive A fibers (light touch and punctate stimuli; blue neuron system) to be perceived as pain (dynamic and punctate mechanical allodynia; '+' indicates gating at synapse via AMPA/KA (α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid and kainate) receptors). Several presynaptic (opioid receptors, calcium channels) and postsynaptic molecular structures (glutamate receptors, NA (adrenceptors), 5-HT (serotonin) receptors, GABA receptors, sodium channels) are involved in central sensitization. Inhibitory interneurons and descending modulatory control systems (green neurons) are dysfunctional after nerve lesions, leading to disinhibition or facilitation of spinal cord dorsal horn neurons and to further central sensitization. (d) Peripheral nerve injury activates spinal cord nonneural glia cells (gray cell), which further enhances excitability in WDR neurons by releasing cytokines and glutamate. Adapted from Baron, R. 2006. Mechanisms of disease: neuropathic pain – a clinical perspective. Nat. Clin. Pract. Neurol. 2, 95–106.

proteins at the membrane some of them only marginally expressed under physiological conditions. Vanilloid receptors (TRPV1) are located predominantly on nociceptive afferent fibers and can be activated by the ingredient of hot chilli pepper (capsaicin). Physiologically, this receptor senses noxious heat (>43 °C) (Catarina, M. J. *et al.*, 2000). Accordingly, TRPV1-deficient knockout (KO) mice have obvious deficits in chemical and thermal heat nociception but normal reactions to noxious mechanical and to noxious cold stimuli.

After partial nerve injury and in streptozotocin-induced diabetic rats the lesion triggers a TRPV1 downregulation on many damaged afferents but a novel expression of TRPV1 on uninjured C and A fibers (Figure 2(b)) (Hudson, L. J. *et al.*, 2001; Hong, S. and Wiley, J. W., 2005) which is likely involved in the development C nociceptor sensitization and the associated symptom of heat hyperalgesia. Recent studies also provides evidence for a an upregulation of TRPV1 in medium and large injured dorsal root ganglion cells (Ma, W. *et al.*, 2005). However, TRPV1 does not appear to be the only transduction mechanism for heat sensitization after nerve injury. After partial sciatic nerve ligation, wild-type and TRPV1-null mice exhibited comparable persistent enhancement of mechanical and thermal nociceptive responses (Catarina, M. J. *et al.*, 2000). In this context, a recent study examined strain differences in the normal sensitivity to noxious heat in mice. These differences reflect differential responsiveness of primary afferent thermal nociceptors to heat stimuli due to a genetic variance in CGRP expression and sensitivity (Mogil, J. S. *et al.*, 2005).

In taxol-induced small-fiber painful polyneuropathy TRPV4 which is normally activated by heat of more than 30 °C seems to play a crucial role in producing taxol-induced mechanical hyperalgesia (Alessandri-Haber, N. *et al.*, 2004).

Investigations into temperature-sensitive excitatory ion channels also identified several cold-sensing ion channels in peripheral neurons. The cold- and menthol-sensitive TRP channel (TRPM8) is activated within the range of 8–28 °C (Patapoutian, A. *et al.*, 2003) and sensitized by menthol. This receptor is expressed in around 10% of all afferent ganglion neurons of rats, primarily within small-diameter cells (McKemy, D. D. *et al.*, 2002). TRPA1 is activated at lower temperatures and its exogenous ligand is cinnamaldehyde, a constituent of cinnamon oil, mustard oil, and horseradish. Peripheral nerve lesions have been shown to upregulate the expression of the latter cold-sensing ion channels in DRG cells of rats that developed cold allodynia (Obata, K. *et al.*, 2005). Therefore, upregulation or gating of these channels after injury may lead to the peripheral sensitization of cold-sensitive C nociceptors, resulting in the sensory phenomenon of cold hyperalgesia.

Besides these temperature-sensitive receptors experimental nerve injury also triggers the expression of functional α_1 or α_2 adrenoceptors on cutaneous afferent fibers, these neurons develop adrenergic sensitivity (Figure 2(b)). I.v. epinephrine or physiological noradrenaline release after stimulation of sympathetic efferents that have regenerated into the neuroma can excite afferent nociceptors. After section and reanastomosis of peripheral nerves, electrical stimulation of the sympathetic trunk at physiological stimulus frequencies activates regenerated C nociceptors through an α_1 adrenoceptor mechanism (Habler, H. J. *et al.*, 1987). Furthermore, sympathetic activity can sensitize identified intact nociceptors following damage to the nerve in which they run via an α_2 adrenoceptor mechanism (Sato, J. and Perl, E. R., 1991). The concept of a pathological coupling between sympathetic postganglionic fibers and afferent neurons via noradrenaline forms the conceptual framework for the therapeutic application of sympathetic blocks in certain pain syndromes, e.g., CRPS (Price, D. D. *et al.*, 1998; Baron, R. *et al.*, 1999b).

There is increasing evidence that also uninjured fibers running in a partially lesioned nerve may take part in pain signaling (Wasner, G. *et al.*, 2005). Uninjured fibers comingle with degenerating fibers in the same nerves. Products associated with Wallerian degeneration released in the vicinity of spared fibers (e.g., nerve growth factor (NGF)) may be the trigger for channel and receptor expression and may alter the properties of uninjured afferents (Hudson, L. J. *et al.*, 2001; Wu, G. *et al.*, 2001). Expression of sodium channels, TRPV1 receptors, adrenoreceptors and an increase of TNF-α sensitivity has been shown to play a role in uninjured fibers adjacent to lesioned axons.

5.57.5.2 Central Sensitization

As a consequence of peripheral nociceptor hyperactivity also dramatic secondary changes in the spinal cord dorsal horn occur. Peripheral nerve injury leads to an increase in the general excitability of nociceptive and multireceptive spinal cord neurons (multiple synaptic input from C as well as A fibers, wide dynamic range neurons). This phenomenon is called central sensitization and is defined as an increased responsiveness of nociceptive neurons in the CNS to their normal afferent input. Central sensitization is manifested by at least three different modes:

1. increase of neuronal activity to noxious stimuli,
2. expansion of size of neuronal receptive fields, and
3. spread of spinal hyperexcitability to other segments.

Central sensitization is initiated and maintained by activity in pathologically sensitized C fibers, which sensitize second-order spinal cord dorsal horn neurons by releasing glutamate acting on *N*-methyl-D-aspartic acid (NMDA) receptors and the neuropeptide substance P. Furthermore, central neuronal voltage-gated N-calcium channels located at the presynaptic sites on terminals of primary afferent nociceptors are involved in central sensitization by facilitation of the release of glutamate and substance P. This channel is overexpressed after peripheral nerve lesion and in rats with streptozotocin-induced diabetes (Luo, Z. D. *et al.*, 2001). As a consequence of peripheral nerve lesion the dorsal horn neurons abnormally express $HNa_v1.3$ (Hains, B. C. *et al.*, 2004) also enhancing central sensitization. Several intracellular cascades contribute to central sensitization, in particular the mitogen-activated protein kinase (MAPK) system (Ji, R. R. and Woolf, C. J., 2001). If central sensitization is established, normally innocuous tactile stimuli become capable of activating spinal cord pain signalling neurons via Aδ and Aβ low-threshold mechanoreceptors (Tal, M. and Bennett, G. J., 1994). By this mechanism, light innocuous mechanical stimuli to the skin induces pain, i.e., punctuate and dynamic mechanical allodynia. Besides these dramatic changes in the spinal cord, sensitized neurons were also found in the thalamus and primary somatosensory cortex after partial peripheral nerve injury (Guilbaud, G. *et al.*, 1992).

There is increasing evidence that neuropathic pain is in part mediated by an interaction of non-neural spinal cord glia and nociceptive neurons (Figure 2(d)). In experimental pain states in animals, astrocytes and microglia are activated by neuronal signals including substance P, glutamate, and fractalkine (Wieseler-Frank, J. *et al.*, 2005). Activation of glia by these substances in turn leads to the release of mediators that then act on other glia and also on central nociceptive neurons. These include proinflammatory cytokines and most likely also other neuroexcitatory compounds like glutamate. By this interaction central sensitization is augmented. While traditional therapies for pathological pain have focused on neuronal targets, glia might be new therapeutic targets.

Some patients with neuropathic pain, in particular patients with CRPS characteristically report 'extraterritorial' and/or 'mirror-' image pain. The pain is experienced not only in the area of trauma but also in neighboring healthy tissues. In cases of mirror-image pain, the pain is perceived from the healthy, corresponding part on the opposite side of the body. New data suggest that communication of activated astrocytes via gap junctions may mediate such spread of pain.

5.57.5.3 Central Disinhibition and Fascilitation

Physiologically dorsal horn neurons receive a strong intraspinal inhibitory control by gamma-aminobutyric acid (GABA)-ergic interneurons. Partial peripheral nerve injury may promote a selective apoptotic loss of these GABA-ergic inhibitory neurons in the superficial dorsal horn of the spinal cord (Moore, K. A. *et al.*, 2002), a mechanism which would further increases central sensitization. Furthermore, there is a novel mechanism of disinhibition following peripheral nerve injury. This mechanism involves a trans-synaptic reduction in the expression of the potassium chloride exporter KCC2 in lamina I nociceptive neurons. This induces a consequent disruption of the anion homeostasis in these dorsal horn neurons. The resulting shift in the transmembrane anion gradient caused normally inhibitory anionic synaptic currents to be excitatory. Due to this mechanism the release of GABA from normally inhibitory interneurons now exerts an excitatory action on lamina I neurons via $GABA_A$ receptors (Coull, J. A. *et al.*, 2003). The changes in lamina I neurons is induced by brain-derived neurotrophic factor (BDNF) released from activated spinal cord glia (Coull, J. A. *et al.*, 2005).

Dorsal horn neurons receive a powerful descending modulating control from supraspinal brainstem centers (inhibitory as well as faciliatory) (Vanegas, H. and Schaible, H. G., 2004) (Figures 2(a) and 2(c)). It was hypothesized that a loss of function in descending inhibitory serotonergic and noradrenergic pathway contributes to central sensitization and pain chronicity. This idea nicely explained the efficacy of serotonin and noradrenaline reuptake blocking antidepressants in neuropathic pain. However, in animals, mechanical allodynia after peripheral nerve injury was dependent upon tonic activation of descending pathways that facilitate pain transmission indicating that structures in the mesencephalic reticular formation – possibly the nucleus cuneiformis (NCF) and the periaqueductal gray (PAG) – are involved in central sensitization in neuropathic pain (Ossipov, M. H. *et al.*, 2000). Interestingly, exactly the same brainstem structures were shown to be active in humans with allodynia using advanced functional MRI (fMRI) techniques

(Zambreanu, L. *et al.*, 2005). Because in most animal pain models descending facilitation and inhibition are triggered simultaneously, it will be important to elucidate why inhibition predominates in some neuronal pools and facilitation in others.

5.57.5.4 Inflammation and Neuropathic Pain

The connective tissue sheath of peripheral nerves is innervated by sensory fibers, the nervi nervorum, which enter the sheath with the nutrient blood vessels. Some of these fine diameter primary afferents are nociceptors (Zochodne, D. W., 1993). Nervi nervorum are a potential source of pain in diseases of peripheral nerve especially in those conditions with an inflammatory component.

A different mechanism involves the production of inflammatory mediators at the site of nerve injury (local inflammation) that might be a critical factor in the cascade of events leading to neuropathic pain. Activated macrophages infiltrating from endoneurial blood vessels have been demonstrated in experimentally injured nerves (Sommer, C. and Myers, R. R., 1996) and also the dorsal root ganglia after nerve transection (Lu, X. and Richardson, P. M., 1993). Proinflammatory cytokines and in particular TNF-α released by activated macrophages can induce ectopic activity in injured but also in adjacent uninjured primary afferent nociceptors at the lesion site (Sorkin, L. S. *et al.*, 1997) and thus is a potential cause of pain and hyperalgesia (Sommer, C. *et al.*, 1998; Wagner, R. *et al.*, 1998; Sommer, C., 2003; Marchand, F. *et al.*, 2005).

5.57.6 Pathophysiological Mechanisms in Patients in Relation to Their Somatosensory Profile

Although we have achieved enormous progress in the understanding of pathophysiological mechanisms generating neuropathic pain the most important question is whether it is possible to translate these concepts into the clinical situation. In the following section the findings of the correlation of mechanisms and somatosensory abnormalities in animal experiments will be matched by observations in human experimental and clinical pain conditions.

In order to get more insight into the puzzle of neuropathic pain and even solve the therapeutic dilemma this type of translational research should be fostered in the future. The solution of the problem neuropathic pain can only be unraveled in the human experiment, that is, in patients that really feel all components of this complex sensation of neuropathic pain.

5.57.6.1 Peripheral Sensitization of Primary Afferent Neurons in Patients

Microneurographic single-fiber recordings support the idea of peripheral sensitzation of primary afferent neurons in patients with painful nerve lesions by demonstrating abnormal activity and reduced thresholds in cutaneous afferents. Abnormal ectopic activity of myelinated mechanosensitive fibers were found in traumatic nerve lesions, entrapment neuropathies, or radiculopathies (Figure 3). Because the ectopic nerve activity correlated in intensity and time course to the perceived paresthesias it is likely that pathological activity in A fibers is the underlying mechanism of positive nonpainful sensations.

Recordings from transected nerves in awake human amputees with phantom limb pain have demonstrated spontaneous ectopic activity as well as barrages of action potential firing in afferent A and C fibers projecting into the neuroma (Nystrom, B. and Hagbarth, K. E., 1981). Ectopic excitation occurred at multiple sites in damaged sensory neurons. Ongoing activity and mechanical sensitivity were recorded proximal to the nerve neuroma. Following local anesthetic blockade of the nerve distal to the recording site, impulses evoked by mechanical stimulation of the neuroma were abolished, but ongoing activity at the recording site continued, suggesting that this residual activity arose from the DRGs. As these patients suffered from spontaneous burning pain and electric shock-like sensations it is very likely that these symptoms are associated with ectopic firing in primary afferent C fibers.

In few patients with characteristic burning pain and heat hyperalgesia microneurographic recordings have provided evidence for sensitized C nociceptors. In patients with erythromelalgia nociceptors displayed ongoing activity, which is normally not observed in nociceptors, and there was a sensitization of mechanically insensitive afferents to nonpainful tactile stimuli. These abnormalities were only present in nociceptive fibers, but not of the sympathetic unmyelinated fibers, as an indicator of a neuropathic process (Figure 4) (Orstavik, K. *et al.*, 2003). In the

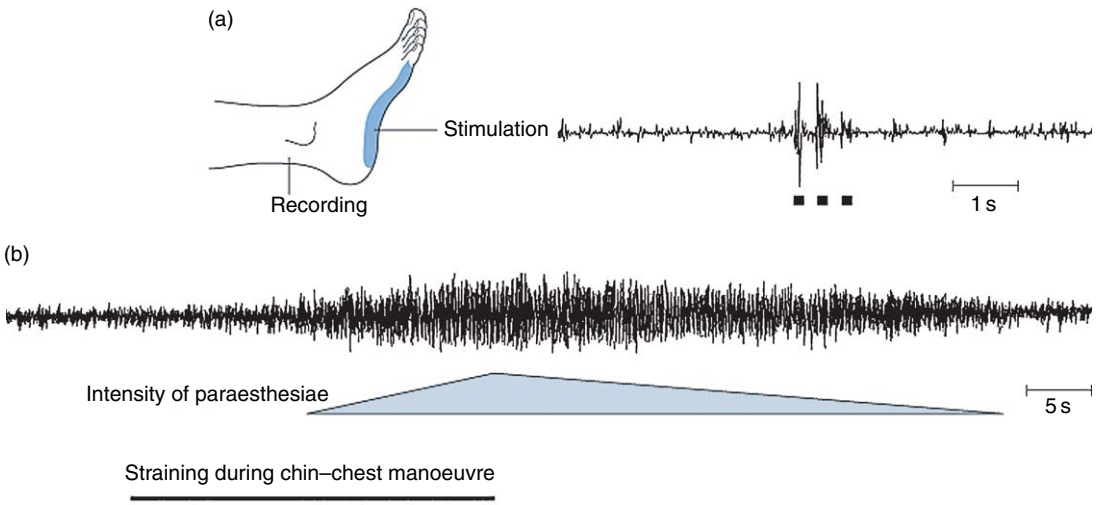

Figure 3 Microneurographic multiunit recording from the sural nerve in a patient with a compression of the S1 spinal root by a herniated disc. (a) Excitation of mechanosensitive units in the receptive field by tactile stimulation (bars). (b) Straining and chin–chest maneuver-provoked paresthesiae and an ectopic discharge of afferent fibers originating from the compressed root. Adapted from Nordin, M., Nyström, B., Wallin, U., and Hagbarth, K. E. 1984. Ectopic sensory discharges and paresthesiae in patients with disorders of peripheral nerve, dorsal roots and dorsal columns. Pain 20, 231–245. Elsevier Ltd.

autosomal dominantly inherited form of erythromelalgia a mutation in SCN9A was found, a gene that encodes the $Na_v1.7$ sodium channel, leading to an altered firing pattern in afferent neurons (Dib-Hajj, S. D. *et al.*, 2005). Hence, erythromelalgia is the first channelopathy associated with chronic pain.

Several clinical observations also support the concept of sensitized nociceptors in PHN patients. About 30% of patients with PHN do not show any loss of sensory function in the affected extremity indicating that in these particular group of patients loss of neurons is minimal or absent. Accordingly, thermal sensory thresholds in their region of greatest pain are either normal or even decreased (heat hyperalgesia) by up to 2–4 °C (Rowbotham, M. C. and Fields H. L., 1996; Pappagallo, M. *et al.*, 2000). The decrease of heat pain perception thresholds is a well-known phenomenon of peripheral nociceptor sensitization. Using skin punch biopsy, it was shown that thermal sensitivity is directly correlated with density of cutaneous innervation in the area of most severe pain (Rowbotham, M. C. *et al.*, 1996). Moreover, in PHN patients with heat hyperalgesia acute topical application of the vanilloid compound capsaicin (TRPV1 agonist), enhances pain, a sign that is indicative of an increased capsaicin sensitivity of nociceptors in the affected skin area and has been attributed to a sensitization of nociceptors as the driving element in some patients (Petersen, K. L. *et al.*, 2000). Furthermore, in a similar group of PHN patients cutaneous iontophoresis of histamine evoked a burning pain sensation whereas only itch was elicited in normal skin. Again, this phenomenon indicates that nociceptive neurons in the affected skin are abnormally sensitive to histamine (Baron, R. *et al.*, 2001) probably due to expression of a novel receptor pattern.

These observations suggest that spontaneous burning pain and heat hyperalgesia at least in part are associated with sensitization of primary afferent C fibers to TRPV1 agonists and histamine or with an altered firing pattern in these fibers due to abnormal sodium channels.

Cutaneous hypersensitivity to cold, i.e., cold hyperalgesia, is particularly prominent in patients with posttraumatic neuralgias, some small-fiber polyneuropathies and chronic CRPS. Another condition of acute cold intolerance occurs after systemic injection of the cancer chemotherapeutic agent oxaliplatin, which is associated with paresthesiae and painful hypersensitivity aggravated by cold. Psychophysical studies of human volunteers using the topical menthol model suggest that sensitization of cold-sensitive nociceptors can produce cold hyperalgesia in normal volunteers (Wasner, G. *et al.*, 2004). Peripheral sensitization also appears to occur in acute oxaliplatin-induced peripheral neuropathy (Lehky, T. J. *et al.*, 2004). Therefore, it is likely that cold hyperalgesia in some patients is induced by sensitization of primary afferent cold-sensitive nociceptors.

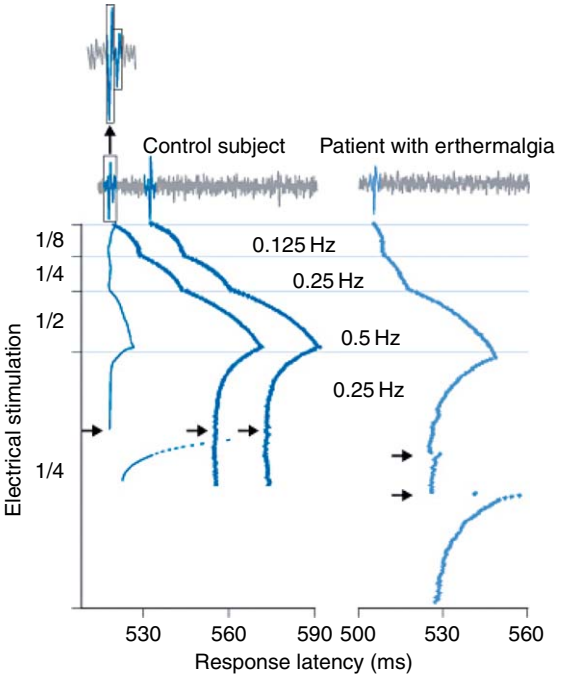

Figure 4 Microneurographic C fiber recordings from the peroneal nerve of a normal volunteer (left) and a patient suffering from erythromelalgia (right). The first trace shows the original nerve signal. The subsequent recordings are a falling leaf display in which each action potential is symbolized by a series of dots. Each row of dots represents the latency, at different electrical stimulation frequencies of the fiber, of its receptive field in the skin. Simultaneous recording of three afferent C fibers in a control subject shows two units with activity-dependent latency increases at low-frequency stimulation, and one unit that displays latency increases when excitation frequency increases to 1 impulse per 2 s. These biophysical features are characteristic for mechanically insensitive and mechanically sensitive nociceptive C fibers, respectively. Stimulation of the receptive field with a 750-mN von Frey hair (arrow) excited only the mechanosensitive C nociceptor, as evidenced by a strong latency shift to electrical stimulation. Mechanically insensitive afferents are not activated by this stimulus. The right panel shows a C fiber recording from a patient with erythromelalgia. The unit had the biophysical properties of a mechanically insensitive C fiber but responded reproducibly to mechanical stimulation (arrows). This is consistent with the hypothesis that mechanically insensitive afferents become sensitized in erythromelalgia. An alternative explanation would be that mechanically sensitive nociceptors start to display a different pattern of activity-dependent latency slowing in this disease. Adapted from Orstavik, K., Weidner, C., Schmidt, R., Schmelz, M., Hilliges, M., Jorum, E., Handwerker, H. and Torebjork, E. 2003. Pathological C-fibres in patients with a chronic painful condition. Brain 126, 567–578. Copyright 2003 Oxford University Press.

5.57.6.2 Sensitization to Catecholamines in Patients

Several clinical observations support the idea that nociceptors acquire a sensitivity to catecholamines that permits an abnormal excitation by either noradrenaline or by circulating catecholamines. This chemical sensitization makes the nociceptors susceptible for noradrenaline released from efferent sympathetic fibers in the periphery. The consecutive pathological sympathetic–afferent coupling forms the conceptual framework for sympathetically maintained pain states.

Noradrenergic sensitivity has been described in several human neuropathies and suggests that the ongoing pain can be caused or maintained by the sympathetic nervous system in selected patients: In amputees, perineuromal administration of physiological doses of norepinephrine induces intense pain as compared with saline injections (Raja, S. N. *et al.*, 1998). Intraoperative stimulation of the sympathetic chain induces an increase of spontaneous pain in patients with causalgia (CRPS II) but not in patients with hyperhidrosis. In PHN, application of norepinephrine into a symptomatic skin area increased spontaneous pain and dynamic mechanical hyperalgesia (Choi, B. and Rowbotham, M. C., 1997). In CRPS II and posttraumatic neuralgias, intracutaneous norepinephrine rekindles pain and hyperalgesia that had been relieved by sympathetic blockade. Also intradermal norepenephrine, in physiologically relevant doses, was demonstrated to evoke greater pain in the affected regions of patients with sympathetically maintained pain (SMP) than in the contralateral unaffected limb, and in control subjects (Ali, Z. *et al.*, 2000). Because noradrenaline-induced pain occurs during a differential blockade of myelinated fibers, unmyelinated fibers appear to signal sympathetically maintained pain (Torebjork, E. *et al.*, 1995).

We performed a study in patients with CRPS I using physiological stimuli of the sympathetic nervous system (Baron, R. *et al.*, 2002). Cutaneous sympathetic vasoconstrictor outflow to the painful extremity was experimentally activated to the highest possible physiological degree by whole body cooling. During the thermal challenge the affected extremity was clamped to 35 °C in order to avoid thermal effects at the nociceptor level. The intensity as well as area of spontaneous pain and mechanical allodynia (dynamic and punctate) increased significantly in patients that had been classified as having SMP by positive sympathetic blocks but not in SIP

patients (Figure 5). The experimental setup used in the latter study selectively alters sympathetic cutaneous vasoconstrictor activity without influencing other sympathetic systems innervating the extremities, i.e., piloarrector, sudomotor, and muscle vasoconstrictor neurons. Therefore, the interaction of sympathetic and afferent neurons measured here is likely to be located within the skin as

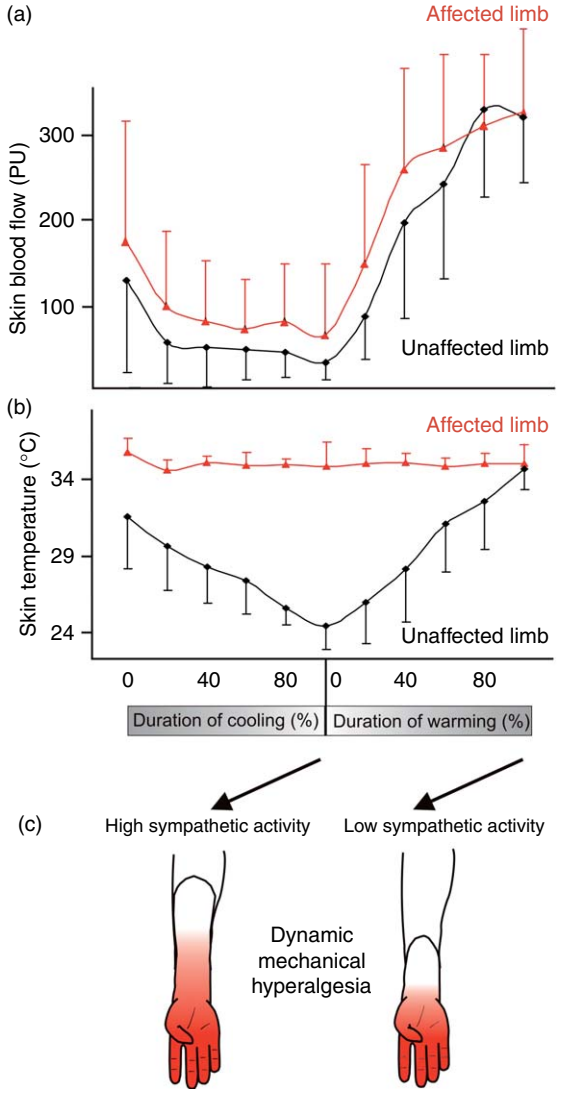

Figure 5 Experimental modulation of cutaneous sympathetic vasoconstrictor neurons by physiological thermoregulatory reflex stimuli in 13 complex regional pain syndrome (CRPS) patients. With the help of a thermal suit, whole-body cooling and warming was performed to alter sympathetic skin nerve activity. The subjects were lying in a suit supplied by tubes, in which running water of 12 °C and 50 °C, respectively (inflow temperature) was used to cool or warm the whole body. By these means sympathetic activity can be switched on and off. (a) High sympathetic vasoconstrictor activity during cooling induces considerable drop in skin blood flow on the affected and unaffected extremity (laser Doppler flowmetry). Measurements were taken at 5-min intervals (mean ± SD). (b) On the unaffected side, a secondary decrease of skin temperature was documented. On the affected side, the forearm temperature was clamped at 35 °C by a feedback-controlled heat lamp to exclude temperature effects on the sensory receptor level. Measurements were taken at 5-min intervals (mean ± SD). (c) Effect of cutaneous sympathetic vasoconstrictor activity on dynamic mechanical hyperalgesia in one CRPS patient with sympathetically maintained pain (SMP). Activation of sympathetic neurons (during cooling) leads to a considerable increase of the area of dynamic mechanical hyperalgesia. From Baron, R., Schattschneider, J., Binder, A., Siebrecht, D. and Wasner, G. 2002. Relation between sympathetic vasoconstrictor activity and pain and hyperalgesia in complex regional pain syndromes: a case–control study. Lancet 359, 1655–1660, with permission.

predicted by the pain-enhancing effect of intracutaneous norepinephrine injections (Ali, Z. *et al.*, 2000). Interestingly, the relief of spontaneous pain after sympathetic blockade was more pronounced than changes in spontaneous pain that could be induced experimentally by sympathetic activation. One explanation for this discrepancy might be that a complete sympathetic block affects all sympathetic outflow channels projecting to the affected extremity. It is very likely that in addition to a coupling in the skin, a sympathetic–afferent interaction may also occur in other tissues, in particular in the deep somatic domain such as bone, muscle, or joints. Supporting this view, especially these structures are extremely painful in some cases with CRPS (Baron, R. and Wasner, G., 2001). Furthermore, there may be patients who are characterized by a selective or predominant sympathetic–afferent interaction in deep somatic tissues sparing the skin (Wasner, G. *et al.*, 1999). In summary, it is likely that sympathetically maintained pain is a consequence of an adrenergic sensitization of C nociceptors.

5.57.6.3 Central Sensitization in Patients

One hallmark of central sensitization of spinal cord neurons in animals is that activity in A fiber mechanoreceptors is allowed to gain access to the nociceptive system and induces pain. These phenomena are called mechanical allodynia or hyperalgesia.

Mechanical hypersensitivity is a common phenomenon in neuropathic pain states in patients. There are several lines of evidence that also in patients central mechanisms contribute to these sensory phenomena. Two distinct types have been described in patients, dynamic mechanical and pinprick mechanical hypersensitivity.

There is consensus that dynamic mechanical allodynia is signaled out of the skin by afferent mechanoreceptors with large myelinated axons that normally encode nonpainful tactile stimuli:

1. Reaction time measurements show dynamic mechanical allodynia in patients to be signaled by afferents with conduction velocities appropriate for large myelinated axons (Lindblom, U. and Verrillo, R. T., 1979; Campbell, J. N. *et al.*, 1988),
2. transcutaneous or intraneural stimulation of nerves innervating the allodynic skin can evoke pain at stimulus intensities which only produce tactile sensations in healthy skin (Gracely, R. H. *et al.*, 1992; Price, D. D. *et al.*, 1992), and
3. using differential nerve blocks dynamic allodynia is abolished at time points when tactile sensations is lost, but other modalities remain unaffected (Campbell, J. N. *et al.*, 1988; Ochoa, J. L. and Yarnitsky, D., 1993).

Therefore, patients with dynamic mechanical allodynia would be expected to have central sensitization as their underlying mechanism.

Hyperalgesia to pinprick stimuli, typically elicited by probing of the skin with a stiff von Frey hair is distinct from dynamic mechanical allodynia because of its different spatial and temporal profile and the fact that it is signaled by nonsensitized, heat-insensitive, Aδ nociceptors.

Notably, in many neuropathic pain patients the mechanically sensitive skin area expands widely into the secondary zone, i.e., the area not affected by the primary nerve lesion, which is also indicative for CNS mechanisms involved. Furthermore, the area of secondary mechanical hypersensitivity is a dynamic phenomenon. In PHN patients with signs of peripheral nociceptor sensitization (heat hyperalgesia, see above) cutaneous capsaicin application into the primary skin area leads to an increase of the allodynic zone into previously nonallodynic and nonpainful skin that had normal sensory function and cutaneous innervation. These observations support the hypothesis that allodynia in a subgroup of PHN patients is a form of chronic secondary hyperalgesia dynamically maintained by input from intact and possibly sensitized ('irritable') primary afferent nociceptors to a sensitized CNS (Fields, H. L. *et al.*, 1998; Petersen, K. L. *et al.*, 2000). Because central sensitization involves the NMDA receptor, the fact that the NMDA receptor antagonist ketamine relieves some neuropathic pain disorders further supports the concept of central sensitization.

Besides these dramatic changes in the spinal cord, there is now evidence that higher centers of the neuraxis demonstrate an increased excitability as well as fundamental changes in the somatosensory representation. Magnetic encephalography (MEG), positron emission tomography (PET), and fMRI studies revealed cortical changes in patients with phantom limb pain, CRPS, and central pain syndromes (Flor, H. *et al.*, 1995; Willoch, F. *et al.*, 2000; Pleger, B. *et al.*, 2004; Willoch, F. *et al.*, 2004; Maihofner, C. *et al.*, 2005a) as well as experimental pain models (Baron, R. *et al.*, 1999a; Baron, R. *et al.*,

2000). Interestingly, these changes correlated with the intensity of the perceived pain and disappeared after successful treatment of the pain (Maihofner, C. *et al.*, 2004; Pleger, B. *et al.*, 2005).

5.57.6.4 Central Disinhibition Leading to Cold Hyperalgesia

Cutaneous hypersensitivity to cold, i.e., cold hyperalgesia is particularly prominent in patients with posttraumatic neuralgias, some polyneuropathies, and chronic CRPS. Some observations in neuropathic pain patients point to central disinhibition as the underlying mechanism in a subgroup of patients.

Cold stimuli are usually transmitted centrally by cold-sensitive Aδ fibers, whereas cold pain is conveyed via nociceptive cold-sensitive C fibers. In patients with polyneuropathies a disproportionate loss of Aδ axons and relative sparing of C fibers have been described (Ochoa, J. L. and Yarnitsky, D., 1994). These patients suffer from the so-called triple cold syndrome (CCC syndrome): cold hypoesthesia in combination with cold hyperalgesia and a cold skin. A selective damage of cold-sensitive Aδ fibers leads to a lack of inhibition (disinhibition) on C nociceptors transmission normally exerted by concomitant activation of myelinated cold Aδ fibers. This mechanism of a central interaction between cold specific afferents and nociceptors would nicely explain the combination of cold hyperalgesia and cold hypoesthesia in the above patients. Furthermore, it is suggested to play a crucial role in central pain syndromes after infarction of the dorsolateral thalamus with cold hyperalgesia and paradoxical heat sensation. In these patients the lesion in the lateral thalamus might disinhibit the nociceptive system projecting through the medial thalamus.

Recently, direct evidence was provided for the central disinhibhition theory of cold hyperalgesia in an experimental pain model in humans. Selective A fiber block induces the symptom combination of cold hyperalgesia and cold hypoesthesia and therefore mimics the situation in polyneuropathy patients with A fiber degeneration. With fMRI the disinhibition of the medial nociceptive system (medial thalamus, anterior cingulate cortex (ACC), and frontal cortices) could be demonstrated.

Thus, a loss of peripheral A fiber function disinhibits the nociceptive system centrally leading to cold hyperalgesia.

This is an entirely different mechanism as compared with the peripheral sensitization process of cold-sensitive C nociceptors described above leading to the same somatosensory phenomenon, cold hyperalgesia.

5.57.6.5 Deafferentation: Hyperactivity of Central Pain Transmission Neurons

The above data convincingly support a role for sensitization mechanisms in the peripheral as well as the CNS in the generation of neuropathic pain. However, in some patients there is a profound cutaneous deafferentation of the painful area. Up to 60% of PHN patients show considerable signs of neuronal degeneration and loss of sensory function within the affected tissues. Interestingly, some of these patients still suffer from severe dynamic mechanical allodynia although the function of nociceptors is diminished or absent in the same skin area (Wasner, G. *et al.*, 2005).

Punch skin biopsies and the anti-PGP 9.5 antibody, a panaxonal marker, were used in PHN patients and zoster patients without pain to quantify sensory nerve endings in the affected skin and compared the numbers with the homologous contralateral site (Rowbotham, M. C. et al., 1996; Oaklander, A.L., 1998; Oaklander, A.L., 2001). A severe loss could be demonstated on the affected side (20% as compared with the controls). Neurite loss was more prominent in the epidermis than in the dermis. Furthermore, the PHN group also had lost half of the neurites in the contralateral epidermis whereas distant areas where unaffected. However, these contralateral changes could not be observed with QST or axon reflex measurements (Baron, R. and Saguer, M., 1994).

Functional studies support the concept of degeneration of cutaneous C nociceptors. By using these C fiber axon reflex reactions it is possible to objectively assess cutaneous C fiber function in the human skin. In some patients the histamine evoked axon reflex vasodilatation and flare size were impaired or abolished in skin regions with intense dynamic allodynia (Baron, R. and Saguer, M., 1993). Similarly, during capsaicin stimulation, a subgroup did not experience worsening of pain (Petersen, K. L. *et al.*, 2000). Using quantitative sensory testing (QST) some chronic PHN patients have extremely high thermal thresholds in areas with marked dynamic allodynia (Nurmikko, T. and Bowsher, D., 1990; Nurmikko, T. *et al.*, 1994; Choi, B. and Rowbotham, M. C.,

1997). Thus, there is a subset of PHN patients with pain and loss of cutaneous C nociceptor function.

Assuming that the DRG cells and the central afferent connections are lost in such patients, their pain must be the result of intrinsic CNS changes. In animal studies, following complete primary afferent loss of a spinal segment, many dorsal horn cells begin to fire spontaneously at high frequencies (Lombard, M. C. and Larabi, Y., 1983; Fields, H. L. *et al.*, 1998). There is some evidence that a similar process may underlie the pain that follows extensive denervating injuries in human. Recordings of spinal neuron activity in a pain patient whose dorsal roots were injured by trauma to the cauda equina revealed high-frequency regular and paroxysmal bursting discharges (Loeser, J. D. *et al.*, 1967). That patient complained of spontaneous burning pain in a skin region that was anesthetic by the lesion (anesthesia dolorosa). Thus, extensive degeneration of primary afferents associated with severe somatosensory deficits points to an increased excitability of deafferented central neurons as underlying mechanism.

5.57.6.6 Inflammation in Patients

In patients with inflammatory demyelinating neuropathies such as acute Guillain–Barré syndrome or vasculitic neuropathies deep proximal aching pain in addition to paroxysmal types of pains is a characteristic phenomenon. Accordingly, COX2 was found to be upregulated in nerve biopsy specimens from patients with chronic inflammatory demyelinating neuropathy and an increased expression of proinflammatory cytokines have been demonstrated in peripheral nerves of most vasculitic neuropathies (Lindenlaub, T. and Sommer, C., 2003). About 15–50% of AIDS patients suffer from distal predominantly sensory neuropathy, which very often is painful. In sarcoidosis, painful small-fiber neuropathy may be present in a subgroup of patients. In the fluid of artificially produced skin blisters significantly higher levels of IL-6 and TNF-α were observed in CRPS-affected extremities as compared with the uninvolved extremity. In CRPS patients with hyperalgesia higher levels of the soluble TNF-α receptor type I were found (Maihofner, C., *et al.*, 2005b). Accordingly, a significant increases in IL-1β and IL-6, but not TNF-α was demonstrated in the CSF of individuals afflicted with CRPS as compared with controls (Alexander, G. M. *et al.*, 2005).

Acute zoster is accompanied by intense inflammation along the affected peripheral nerve that typically resolves in several weeks. However, a small subgroup of patients with PHN has inflammatory infiltrates throughout the affected peripheral nerve, DRG, and dorsal root (Watson, C. P. *et al.*, 1991). Moreover, Gilden D. H. *et al.* (1991) have described a subpopulation of PHN patients with evidence of continuing low-level viral expression whose pain responds to antiviral agents. Thus continuing VZV expression could produce sensitization and activity in primary afferents secondary to inflammation.

5.57.7 Diagnostic Tools for Neuropathic Pain

Modern research into the mechanisms of neuropathic pain clearly revealed that the nerve lesion leads to dramatic changes in the PNS and CNS that makes it distinct from other chronic pain types in which the nociceptive system is intact (chronic nociceptive pain, e.g., osteoarthritis). Furthermore, neuropathic pain states require different therapeutic approaches, e.g., anticonvulsants, that are not effective in nociceptive pain. To make the situation even more complex, many chronic pain states are characterized by a combination of both the pain types. Best examples for the so-called mixed pain syndromes are chronic radicular back pain, tumor pain, or CRPS.

For the clinician, it is, therefore, of utmost importance to have valid diagnostic tools that differentiate neuropathic from nociceptive pain or estimate the neuropathic pain component in mixed pain syndromes.

The easiest approach to this would be to use somatosensory symptoms assessed by questionnaires or history questions or simple signs testable at the bedside that are characteristic for neuropathic pain.

However, a recent study on this issue raised several caveats (Rasmussen, P. V. *et al.*, 2004): This study prospectively looked at symptoms and signs in 214 patients with suspected chronic neuropathic pain that were *a priori* classified by pain experts as having the so-called definite, possible or unlikely neuropathic pain. Pain symptoms including pain descriptors were recorded and sensory tests including repetitive pinprick stimulation, examination for cold-evoked pain by an acetone drop and brush-evoked pain were carried out in the maximal pain area and in a control area in order to determine if symptoms and signs cluster differentially in groups of patients with increasing evidence of neuropathic pain. Several symptoms (touch- or cold-provoked pain) and signs

(brush-evoked allodynia) were more prominent in patients with definite or possible neuropathic pain; however, there was considerable overlap with the clinical presentation of patients with unlikely neuropathic pain. Even worse, the used pain descriptors could not at all distinguish between the three clinical categories.

5.57.7.1 Questionnaires

Other approaches to find easy screening tools for neuropathic pain gave more promising results: a clinician-administered 10-item questionnaire (DN4) consists of sensory descriptors (seven items) as well as signs related to bedside sensory examination (three items) (Bouhassira, D. *et al.*, 2004). The interview questions address the quality of the pain (burning, painful cold, and electric shocks) and associated symptoms (tingling, pins and needles, numbness, and itching). The examination consists of the assessment of hypoesthesia to touch, prick and allodynia to brush. This questionnaire was validated in a prospective study of 160 patients presenting with pain of nociceptive and neuropathic origin and showed 86.0% of correctly identified patients (sensitivity 82.9%, specificity 89.9%).

A different approach to distinguish neuropathic from nonneuropathic pain uses a patient-based questionnaire with nine questions without the need of examinations by the physician (PainDetect) (Freynhagen, R. *et al.*, 2006). The questionnaire consists of slightly different sensory descriptors (seven items, burning pain, tingling or prickling (electricity), sensitivity to touch (clothes, blanket), pain caused by light pressure (e.g., with finger), shooting pain or electric shock-like pain, occasional painful cold or heat (e.g., bath tub), and numbness), the question whether the pain is spatially radiating and a questions addressing the individual pain pattern. In the latter, the patients have to choose one of four graphically illustrated pain patters (permanent pain with a light variability, stable permanent pain with paroxysmal pain attacks, paroxysmal pain attacks with no permanent pain, and pain attacks with fluctuating permanent pain in between). This questionnaire was validated in 392 patients recruited at 10 highly specialized pain centers with either pain of pure predominant neuropathic origin ($n = 167$, e.g., PHN, painful polyneuropathies, and nerve trauma) or pure or predominant nociceptive origin ($n = 225$, e.g., ostheoathritis, mechanical low back pain, and inflammatory arthropathies). Patients were diagnosed according to the results of two independent pain specialists who determined the predominant pain type (neuropathic versus nociceptive) by means of clinical experience as well as neurological examination, electrophysiologic, or imaging techniques. This questionnaire showed a correct classification rate of 82.5% with a sensitivity of 80.8% and a specificity 84.7%.

5.57.7.2 Bedside Assessment of Neuropathic Pain

Patients with neuropathic pain demonstrate a variety of distinct sensory symptoms and signs that can coexist in combinations (see above). Therefore, the sensory bedside examination should include the following qualities: touch, pinprick, pressure, cold, heat, vibration, temporal summation, and after sensations (Bouhassira, D. *et al.*, 2004; Cruccu, G. *et al.*, 2004, definition in Table 6). To assess either a loss (negative) or a gain of somatosensory function (positive sensory signs) the responses can be graded as normal, decreased or increased. The stimulus-evoked (positive) pain types are classified as hyperalgesic or allodynic, and according to the dynamic or static character of the stimulus (Rasmussen, P. V. *et al.*, 2004).

Touch can be assessed by gently applying cotton wool to the skin, pinprick sensation by the response to sharp pinprick stimuli, deep pain by gentle pressure on muscle and joints, and cold and heat sensation by measuring the response to a thermal stimulus, for example, thermorollers kept at 20 or 45 °C. Cold sensation can also be assessed by the response to acetone spray. Vibration can be assessed by a tuning fork placed at strategic points (interphalangeal joints, etc.). Abnormal temporal summation is the clinical equivalent to increasing neuronal activity following repetitive C fiber stimulation >0.3 Hz. This windup-like pain can be produced by mechanical and thermal stimuli. After-sensations – the persistence of pain long after termination of a painful stimulus – is another characteristic feature of neuropathic pain, which is closely related to a coexistent dynamic or static hyperalgesia. When present, allodynia or hyperalgesia can be quantified by measuring intensity and area. At present, it is generally agreed that assessment should be carried out in the area of maximal pain using the contralateral area as control. However, contralateral segmental changes following a unilateral nerve or root lesion cannot be excluded, so an examination at mirror sites may not necessarily represent a true control site.

Table 6 Definition and assessment of negative and positive sensory symptoms or signs in neuropathic pain

Symptom/sign	*Definition*	*Assessment Bedside exam*	*Expected pathological response*
Negative signs and symptoms			
Hypoesthesia	Reduced sensation to nonpainful stimuli	Touch skin with painters brush, cotton swab, or gauze	Reduced perception, numbness
Pall hypoesthesia	Reduced sensation to vibration	Apply tuning fork on bone or joint	Reduced perception threshold
Hypoalgesia	Reduced sensation to painful stimuli	Prick skin with single pin stimulus	Reduced perception, numbness
Thermhypoesthesia	Reduced sensation to cold/warm stimuli	Contact skin with objects of 10 °C (metal roller, glass with water, coolants like acetone) Contact skin with objects of 45 °C (metal roller, glass with water)	Reduced perception
Spontaneous sensations/pain			
Paraesthesia	Nonpainful ongoing sensation (ant crawling)	Grade intensity (0–10) Area in cm^2	–
Paroxysmal pain	Shooting electrical attacks for seconds	Number per time Grade intensity (0–10) Threshold for evocation	–
Superficial pain	Painful ongoing sensation often of burning quality	Grade intensity (0–10) Area in cm^2	–
Evoked pain			
Mechanical dynamic allodynia	Normally nonpainful light moving stimuli on skin evoke pain	Stroking skin with painters brush, cotton swab, or gauze	Sharp burning superficial pain Present in the primary affected zone but spread beyond into unaffected skin areas (secondary zone)
Mechanical static allodynia	Normally nonpainful gentle static pressure stimuli at skin evoke pain	Manual gentle mechanical pressure at the skin	Dull pain Present in the area of affected (damaged or sensitized) primary afferent nerve endings (primary zone)
Mechanical punctuate, pinprick hyperalgesia	Normally not painful/slightly stinging stimuli evoke pain	Manual pricking the skin with a safety pin, sharp stick, or stiff von Frey hair	Sharp superficial pain Present in the primary affected zone but spread beyond into unaffected skin areas (secondary zone)
Temporal summation	Repetitive application of identical single noxious stimuli is perceived as increasing pain sensation (windup like pain)	Pricking skin with safety pin at interval <3 s for 30 s	Sharp superficial pain of increasing intensity
Cold allodynia hyperalgesia	Normally nonpainful/slightly painful cold stimuli evoke pain	Contact skin with objects of 20 °C (metal roller, glass with water, coolants like acetone) Control: contact skin with objects of skin temperature	Painful often burning temperature sensation Present in the area of affected (damaged or sensitized) primary afferent nerve endings (primary zone)
Heat allodynia hyperalgesia	Normally nonpainful/slightly painful heat stimuli evoke pain	Contact skin with objects of 40 °C (metal roller, glass with water)	Painful burning temperature sensation

(*Continued*)

Table 6 (Continued)

Symptom/sign	*Definition*	*Assessment Bedside exam*	*Expected pathological response*
		Control: contact skin with objects of skin temperature	Present in the area of affected (damaged or sensitized) primary afferent nerve endings (primary zone)
Mechanical deep somatic allodynia	Normally nonpainful pressure on deep somatic tissues evoke pain	Manual light pressure at joints or muscle	Deep pain at joints or muscles

It is important to realized the spatial distribution of abnormal sensations. In neuropathic conditions, the distinction between primary and secondary area corresponds to the tissue supplied by damaged nerves and the area outside this innervation territory. Mechanical hypersensitivity often expands into the secondary area.

In Table 6 several sensory signs that can be found in peripheral neuropathies are defined and the appropriate tests to assess these signs clinically are summarized.

5.57.7.3 Apparative Assessment of Somatosensory Phenotypes

It is important to realize that conventional electrophysiological techniques like NCS, SEP, etc., only assess the function of myelinated peripheral axonal systems, the affection of small fibers including nociceptors are missed. Similarly, SEP measures the conduction in the lemniscal system (dorsal columns) and not the spinothalamic tract, which conveys noxious information. Therefore, alternative diagnostic procedures have to be used to analyze nociceptive fibers and tracts in the peripheral or CNS, especially to diagnose small fiber neuropathies and central pain states that are associated with a isolated damage to central nociceptive systems.

A sophisticated neurophysiologic technique to test both systems in the PNS and the CNS is QST, which uses standardized mechanical and thermal stimuli (graded von Frey hairs, several pinprick stimuli, pressure algometers, quantitative thermotesting, etc.). Another advantage of QST is that it assesses a loss of function (minus signs) as well as a gain of function (positive signs). For example Allodynia or hyperalgesia, can be quantified by measuring intensity, threshold for elicitation, duration, and area.

A standardized protocol for QST was recently proposed by the nationwide German Network on Neuropathic Pain (Rolke R. *et al.*, 2006) including 13 parameters of sensory testing procedures for the analysis of the exact somatosensory phenotype of neuropathic pain patients (Figure 6). To evaluate plus or minus signs in patients, an age- and gender-matched database for absolute and relative QST reference data was established for healthy human subjects. Until now this nationwide multicenter trial comprises complete sensory profiles of 180 healthy human subjects and more than 1500 neuropathic pain patients of a variety of entities. Thermal detection and pain thresholds including a test for the presence of paradoxical heat sensations, mechanical detection thresholds to von Frey filaments and a 64-Hz tuning fork, mechanical pain thresholds to pinprick stimuli and blunt pressure, stimulus/response functions for pinprick and dynamic mechanical allodynia (pain to light touch), and pain summation (windup ratio) using repetitive pinprick stimulation are determined. Data of healthy human subjects were analyzed for the influence of body side and region, age, and gender. For most variables pathological values of positive and negative signs can be detected on the basis of reference data.

5.57.7.4 Skin Biopsies

The advent of skin biopsy as a diagnostic and investigative tool has changed the diagnostic picture in neuropathic pain; skin biopsies can be done at several sites to establish a spatial profile of nerve fiber involvement, and can be repeated over time. They have generally met good patient acceptance in neuropathies, and even in allodynic states like PHN. They can be used to assess epidermal nerve fibers, predominantly C fiber nociceptors, sympathetic fibers innervating the cutaneous sweat glands, and myelinated Aβ and Aδ fibers in the dermis.

Immunostaining of skin punch biopsies for the panaxonal marker protein gene product 9.5 (PGP9.5), a neuronal ubiquitin hydrolase is believed to identify axons of all categories of nerve fibers. In a

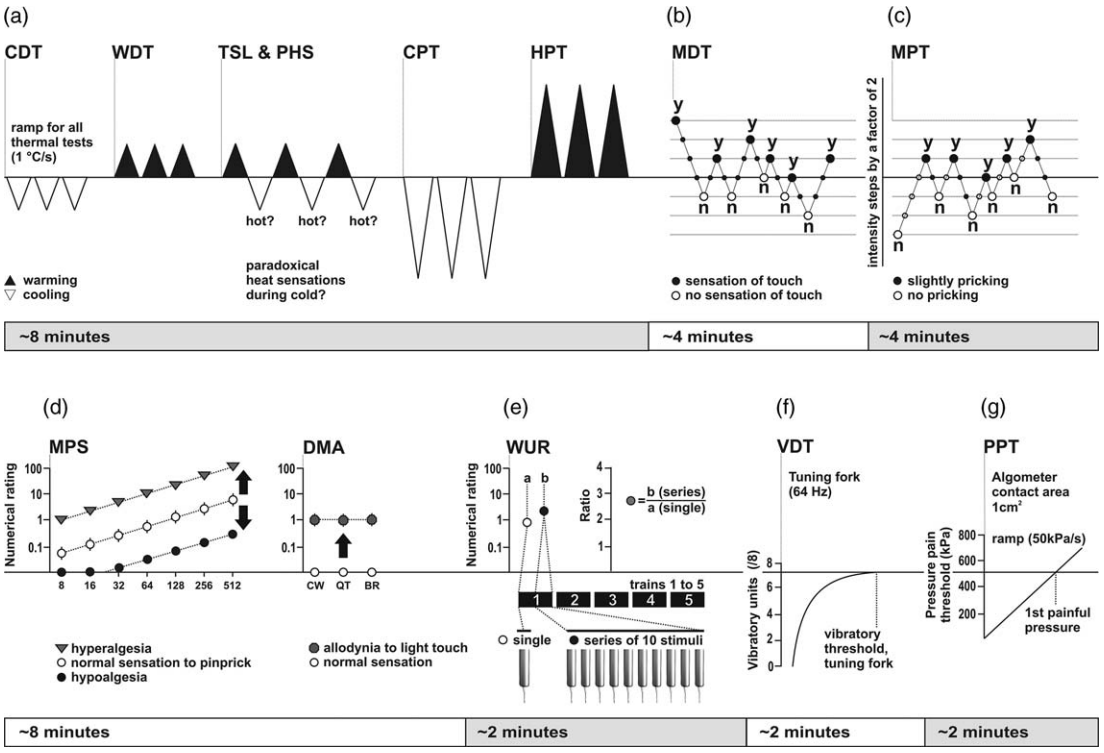

Figure 6 Quantitative sensory testing (QST) – a battery of sensory tests: figure of methods. The standardized QST protocol assesses 13 variables in seven test procedures (a–g). All procedures are presented including a time frame for testing over one area. (a) (thermal testing; CDT, cold detection threshold; WDT, warm detection threshold; TSL, thermal sensory limen for alternating warm and cold stimuli; PHS, number of paradoxical heat sensations during the TSL procedure; CPT, cold pain threshold; HPT, heat pain threshold) comprises detection and pain thresholds for cold, warm, or hot stimuli (C and Aδ fiber mediated). (b) (MDT, mechanical detection threshold) tests for Aβ fiber function using von Frey filaments. (c) (MPT, mechanical pain threshold) tests for Aδ-fiber-mediated hyper- or hypoalgesia to pinprick stimuli. (d) (stimulus/response functions: MPS for pinprick stimuli, and ALL for dynamic mechanical allodynia) assesses again Aδ-mediated sensitivity to sharp stimuli (pinprick), and also Aβ-fiber-mediated sensitivity to stroking light touch (CW, cotton wisp; QT, cotton wool tip; BR, brush). (e) (WUR, windup ratio) compares the verbal ratings within five trains of a single pinprick stimulus (*a*) with a series (*b*) of 10 repetitive pinprick stimuli to calculate WUR as the ratio: *b*/*a*. (f) (VDT, vibration detection threshold) tests again for Aβ fiber function using a Rydel–Seiffer 64-Hz tuning fork. (g) (PPT, pressure pain threshold) is the only test for deep pain sensitivity, most probably mediated by muscle C and Aδ fibers.

variety of neuropathies affecting small caliber nerve fibers, denervation has been documented to occur in a length-dependent manner. These include diabetes mellitus, HIV-associated sensory neuropathy (Polydefkis, M. *et al*., 2002), Fabry's disease (Scott, L. J. *et al*., 1999), restless legs syndrome, and idiopathic small-fiber sensory neuropathies (Holland, N. R. *et al*., 1997).

Punch skin biopsies have more recently been used as a serial measure, to examine changes in epidermal innervation over time, or after therapeutic interventions in various neuropathic conditions. For example, epidermal reinnervation occured concomitant with symptomatic improvement in sensory neuropathy (Nodera, H. *et al*., 2003), and impressive increases in epidermal, dermal, and sweat gland innervation densities have been documented with improvement in neuropathic status spontaneously or after therapies (Hart, A. M. *et al*., 2002).

Cutaneous innervation is usually reduced in PHN skin compared to mirror-image skin when assessed with PGP (Rowbotham, M. C. *et al*., 1996; Oaklander, A.L. *et al*., 1998; Petersen, K. L. *et al*., 2000) (Figure 7). However, a significant proportion of PHN subjects have similar fiber densities in both PHN and mirror-image skin, suggesting that the symptoms of pain and sensory dysfunction is not due to a mere loss in overall innervation density (Rowbotham, M. C. *et al*., 1996; Petersen, K. L. *et al*., 2000). Oaklander demonstrated that the average cutaneous fiber density was lower in subjects with established PHN than in those who had recovered without PHN after herpes zoster.

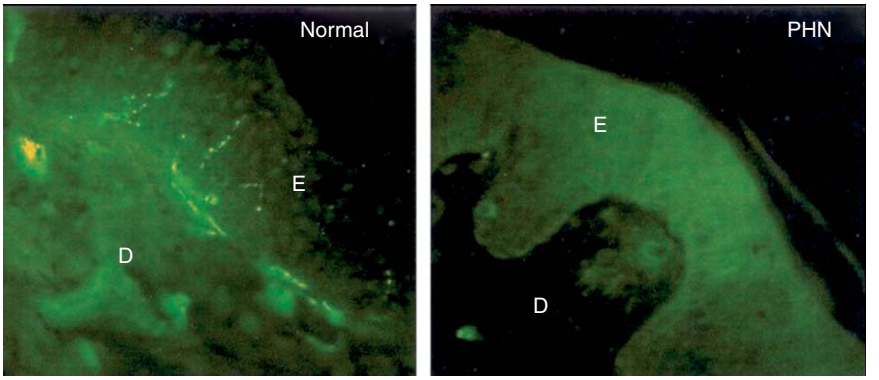

Figure 7 Representative skin biopsy samples from a postherpetic neuralgia (PHN) patient. PGP 9.5 immunofluorescence in normal and mirror-image painful PHN skin. The patient suffered from spontaneous pain and allodynia, but had a marked loss of thermal sensation (heat pain threshold elevated by 7.3 °C). D, dermis; E, epidermis. (Reprinted from Rowbotham, M. C., Yosipovitch, G., Connolly, M.K., Finlay, D., Forde, G. and Fields, H. L. 1996. Cutaneous innervation density in the allodynic form of postherpetic neuralgia. Neurobiol. Dis. 3, 205–214. Copyright 1996 Academic Press.)

Furthermore, mirror-image skin had lower fiber densities than distant control skin in subjects with established PHN (Oaklander, A.L. *et al.*, 1998).

5.57.7.5 Microneurography

Microneurography has been used to assess functional abnormalities in single small fibers. This technique makes it possible to subgroup C nociceptors in healthy controls into a variety of physiologically different classes. The technique requires huge technical skills from the researcher and is very time consuming.

Regarding pathological states it has been possible to identify spontaneously active C fibers in patients e.g., with erythromelalgia (Orstavik, K. *et al.*, 2003) (Figure 4). However, the results about abnormal firing patterns in diabetic neuropathy patients obtained so far have not been conclusive (Handwerker, personal communication). One major problem has been that normal aging changes the functional properties of C afferents dramatically. As the patient populations are generally older, normative data from a cohort of healthy older subjects have to be obtained. Furthermore, as recordings are performed from single afferent C fibers and not from whole nerves it is not possible to obtain reliable quantitative data about fiber numbers.

5.57.7.6 Indirect Test of Afferent Unmyelinated Fiber Function

The function of afferent unmyelinated fibers in the skin can be objectively assessed by using the efferent effector component of C fibers as indirect means (Baron, R. and Saguer, M., 1993; Schuller, T. B. *et al.*, 2000). Studies of the axon reflex vasodilatation (neurogenic flare) using visual inspection (Figure 8), thermography, or laser Doppler flowmetry in response to a chemical stimulus that activates cutaneous C fibers (histamine, capsaicin) are commonly used. While independent of patient cooperation, a major drawback of this technique is the dependence on a variety of other factors that affect the effector response.

Figure 8 Histamine flares in a patient with severe postherpetic neuralgia in the right segment Th6. Histamine iontophoresis was performed within the allodynic transitional zone at the cranial border of the affected and adjacent segment and on the contralateral corresponding site. The formerly affected dermatome is characterized by heavy scar tissue, whereas the allodynic area shows no scars or secondary pigmentation. Note the difference in flare size (ipsilateral 260 mm^2, contralateral 2060 mm^2) indicating an impairment of nociceptive C fiber function in the allodynic region. Adapted from Baron, R. and Saguer, M. 1993. Copyright 1993 Oxford University Press.

5.57.7.7 Imaging Techniques

A new MRI technique, MR neurography makes it possible to identify small patches of inflammation in peripheral nerves. This might be of value in inflammatory neuropathies, acute zoster, or schwannoma and neuroma detection (Haanpaa, M. *et al.*, 1998; Bendszus, M. *et al.*, 2004) (Figure 9). More patients with visable lesions associated with acute herpes zoster still had pain after 3 months. No data are available to demonstrate changes that occur in chronic PHN. MRI can also identify changes in peripheral nerves and secondary neurogenic alterations in skeletal muscle (Koltzenburg, M. and Bendszus, M., 2004). Prolongation of the T2 relaxation time and gadolinium enhancement of denervated muscle develop in parallel with the development of pathological spontaneous activity on EMG that is a feature of axonal damage. Axonal nerve lesions cause a hyperintense signal on T2-weighted MRI of the affected nerve at and distal to the lesion site, which correlates with Wallerian degeneration and nerve edema. While the MRI changes do not distinguish between painful and painless nerve lesions, they supplement the differential diagnosis of peripheral nerve disease. Furthermore, diffusion tensor imaging technique is capable of detecting degeneration of fibers in the dorsal columns in severe peripheral neuropathies.

5.57.7.8 Do We Have Diagnostic Tool to Dissect Individual Mechanisms in Neuropathic Pain?

The modern theoretical concept of a mechanism-based therapy uses the assumption that a specific symptom predicts a specific underlying mechanism. It should be possible for a clinician to identify a particular mechanism by assessing a specific sensory symptom. There are, however, some important caveats with such an approach. Recent clinical experimental studies indicate that it is not appropriate to link one single symptom with exactly one mechanism. It was shown that one specific symptom may be generated by several entire different underlying pathophysiological mechanisms. It became clear that only a specific symptom constellation, a symptom profile, i.e., a combination of negative and positive sensory phenomena, might be able to predict the mechanisms and not just one single symptom. In order to translate these ideas into the clinical framework of neuropathic pain the most important approach is to characterize the somatosensory phenotype of the patients as precisely as possible.

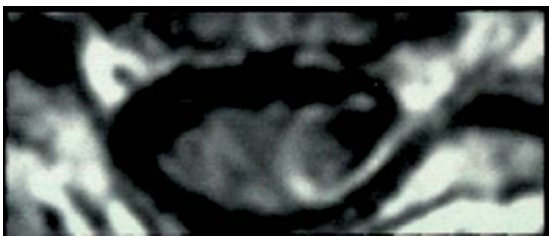

Figure 9 Magnetic resonance image of a patient with acute herpes zoster. Spinal cord in the cervical affected region. Note the contrast enhancement in the dorsal root, dorsal horn of the spinal cord, and lesser also in the ventral root. The patients was severely affected with pain and motor weakness at the left arm (T1 image with contrast medium). Photo courtesy of Prof. Dr. T. Tölle, Munich.

For example, standardized QST methods described above can nicely distinguish between phenotypic subtypes of PHN patients with distinct sensory symptom constellations that are likely correlated with different underlying mechanisms (sensitization type, deafferentation type, see above). Distinct pathophysiological changes in the excitability of peripheral and central neurons are likely involved in pain generation (for details, see Figure 10).

As attractive a subtype classification based on the nociceptor function and evoked pain types might be it should be emphasized that not all PHN patients fit exactly into one category or the other. It rather seems to be a continuum. Furthermore, in a large group of PHN patients many heterogeneous patterns of sensory dysfunction were detected (Pappagallo, M. *et al.*, 2000). Accordingly, detailed testing of sensory function, chemical stimulation, and cutaneous innervation in one PHN patient clearly showed areas of relative preservation in close vicinity to impaired thermal sensation, both within the affected dermatome (Petersen, K. L. *et al.*, 2000). Furthermore, the sensory patterns showed a variation over the time course of PHN. However, by classification of PHN patients due to sensory perception thresholds within the most painful skin area it is possible to detect the predominant individual sensory profile and the most likely underlying pain-generating mechanism.

Another caveat addressing the predictive value of QST measurements for therapy was recently revealed by two independent studies. It was hypothesized that topically applied lidocaine that is believed to act on ectopic discharges in nociceptive fibers would be in particular beneficial for patients with sensitized peripheral nociceptors as compared with patients with a loss of dermal nociceptors. In contrast to the hypothesis, however, skin biopsies, QST, histamine test as well nerve conduction studies could not identify

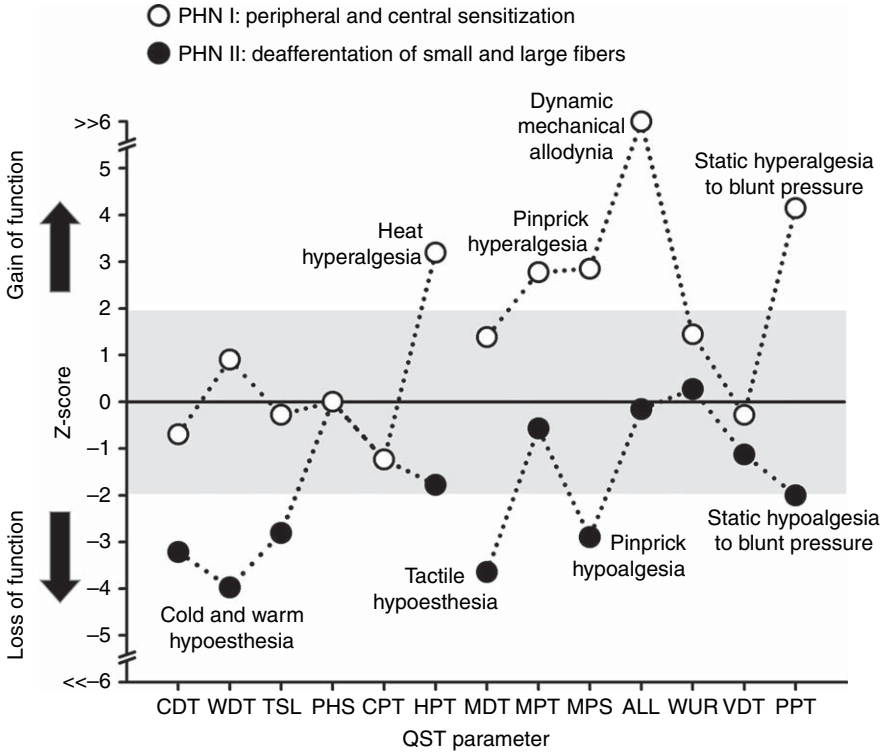

Figure 10 *Z*-score sensory profiles of two patients suffering from postherpetic neuralgia (PHN). Patient PHN I (open circles) presents the Quantitative sensory testing (QST) profile of a 70-year-old woman suffering from PHN for 8 years. Ongoing pain was 80 on a 0 to 100 numerical rating scale. The profile shows a predominant gain of sensory function in terms of heat pain hyperalgesia (HPT), pinprick mechanical hyperalgesia (MPS), dynamic mechanical allodynia (ALL), and static hyperalgesia to blunt pressure (PPT) outside the 95% confidence interval of the distribution of healthy subjects (=gray zone). This profile is consistent with a combination of peripheral and central sensitization. Patient PHN II (filled circles) shows the QST profile of a 71-year-old woman with pain for 8 months. Ongoing pain was 70 on a 0 to 100 numerical rating scale. The QST profile shows predominant loss of sensory function. Note the cold (CDT), warm detection thresholds (WDT), thermal sensory limen (TSL), heat pain thresholds (HPT), tactile detection thresholds (MDT), and mechanical pain thresholds to pinprick stimuli (MPT) outside the normal range as presented by the gray zone. This profile is consistent with a combined small- and large-fiber sensory deafferentation. *Z*-score: Numbers of standard deviations between patient data and group-specific mean value. Adapted from Rolke, R., Baron, R., Maire, C., Tölle, T. R., Treede, R. D., Binder, A., Birbaumer, N., Birklein, F., Bötefür, C. I., Braune, S., Flor, H., Huge, V., Klug, R., Landwchrmeyer, G. B., Magerl, W., Maihöfer, G., Rolko, C., Scherens, A., Sprenger, T., Valet, M., and Wasserka, B. 2006. Quantitative Sensory testing in the German Research Network on Neuropathic Pain (DFNS): standardized protocol and reference values. Pain 123, 231–243.

lidocaine responders in painful neuropathies (Herrmann, D. N. *et al.*, 2006) and PHN (Wasner, G. *et al.*, 2005). Alternatively, it might be possible that surviving A fibers in C-nociceptor-deprived skin may express sodium channels, develop ectopic firing and might therefore be the target for lidocaine.

5.57.8 Therapy

The number of trials for peripheral neuropathic pain has expanded greatly in the past few years. These have been summarized in several recent meta-analyses that are referred to in the following (Baron, R. and Wasner, G., 2006;; McQuay H. *et al.*, 1995; McQuay, H. J. *et al.*, 1996; Sindrup, S. H. and Jensen, T. S., 1999; Dworkin, R. H. *et al.*, 2003; Finnerup, N. B. *et al.*, 2005; Siddall, P. J. and Middleton, J. W., 2005). For central neuropathic pain there are limited data. The treatments discussed below have all been demonstrated to provide statistically significant and clinically meaningful treatment benefits compared with placebo in multiple randomized controlled trials (Table 7).

Nonmedical treatments, i.e., interventional procedures, neurostimulation techniques, neurosurgical destructive techniques, psychological therapy as well as physiotherapy and occupational therapy are not the focus of this review.

Table 7 Pharmacological therapy of neuropathic pain syndromes

Compound	*Evidence*
Antidepressants	
Amitriptyline	PHN ⇑⇑, PNP ⇑⇑, PTN ⇑, STR ⇑
Venlafaxine	PNP ⇑⇑
Duloxetine	PNP ⇑⇑
Anticonvulsants (Na channel)	
Carbamazepine	PNP ⇑, TGN ⇑⇑
Oxcarbazepine	PNP ⇑
Lamotrigine	HIV ⇑, PNP ⇑, STR ⇑
Anticonvulsants (Ca channel)	
Gabapentin	PHN ⇑⇑, PNP ⇑⇑, HIV ⇑, CRPS ⇑, PHAN ⇑, SCI ⇑, MIX ⇑, CANC ⇑
Pregabalin	PHN ⇑⇑, PNP ⇑⇑, SCI ⇑
Tramadol	PHN ⇑, PNP ⇑⇑
Long-acting strong opioids	
Morphine	PHN ⇑, PHAN ⇑
Oxycodone	PHN ⇑, PNP ⇑⇑
Cannabinoids	MS ⇑⇑, PA ⇔, MIX ⇑
Topical therapy	
Capsaicin cream	PHN ⇑, PNP ⇑, PTN ⇑
Lidocaine patch	PHN ⇑⇑, MIX ⇑

CANC, neuropathic cancer pain; CRPS, complex regional pain syndrome; HIV, HIV neuropathy; MIX, mixed neuropathic pain cohort; MS, central neuropathic associated with MS (multiple sclerosis); PA, central neuropathic pain after plexus avulsion; PHAN, phantom pain; PHN, postherpetic neuralgia; PNP, polyneuropathy (mainly diabetic); PTN, posttraumatic neuralgia; SCI, spinal cord injury; STR, poststroke pain; TGN, trigeminal neuralgia.
Levels of evidence: ⇑⇑, several randomized clinical trials (RCTs) or meta-analyses; ⇑, at least 1 RCT; ⇔, unclear.

5.57.8.1 Antidepressants

The effectiveness of tricyclic antidepressants (TCAs) in neuropathic pain may account for their broad range of pharmacological actions. These compounds are inhibitors of the reuptake of monoaminergic transmitters. They are believed to potentiate the effects of biogenic amines in CNS pain-modulating pathways. In addition, they block voltage dependent sodium channels and α adrenergic receptors.

Venlafaxine and duloxetine that blocks both serotonin and norepinephrine reuptake (serotonin noradrenaline reuptake inhibitors (SNRI)) were efficacious in diabetic painful neuropathy (DPN). In a comparison of venlafaxine and imipramine in patients with painful polyneuropathy, both antidepressants demonstrated superior pain relief compared with placebo but did not differ from each other.

Selective serotonin reuptake inhibitors (SSRI) have fewer adverse effects and are generally better tolerated than TCAs. However, they did not show convincing efficacy in neuropathic pain states.

5.57.8.2 Anticonvulsants (Ca Channel Modulators)

There are extensive clinical trials of gabapentin for chronic neuropathic pain. These studies examined patients with PHN, DPN, mixed neuropathic pain syndromes, phantom limb pain, Guillain–Barré syndrome, and acute and chronic pain from SCI. Improvements in sleep, mood, and quality of life were also demonstrated. Pregabalin, the successor drug of gabapentin was shown to be efficacious in PHN, DPN, and SCI. There is growing evidence supporting the mechanism of action on the $\alpha 2\delta$ subunit of neuronal calcium channels partly located at the presynaptic spinal terminals of primary afferent nociceptors. One advantage over gabapentin is its superior bioavailability, which makes it easier to use without the need of long titration periods. Gabapentin and pregabalin are generally well tolerated, safe, have no drug interactions, and no negative impact on cardiac function. This advantages makes them a suitable option especially for the elderly, a population very often suffering from several comorbidities that need multiple drug therapies.

5.57.8.3 Anticonvulsants (Na Channel Blockers)

For lamotrigine there is evidence of efficacy for HIV sensory neuropathy, DPN, and central poststroke pain. Carbamazepine is very effective in trigeminal neuralgia. However, the strength of evidence is much lower for the benefit of these drugs in other types of neuropathic pain. Oxcarbazepine which has fewer side effects and drug–drug interactions than carbamazepine was shown to be effective in painful diabetic neuropathy (Dogra, S. *et al.*, 2005).

5.57.8.4 Tramadol and Opioid Analgesics

Tramadol is a norepinephrine and serotonin reuptake inhibitor with a major metabolite that is a μ opioid agonist. Sustained efficacy for several weeks has been demonstrated for oral tramadol in PHN, DPN, and in patients with painful polyneuropathy of various causes.

Strong opioids are clearly effective in postoperative, inflammatory, and cancer pain. However, the use of narcotic analgesics for patients with chronic neuropathic pain was highly controversial, even among experts in the field of pain management. However, to date several positive trials of oral strong opioid analgesics in various neuropathic pain entities have been published. In an interesting three-period crossover study comparing treatment with opioid analgesics, TCAs, and placebo in patients with PHN, controlled-release morphine provided statistically significant benefits for pain and sleep but not for physical function and mood. In that trial, patients preferred treatment with opioid analgesics compared with TCAs and placebo despite a greater incidence of adverse effects and more dropouts during opioid treatment (Raja, S. N. *et al.*, 2002). Our experience is that many patients with pain due to central and peripheral nerve injury can be successfully and safely treated on a chronic basis with stable doses of narcotic analgesics. However, the use of opioids requires caution in patients with a history of chemical dependence or pulmonary disease. We recommend using long-acting opioid analgesics (e.g., sustained release preparation or transdermal applications) when alternative approaches to treatment have failed.

5.57.8.5 Topical Medications

5.57.8.5.1 Topical capsaicin

Capsaicin is an agonist of the vanilloid receptor (TRPV1) that is present on the sensitive terminals of primary nociceptive afferents. On initial application, it has an excitatory action and produces burning pain and hyperalgesia, but with repeated or prolonged application it inactivates the receptive terminals of nociceptors. Therefore, this approach is reasonable for those patients whose pain is maintained by anatomically intact sensitized nociceptors. Capsaicin has been reported to reduce the pain of PHN and DPN.

5.57.8.5.2 Topical lidocaine

A second topical medication for neuropathic pain is local anesthetics. Local anesthetics block voltage-dependent sodium channels. Although the site of action of membrane-stabilizing drugs for relief of pain has not been proven in patients, *in vitro* studies have shown that ectopic impulses generated by damaged primary afferent nociceptors are abolished by concentrations of local anesthetics much lower than that required for blocking normal axonal conduction. Studies report pain relief with topically applied special formulations of local anesthetic (lidocaine patches (5%)) in PHN and other neuropathies.

5.57.8.6 *N*-Methyl-D-Aspartic Acid Receptor Antagonists

These drugs block excitatory glutamate receptors in the CNS that are thought to be responsible for the increased central excitability (central sensitization) following noxious stimuli. Clinically available substances with NMDA receptor blocking properties include ketamine, dextromethorphane, memantine, and amantadine. Studies of small cohorts have generally confirmed the analgesic effects of ketamine in patients suffering from PHN. However, studies with oral NMDA antagonists formulations (e.g., dextromethorphane) showed positive results in DPN but the drug was without beneficial effect in PHN.

5.57.8.7 Cannabinoids

Cannabinoid receptors type 1 (CB1) have been demonstrated in upper laminae of the spinal dorsal horn intimately concerned with the processing of nociceptive information as well as on the cell bodies of primary afferent neurons. Relief of central pain was found with the oral tetrahydocannabinol dronabinol in MS patients and in plexus avulsion pain

although in the latter the primary outcome measure defined in the hypothesis was failed. Cannabinoids were also effective in mixed peripheral neuropathic pain.

5.57.8.8 Treatment Guideline

In the previous section a variety of treatment regimens were reviewed that have shown to be effective. In summary, the relevant medical management of neuropathic pain consists of five main classes of oral medication (serotonin-/norepinephrine-modulating antidepressants, Na blocker anticonvulsants, Ca modulator anticonvulsants, tramadol, and opioids) and two categories of topical medications mainly for patients with cutaneous allodynia and hyperalgesia (capsaicin and local anesthetics).

A useful way to compare the efficacy of different treatments is the consultation of systematic reviews to determine the best available drugs (Sindrup, S. H. and Jensen, T. S., 1999; 2000; Dworkin, R. H. and Schmader, K. E., 2003). Up to now, more than 110 randomized controlled trials for the medical treatment of neuropathic pain have been published. In this respect, the measure: "Numbers needed to treat (NNT)" has been a useful measure. Numbers needed to treat is: the number of patients needed to treat with a certain drug to obtain one patient with a defined degree of pain relief. This method permit a comparison between different drugs and diseases and it allows generation of large numbers in order to provide reliable information about efficacy. Usually the NNT for more than 50% pain relief is used because it is easily understood and seems in many cases to be a relevant clinical effect. However, the methodological complexity of pooling data from small crossover and large parallel group trials and methodological shortcomings of some trials in a systematic review, remain as limitations.

In Figure 11 the NNT values of drugs for treatment of neuropathic pain is shown in relation to the number of patient that have been treated with each of the drug to get a sense of the validity of the different trials.

Because more than one mechanism is at work in most patients, a combination of two or more analgesic agents to cover multiple types of mechanisms will generally produce greater pain relief and fewer side effects. Therefore, in most patients, a stepwise proceeding with a successive monotherapy is not appropriate. Early combinations of two or three compounds out of different classes is the general practical approach. In fact, in a controlled four-period crossover trial, combined gabapentin and morphine achieved better analgesia at lower doses of each drug than either as a single agent, with constipation, sedation, and dry mouth as the most frequent adverse effects.

Drug-related adverse effects are common in the treatment of neuropathic pain, not only because of the specific medications used but also because many patients with this condition are older, take other medications, and have comorbid illnesses. Therefore, the drugs of first choice has to be judged on the basis of these data.

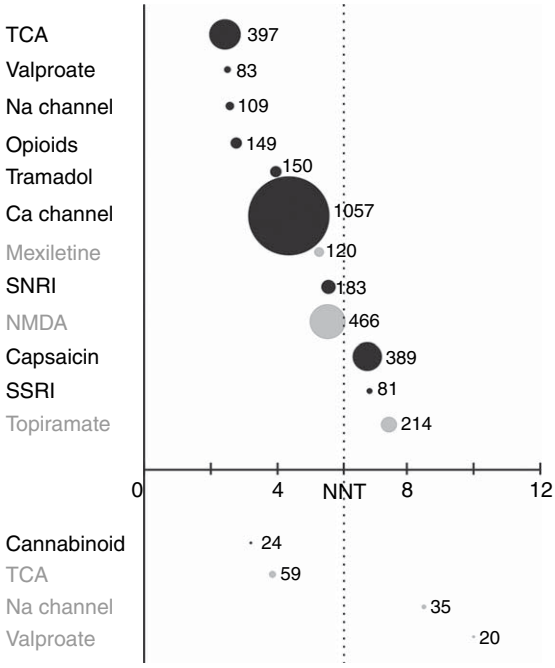

Figure 11 Numbers needed to treat in peripheral and central neuropathic pain. Combined numbers needed to treat (NNT) to obtain one patient with more than 50% pain relief in (a) peripheral neuropathic pain (painful polyneuropathy, postherpetic neuralgia, and peripheral nerve injury pain) and (b) central pain (central poststroke pain, pain following spinal cord injury and multiple sclerosis). SNRI, serotonin noradrenaline reuptake inhibitors; SSRI, selective serotonin reuptake inhibitor. Circle size and related numbers indicate number of patients who have received active treatment. Gray circle: at least half of conducted trials showed no significant effect. Right to Dotted line: clinical relevance should be questioned. (After Finnerup, N. B., Otto, M., McQuay, H. J., Jensen, T. S., Sindrup, S. H. 2005. Algorithm for neuropathic pain treatment: an evidence based proposal. Pain 118, 289–305.)

There are several exceptions from the above general treatment recommendations that should be emphasized: First, treatment guidelines for trigeminal neuralgia are distinct and include carbamazepine and baclofen. Second, the pharmacological therapy may be similar in CRPS, although controlled trials of first-line medications are lacking. However, it is very likely that antiinflammatory strategies in particular in the acute phase might be helpful. Third, although chronic neuropathic back pain (i.e., cervical and lumbar radiculopathic pain) is probably the most prevalent pain syndrome to which neuropathic mechanisms contribute, there are no accepted diagnostic criteria for identifying this neuropathic component. It is likely that a combination of neuropathic, skeletal, and myofascial mechanisms account for this type of pain in many patients.

Glossary

ACE Angiotensin-converting enzyme.
CGRP Calcitonin gene-related peptide is the most potent vasodilator neuropeptide released from primary afferent nociceptors.
C-nociceptors Free nerve endings with high activation thresholds.
dermal microdialysis Single hollow semipermeable fibers are inserted into the skin.
laser Doppler Monochromatic light is directed to the skin. The frequency shift of the backscattered is proportional to skin perfusion.
NEP Neutral endopeptidase.
NGF Nerve growth factor.
NK1-R Substance P receptors.
polymorphism Common genetic variability.
QSART Quantitative measurement of peripheral axon reflex sweating.
SP Substance P binds to NK1 receptors at venoles and mediates plasma protein extravasation.
TNF-α Tumor necrosis factor-alpha.
TST Sweating induced by body heating – thermoregulatory sweating.

5.58.1 Principles and Mechanisms of Neurogenic Inflammation – Basic Research

5.58.1.1 Concept of Neurogenic Inflammation

It has been more than 100 years since Bayliss W. M. (1901) described antidromic vasodilation following electrical stimulation of centrally cut dorsal roots. Meanwhile it has become clear that retrogradely conducted action potentials invade the arborizations of the primary afferent neurons (axon reflex) and release neuropeptides from their terminals (Szolcsanyi, J., 1996). The acute effects of neuropeptide release in rodent skin are vasodilation and protein extravasation, the combination of which has

been termed neurogenic inflammation. Pivotal neuropeptides in the induction of neurogenic inflammation comprise calcitonin gene-related peptide (CGRP) for vasodilation and substance P (SP) for the induction of protein extravasation (Holzer, P., 1998).

5.58.1.2 Neuronal Basis of Neurogenic Inflammation

Chemical, thermal, and electrical stimulation has been widely used to elicit neurogenic inflammation. As a result of previous studies, mechanoinsensitive, but heat and chemosensitive C-nociceptors have been found responsible for the neurogenic vasodilation in pig (Lynn, B. *et al.*, 1996) and human skin (Schmelz, M. *et al.*, 2000), whereas in rodent, skin polymodal nociceptors play a crucial role (Gee, M. D. *et al.*, 1997).

A few approaches so far have tried to directly measure neuropeptide release in the skin, for example, *ex vivo* analysis by superfusion of excised rat skin (Kilo, S. *et al.*, 1997; Kress, M. *et al.*, 1999). In most studies, neurogenic vasodilation and protein extravasation have been used to functionally assess nociceptor activation. Vasodilation has been measured by laser Doppler techniques and infrared thermography. Assessment of protein extravasation requires more invasive techniques, for example, extravasation of albumin bound dyes like Evans blue, which can be photometrically quantified *ex vivo*. Recent advances in dermal microdialysis have opened new possibilities by allowing *in vivo* measurement of local mediator concentrations, including protein extravasation (Sauerstein, K. *et al.*, 2000).

5.58.1.3 Humoral Interactions between Neurons and Inflammatory Cells

In addition to the classical features of neurogenic inflammation, that is, vasodilation and protein extravasation, neuropeptides also directly interact with inflammatory cells. Primary afferent nociceptors release a variety of neuropeptides like neurokinin A, neurokinin B, somatostatin, corticotropin-releasing hormone (CRH), pituitary adenylate cyclase-activating polypeptide (PACAP), vasoactive intestinal peptide (VIP), galanin, and endomorphins (Steinhoff, M. *et al.*, 2003). A summary of important activating (Figure 1(a)) and inhibitory interactions (Figure 1(b)) between nociceptive nerve endings, tissue cells, and inflammatory cells is shown below. As an example, nerve growth factor (NGF) derived from keratinocytes and mast cells sensitizes nociceptors and also increases expression of mast cell tryptase and histamine (Groneberg, D. A. *et al.*, 2005) in mast cells. Histamine and tryptase activate nociceptive terminals via H1 and proteinase-activated receptors (PAR2) and release SP from the terminals (Steinhoff, M. *et al.*, 2000). SP via activation of NK1 receptors on the mast cells (van der Kleij, H. P. *et al.*, 2003) increases expression of histamine and tumor necrosis factor-alpha (TNF-α) (Ansel, J. C. *et al.*, 1993; Cocchiara, R. *et al.*, 1999), which in return sensitizes nociceptive terminals via activation of the TNF receptor.

5.58.2 Animal Models of Neuropathic Pain, Which Focus on Neurogenic Inflammation

Different animal models have been used to study the nature of neuropathic pain. Unfortunately, most studies focused on mechanisms and symptoms of pain but did not look at symptoms that characterize neurogenic inflammation after nerve lesion. Nevertheless, these pain models indicate that cytokines (TNF-α and NGF) were upregulated in the injured nerve (Herzberg, U. *et al.*, 1997a; 1997b; Schafers, M. *et al.*, 2002) and that neutralizing TNF-α reduces pain behavior (Sommer, C. *et al.*, 2001). It is the merit of Wade Kingery and his group that these shortcomings were meanwhile eliminated.

5.58.2.1 Bone Fracture Model for Complex Regional Pain Syndrome I

Most cases of complex regional pain syndrome (CRPS) I develop after bone fractures, e.g. to the wrist or the calf. Therefore, the most interesting animal model may be a controlled fracture of a large extremity bone. Very recently, skin temperature increase, edema, plasma protein extravasation (PPE), osteoporosis at the metaphysal parts of bones, and hyperalgesia-like behavior over weeks were observed in a rat model of tibial fracture (Guo, T. Z. *et al.*, 2004). As indicated above, these are signs of neurogenic inflammation, which can also be found in acute CRPS after bone fracture. These signs were even pronounced if the limbs of the rats were immobilized – as it is a common treatment in most human fractures. Supporting the neurogenic inflammation hypothesis of these symptoms, skin temperature difference, edema, and pain behavior can be reversed by NK1 antagonism (Kingery, W. S. *et al.*, 2003).

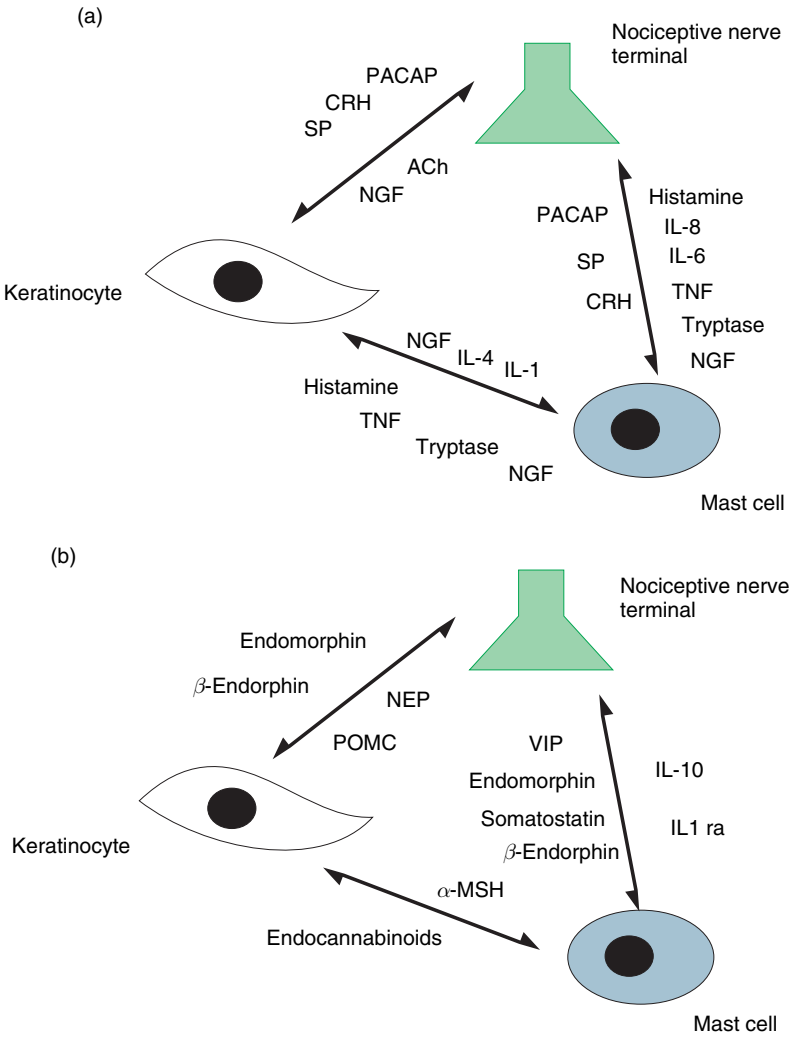

Figure 1 (a) Excitatory and (b) inhibitory neuroimmune interactions at peripheral nociceptors.

5.58.2.2 Nerve Transection Model for Complex Regional Pain Syndrome II

The sciatic nerve transection model was introduced as a surrogate for CRPS II. Soon after transection of the sciatic nerve, similar to the fracture model, rats develop increased skin temperature, paw edema, regional osteoporosis, and hyperalgesia-like behavior. Thus, symptoms after nerve transection also resemble acute CRPS. In this model, different treatments were tested. Steroids were able to reverse inflammatory symptoms (Kingery, W. S. *et al.*, 2001a; 2001b), and as described in the bone fracture model, NK1 antagonism was also effective (Kingery, W. S. *et al.*, 2003).

Taken together, both the bone fracture and the sciatic nerve transection model corroborates that many of the peripheral symptoms in acute posttraumatic CRPS may be due to C-fiber-mediated neurogenic inflammation.

5.58.3 Clinical Symptoms Suggesting Neurogenic Inflammation in Complex Regional Pain Syndrome

In general, neurogenic inflammation in CRPS can only assumed only if there has been an adequate limb trauma and if the initial clinical presentation corresponds to the primarily warm CRPS subtype (Veldman, P. H. J. M. *et al.*, 1993). In CRPS cases after minor trauma, which often start with a cold extremity (primarily cold), neurogenic inflammation

may not be present. Corresponding to the animal models, CRPS I and CRPS II could not be distinguished without detailed neurological investigation. CRPS II can be diagnosed when there is obvious evidence of peripheral nerve lesion – clinically (sensory loss, muscle weakness, and reflex loss) or neurophysiologically (nerve conduction and electromyography) (Harden, N. and Bruehl, S., 2004). However, these peripheral nerve lesions must involve either major nerves or skin nerves to be clinically recognized. Nerve lacerations (from broken bones) or stretches (from joint distraction) are usually unrecognizable. Injuries to small distal nerve branches, especially to purely sensory branches that innervate skin or bone, may not cause weakness or loss of reflexes, and thus go undetected in most clinical settings (Oaklander, A. L. and Birklein, F., 2004). For instance, a seemingly minor knee sprain can trigger CRPS if it is evaluated by knee arthroscopy, a well-documented cause of painful damage to the infrapatellar branch of the saphenous nerve (Mochida, H. and Kikuchi, S., 1995). Seemingly trivial medical procedures such as routine venipuncture can cause CRPS-inducing nerve damage to forearm nerves (Horowitz, S. H., 2001). Thus, we will not continue the traditional but often virtual differentiation between CRPS I and II in this chapter.

5.58.3.1 Pain and Hyperalgesia

In CRPS, pain and hyperalgesia are the most distressing symptoms. Since the initial trauma for CRPS usually does not include a complete nerve lesion, there are no serious reasons to doubt that pain and hyperalgesia result, at least partially, from activation of peripheral nociceptors. If these nociceptors are sensitized, they might be spontaneously active causing pain at rest (Orstavik, K. *et al.*, 2003) or they might respond more vigorously to physiological stimuli causing pain, for example, while moving a joint (Schaible, H. G. *et al.*, 2002). Nociceptor sensitization might furthermore drive spinal sensitization, which reinforces mechanical hyperalgesia. Since neurogenic inflammation, for example, the release of neuropeptides from nociceptors, is inevitably linked to nociceptor activation (even subthreshold for pain might be enough; Magerl, W. *et al.*, 1990), we regard pain and hyperalgesia as the one clinical symptom pointing to neurogenic inflammation in CRPS. In a study of 145 patients with untreated CRPS (Birklein, F. *et al.*, 2000), 75% reported pain even when the limb was completely at rest, but nearly all patients reported worsening of pain under certain circumstances – clinically indicating hyperalgesia. The most powerful stimulus that increased pain was joint movement. Accordingly, quantitative sensory testing revealed that on the affected skin there is a moderate decrease (about 4°C) of heat pain thresholds (Tahmoush, A. J. *et al.*, 2000). Heat pain sensitization of skin nociceptors is regarded as a clinical sign for peripheral sensitization (Baron, R., 2000). Even more obvious was the decrease of mechanical pain thresholds on the affected side. Our group investigated 40 CRPS patients and regularly found the presence of hyperalgesia to brief mechanical impact stimuli (Sieweke, N. *et al.*, 1999).

5.58.3.2 The Increase of Skin Perfusion and Temperature

In posttraumatic CRPS, skin temperature is increased usually during the first 6 months of the disease. The maximum skin temperature difference might be up to 10 °C (Birklein, F. *et al.*, 1997a; 1997b) Accordingly, skin color in this stage is reddish and the skin appears hyperemic. Only with disease chronification, skin temperature decreases on the affected side, the skin becomes bluish and appears thin and shiny (Birklein, F. *et al.*, 1998).

5.58.3.3 Hyperhidrosis

In 50% of the patients with CRPS, increased sweating can be clinically observed (Birklein, F. *et al.*, 1997a; 1997b); Two tests were used to localize sudomotor dysfunction along the neuraxis: thermoregulatory sweating test (TST) activates central thermoreceptors in the ventral hypothalamus (Jänig, W., 1990) and quantitative sudomotor axon reflex test (QSART) tests purely the peripheral sudomotor axon reflex (Low, P. A. *et al.*, 1983). In acute CRPS both TST and QSART are increased pointing to sudomotor dysfunction in the peripheral nervous system. From basic experiments we know that the capacity of sweat glands increases with increasing skin temperature (Sato, K. *et al.*, 1993) and that the neuropeptide CGRP, which might be responsible for increased skin temperature and perfusion, itself enhances sweat gland activity (Kumazawa, K. *et al.*, 1994).

5.58.3.4 Limb Edema

Edema is the most striking clinical sign in CRPS. During acute stages 81% of patients have visible edema on the affected limb (Birklein, F. *et al.*, 2000). The edema is pronounced at backs of hands or feet. After exercise or during the course of a day, when repeated nociceptor activation has occurred, edema increases. Only if CRPS persists longer and becomes chronic, edema dwindles (Birklein, F. *et al.*, 1999).

5.58.3.5 Trophic Changes

Trophic changes can be found in more than 50% of patients. Increased hair and nail growth appears several days after the onset of symptoms (Birklein, F. *et al.*, 2000). The well-known periarticular patchy osteoporosis, which can bee seen on X-ray pictures, belongs to the same group of symptoms (Maresca, V., 1985). This osteoporosis is a so-called high-turnover osteoporosis with increased osteoclastic activity (Leitha, T. *et al.*, 1996). Interestingly, TNF-α and SP (Goto, T. *et al.*, 1998) activate osteoclasts, and CGRP promotes hair growth (Hagner, S. *et al.*, 2002).

5.58.4 Clinical Investigations Proving Neurogenic Inflammation in Complex Regional Pain Syndrome

5.58.4.1 Experimental Studies

Many clinical symptoms of acute CRPS resemble inflammation: pain, edema, increased skin temperature, and blood flow. Inflammation in the classical sense with positive blood markers has not been proven, but any inflammation has a neurogenic component (Brain, S. D. and Williams, T. J., 1988). Peripheral trauma, in particular if it is accompanied by partial peripheral nerve lesion, causes a rapid release of cytokines like NGF (Herzberg, U. *et al.*, 1997a; 1997b) and TNF-α (Grellner, W., 2002). Both cytokines are able to activate and sensitize primary afferents, locally at the injury site or proximally in the respective nerve trunk. Recently, increased TNF-α has been shown in CRPS skin by analysis of suction blister fluids (Huygen, F. J. *et al.*, 2002). Our own group was able to demonstrate increased TNF-α in plasma samples of two different independent CRPS patients groups (Maihofner, C. *et al.*, 2005). Increase of TNF-α was correlated to mechanical hyperalgesia, a clinical surrogate for nociceptive sensitization.

Cytokines also increase the neuropeptide content of primary afferent neurons (Opree, A. and Kress, M., 2000). Activation of sensitized primary afferents then causes an increased release of neuropeptides into the affected body region (SP and CGRP). Chronic release of neuropeptides might be responsible for the above-mentioned CRPS symptoms. In addition, central neuropeptide release facilitates nociceptive sensitization. In analogy to migraine studies, we therefore measured CGRP in serum samples from patients with acute CRPS. CGRP was significantly increased, in particular when clinical inflammatory signs were present and when there was evidence for trauma-related nerve lesion (Birklein, F. *et al.*, 2001). In order to verify that increased CGRP indeed comes from primary nociceptive afferents, neurogenic inflammation was elicited directly in the skin by transcutaneous electrical stimulation via intradermal microdialysis capillaries. We first investigated the flare by using laser Doppler scanning on the affected and the unaffected side in our CRPS patients. Neurogenic flare was significantly more intense in patients, surprisingly on both sides – the affected and the clinically unaffected one (Leis, S. *et al.*, 2004). Another characteristic of neurogenic inflammation in rodents is SP-mediated PPE. In healthy humans, C fibers usually contain too less SP to induce PPE. In CRPS, however, significant PPE could be shown in almost all patients investigated. In contrast to the flare response, this increased PPE was limited to the affected side (Weber, M. *et al.*, 2001). These results suggested two possible pathomechanisms leading to facilitated neurogenic inflammation in CRPS – either increased release, hampered inactivation of neuropeptides, or both. In order to further unravel these mechanisms, we perfused SP in ascending concentrations through dermal microdialysis fibers in CRPS patients and controls. We found SP to be significantly more effective at inducing PPE in CRPS patients. Similar to the increased flare response, this increased responsiveness to SP was present on both the affected and the unaffected limbs (Leis, S. *et al.*, 2003) (Figure 2).

To summarize, in this series of experiments we found a trauma-related upregulation of neuropeptide release from primary afferent on the affected side and in addition an impaired inactivation of neuropeptides on both sides, possibly as a predisposing factor. Neuropeptide action in human tissue is terminated by degradation of peptidases. The most familiar peptidase, which cleaves SP and CGRP, is the angiotensin-converting enzyme (ACE). A previous

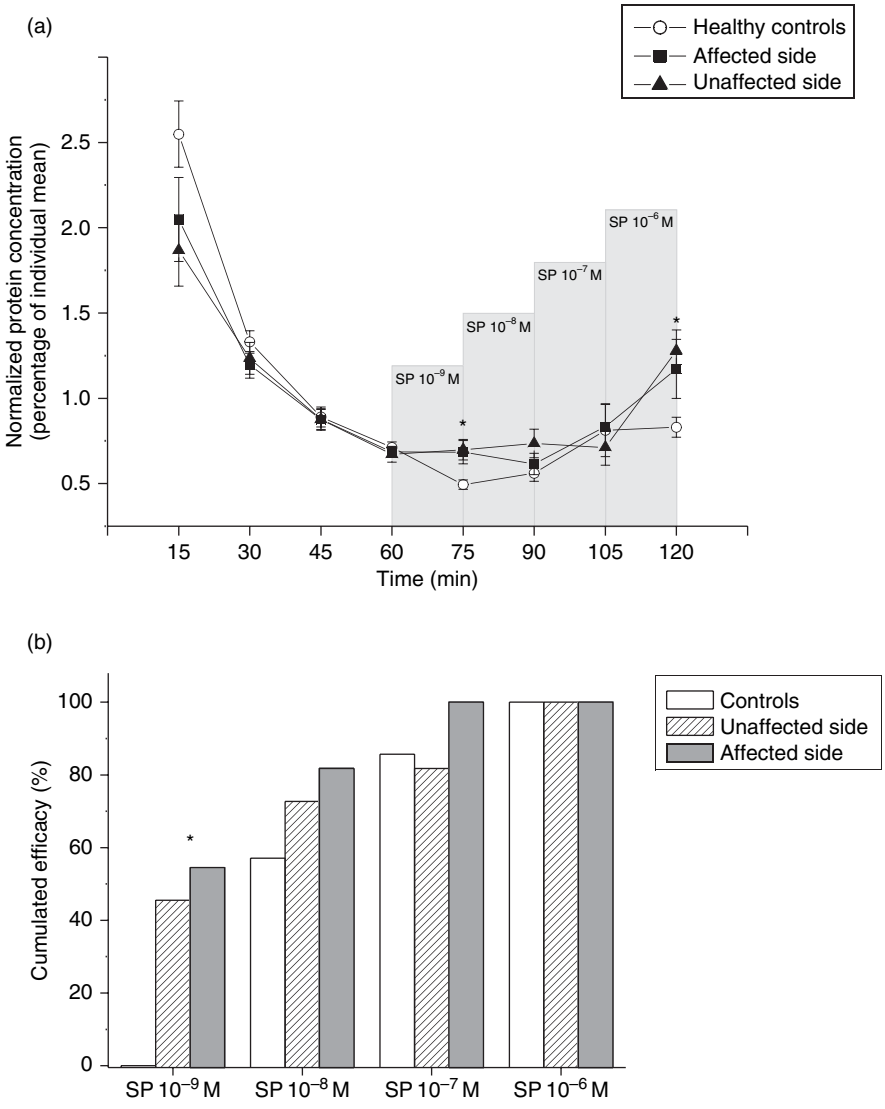

Figure 2 Substance P (SP) induced significantly increased protein extravasation in complex regional pain syndrome (CRPS) patients on the ipsilateral affected side (circles) and the contralateral unaffected side (triangles) as compared to healthy controls (squares). Significant differences at SP 10^{-9} M (receptor-dependent) and SP 10^{-6} M (receptor-independent) are marked. Results with intermediate SP concentrations might be false-negative due to SP receptor internalization.

report of an insertion/deletion (I/D) polymorphism in intron 16 within the ACE gene implicated an increased risk to develop CRPS I associated with the D allele (Kimura, T. *et al.*, 2000). However, in a linkage study in CRPS families, we failed to show any cosegregation of this polymorphism and the CRPS phenotype (Hühne, K. *et al.*, 2004). Therefore, we will focus on other enzymes that are involved in neuropeptide degradation. One promising example is the neutral endopeptidase (NEP). Blocking the NEP facilitates neurogenic inflammation in a way, which resembles the findings on the unaffected side in CRPS patients (Krämer, H. H. *et al.*, 2005).

5.58.4.2 Treatment Studies

Another indication for neurogenic inflammation in warm posttraumatic CRPS cases is the effectiveness of anti-inflammatory treatment with steroids, which is based on small, but controlled studies (Christensen, K. *et al.*, 1982). Cortisone has multiple effects in

CRPS – it inhibits the production of inflammatory mediators, reduces the transcription rate in dorsal root ganglia cells, and thereby reduces neuropeptide content of sensory neurons (Kingery, W. S. *et al*., 2001a; 2001b). Furthermore, it even facilitates the degradation of neuropeptides (Nadel, J. A., 1992) and inhibits ectopic impulse generation after nerve trauma by stabilizing nerve membranes. Thus, steroids may prevent the development of facilitated neurogenic inflammation and of neuropathic pain in warm CRPS.

CRPS Complex regional pain syndrome.
DRG Dorsal root ganglion, spinal ganglion.
MEG Magnetic encephalography.
PET Positron emission tomography.
QST Quantitative sensory testing.
TNF Tumor necrosis factor.

5.59.1 Introduction

The term complex regional pain syndrome (CRPS) describes a variety of painful conditions following injury, which appears regionally with a distal predominance of abnormal findings. The symptoms exceed in both magnitude and duration the expected clinical course of the inciting event and often result in significant impairment of motor function. The disorder shows a variable progression over time. These chronic pain syndromes comprise different additional clinical features including spontaneous pain, allodynia, hyperalgesia, edema, autonomic abnormalities, and trophic signs. In CRPS type I (reflex sympathetic dystrophy) minor injuries or fractures of a limb precede the onset of symptoms. CRPS type II (causalgia) develops after injury to a major peripheral nerve (Baron, R. *et al.*, 2002a; Janig, W. and Baron, R., 2003; Baron, R., 2004).

5.59.2 Complex Regional Pain Syndrome Type I (Reflex Sympathetic Dystrophy)

The most common precipitating event is a trauma affecting the distal part of an extremity (65%), especially fractures, postsurgical conditions, contusions, and strain or sprain. Less common occasions are central nervous system (CNS) lesions like spinal cord injuries and cerebrovascular accidents as well as cardiac ischemia (Wasner, G. *et al.*, 2003).

CRPS I patients develop asymmetrical distal extremity pain and edema without presenting an overt nerve lesion. These patients often report a burning spontaneous pain felt in the distal part of the affected extremity. Characteristically, the pain is disproportionate in intensity to the inciting event. The pain usually increases when the extremity is in a dependent position. Stimulus-evoked pains are a striking clinical feature. These sensory abnormalities often appear early, are most pronounced distally, and have no consistent spatial relationship to individual nerve territories or to the site of the inciting lesion. Typically, pain can be elicited by movement of and pressure on the joints (deep somatic allodynia), even if these are not directly affected by the inciting lesion.

Autonomic abnormalities include swelling and changes of sweating and skin blood flow. In the acute stages of CRPS I, the affected limb is often warmer than the contralateral limb. Sweating abnormalities, either hypohidrosis or, more frequently, hyperhidrosis are present in nearly all CRPS I patients. The acute distal swelling of the affected limb depends very critically on aggravating stimuli. Since it diminishes after sympathetic blocks, it is likely that it is maintained by sympathetic activity.

Trophic changes such as abnormal nail growth, increased or decreased hair growth, fibrosis, thin glossy skin, and osteoporosis may be present, particularly in chronic stages. Restrictions of passive movement are often present in long-standing cases and may be related to both functional motor disturbances and trophic changes of joints and tendons.

Weakness of all muscles of the affected distal extremity is often present. Small accurate movements are characteristically impaired. Nerve conduction and electromyography studies are normal, except in patients in very chronic and advanced stages. About half of the patients have a postural or action tremor representing an increased physiological tremor. In about 10% of the cases, dystonia of the affected hand or foot develops.

5.59.3 Complex Regional Pain Syndrome Type II (Causalgia)

The symptoms of CRPS II are similar to those of CRPS I. The only exception is that a lesion of peripheral nerve structures and subsequent focal deficits are mandatory for the diagnosis. The symptoms and signs spread beyond the innervation territory of the injured peripheral nerve and often occur remote from the site of injury but a restriction to the territory is not in conflict with the current definition.

5.59.4 Important Issues that Are Unique in Complex Regional Pain Syndrome

5.59.4.1 Motor Abnormalities

About 50% of the patients with CRPS show motor abnormalities (Deuschl, G. *et al.*, 1991; Bhatia, K. P. *et al.*, 1993). It is unlikely that these motor changes are related to a peripheral process (e.g., influence of the sympathetic nervous system on neuromuscular transmission and/or contractility of skeletal muscle). These somatomotor changes are more likely generated by central changes of activity in the motoneurons. With kinematic analysis of target reaching as well as grip force analysis to quantitatively assess motor deficits in CRPS patients (Schattschneider, J. *et al.*, 2001) abnormalities in the cerebral motor processing were revealed. A pathological sensorimotor integration located in the parietal cortex may induce an abnormal central programming and processing of motor tasks. Interestingly, the motor performance is also slightly impaired on the contralateral unaffected side (Ribbers, G. M. *et al.*, 2002). According to this view, a neglect-like syndrome was clinically described to be involved in the disuse of the extremity (Galer, B. S. *et al.*, 1995). Recent controlled studies also support an incongruence between central motor output and sensory input as underlying mechanism in CRPS. Using the method of mirror visual feedback, the visual input from a moving unaffected limb to the brain was able to reestablish the pain-free relationship between sensory feedback and motor execution. After 6 weeks of therapy, pain and function were improved as compared with the control group (McCabe, C. S. *et al.*, 2003; Moseley, G. L., 2004). Furthermore, a sustained inhibition of the motor cortex was found in CRPS patients on the contralateral as well as ipsilateral hemisphere (Juottonen, K. *et al.*, 2002; Schwenkreis, P. *et al.*, 2003).

5.59.4.2 Inflammatory Processes

Some of the clinical features of CRPS particularly in its early phase, that is, calor, dolor, rubor, functio lesae, and swelling suggest that the pathological extremity is exhibiting an excessive inflammatory

process (Leitha, T. *et al.*, 1996; van der Laan, L. and Goris, R. J., 1997; Calder, J. S. *et al.*, 1998). The idea of an inflammatory processes, in particular in the deep somatic tissues including bones, goes back to Sudeck who believed that this syndrome is an inflammatory bone atrophy ("entzündliche Knochenatrophie") (Sudeck, P., 1902; 1931). There are now several lines of evidence supporting this view.

5.59.4.2.1 Immune cell-mediated inflammation and cytokine release

Several studies in CRPS patients address the question to what extend an immune cell-mediated inflammation is involved. Skin biopsies in these patients showed a striking increase in the number of Langerhans cells that can release immune cell chemoattractants and proinflammatory cytokines (Calder, J. S. *et al.*, 1998). In accordance, in the fluid of artificially produced skin blisters significantly higher levels of IL-6 and tumor necrosis factor alpha (TNF-α) as well as tryptase (a measure of mast cell activity) were observed in the involved extremity as compared with the uninvolved extremity (Huygen, F. J. *et al.*, 2001; 2002). In CRPS patients with hyperalgesia, higher levels of the soluble TNF-α receptor type I were found (Maihofner, C. *et al.*, 2005b). Accordingly, a significant increases in IL-1β and IL-6, but not TNF-α was demonstrated in the cerebrospinal fluid (CSF) of individuals afflicted with CRPS as compared with controls (Alexander, G. M. *et al.*, 2005).

In this context, it is of particular interest that cutaneous denervation can cause rapid activation and proliferation of Langerhans cells that continues until reinnervation occurs. Thus, one might speculate that such cell proliferation may reflect also a functional denervation of cutaneous sympathetic outflow that occurs in CRPS (Wasner, G. *et al.*, 1999; 2001).

The patchy osteoporosis which is found in more advanced CRPS cases may also be consistent with a regional inflammatory process in deep somatic tissues. Both IL-1 and IL-6 cause proliferation and activation of osteoclasts and suppress the activity of osteoblasts.

Changes in hair growth can also be created by proinflammatory cytokines. TNF and IL-1 directly inhibit hair growth. Keratocyte-derived TNF and IL-6 cause retarded hair growth, signs of fibrosis, and in turn immune infiltration of the dermis, all present in CRPS patients.

5.59.4.2.2 Neurogenic inflammation and nociceptor sensitization

Because infection has so far not been shown to account for the inflammatory reactions in CRPS an exaggerated neurogenic inflammation has been proposed. Axon reflex vasodilatation was significantly increased on the affected side as measured with laser Doppler flowmetry after electrical C-fiber stimulation. Accordingly, systemic CGRP levels were found to be increased in acute CRPS but not in chronic stages (Birklein, F. *et al.*, 2001). Also, increased axon reflex sweating could be explained by release of CGRP from nociceptive terminals during nociceptor sensitization that act on peripheral sweat glands (Birklein, F. *et al.*, 2001).

In acute untreated CRPS I patients axon reflex activation was elicited by strong transcutaneous electrical stimulation of peptidergic unmyelinated afferents via intradermal microdialysis capillaries. Protein extravasation that was simultaneously assessed by the microdialysis system was only provoked on the affected extremity as compared with the normal side. The time course of electrically induced protein extravasation in the patients resembled the one observed following application of exogenous substance P (SP) (Weber, M. *et al.*, 2001).

Plasma extravasation could also be demonstrated with other experimental techniques: Bone scintigraphy demonstrated periarticular tracer uptake in acute CRPS (Leitha, T. *et al.*, 1996) and analysis of joint fluid and synovial biopsies in CRPS patients have shown an increase in protein concentration and synovial hypervascularity (Renier, J. C. *et al.*, 1983). Furthermore, synovial effusion is enhanced in affected joints as measured with magnetic resonance imaging (MRI) (Graif, M. *et al.*, 1998). Scintigraphic investigations with radiolabeled immunoglobulins show extensive plasma extravasation (Oyen, W. J. *et al.*, 1993).

5.59.4.2.3 Autoimmune etiology

There are several studies focusing at an autoimmune response in patients with CRPS. Autoantibodies against rat sympathetic neurons were detected in 40% of CRPS patients, whereas only 5% of other neuropathy patients showed these autoantibodies (Blaes, F. *et al.*, 2004). Immunoreactivity to *Campylobacter* was found in many early CRPS patients in particular associated with minimal trauma indicating a postinfectious autoimmune basis in some patients (Goebel, A. *et al.*, 2005).

5.59.4.3 Sensitization to Adrenergic Stimuli – Sympathetically Maintained Pain

After nerve lesion in animal experiments (Baron, R. *et al.*, 1999), afferent nociceptive and nonnociceptive neurons undergo dramatic functional and anatomical changes including upregulating of α-adrenoceptors. Noradrenaline released by the sympathetic nerve fibers may activate and/or sensitize the afferent neurons. This sympathetic–afferent coupling forms the theoretical basis for the clinical phenomenon of sympathetically maintained pain (SMP). The interaction may occur at the lesion site, along the lesioned nerve or even in the dorsal root ganglion (DRG).

Clinical studies in CRPS support the idea that nociceptors may develop catecholamine sensitivity (Baron, R. *et al.*, 1999): intraoperative stimulation of the sympathetic chain induces an increase of spontaneous pain in patients with causalgia (CRPS II) but not in patients with hyperhidrosis. In CRPS II, intracutaneous application of norepinephrine into a symptomatic area rekindles spontaneous pain and dynamic mechanical hyperalgesia that had been relieved by sympathetic blockade, supporting the idea that noradrenergic sensitivity of human nociceptors is present after partial nerve lesion. Also intradermal NE, in physiologically relevant doses, was demonstrated to evoke greater pain in the affected regions of patients with SMP, than in the contralateral unaffected limb, and in control subjects (Ali, Z. *et al.*, 2000).

We performed a study in patients with CRPS I using physiological stimuli of the sympathetic nervous system (Baron, R. *et al.*, 2002b). Cutaneous sympathetic vasoconstrictor outflow to the painful extremity was experimentally activated to the highest possible physiological degree by whole body cooling. The intensity as well as area of spontaneous pain and mechanical hyperalgesia (dynamic and punctate) increased significantly in patients that had been classified as having SMP by positive sympathetic blocks but not in sympathetically independent pain (SIP) patients. It is very likely that in addition to a coupling in the skin, a sympathetic–afferent interaction may also occur in other tissues, in particular in the deep somatic domain such as bone, muscle, or joints. Supporting this view, especially these structures are extremely painful in some cases with CRPS (Baron, R. and Wasner, G., 2001). Furthermore, there may be patients who are characterized by a selective or predominant sympathetic–afferent interaction in deep somatic tissues sparing the skin (Wasner, G. *et al.*, 1999).

5.59.5 Future Research, Diagnostic Classification, and Therapeutic Strategies

5.59.5.1 Integration of the Clinics and Basic Research

Recently a new animal model for CRPS I was introduced (Coderre, T. J. *et al.*, 2004). The clinical observation that signs of tissue inflammation and ischemia are present in many CRPS I patients led to the hypothesis that CRPS I might depend on an ischemia–reperfusion injury, which may at least in part induce the classical CRPS symptomatology. Consequently, an animal pain model was established that utilizes prolonged hindlimb ischemia for 3 h, followed by reperfusion, which produces a chronic postischemia pain syndrome. The reproducibility of this model awaits further confirmation.

In the future an integrative research approach on animal and human models combined with clinical research on patients who suffer from CRPS is a necessity if we are to unravel the mechanisms operating in CRPS and if we are to find the organising pathophysiological principles that orchestrate the different changes. It is essential that research on animal and human models and clinical investigations of CRPS should be closely aligned.

5.59.5.2 The Long Path Approaching the Central Nervous System

In recent years, research concentrated on investigation of peripheral mechanisms underlying the symptoms of CRPS. We are just now at a turning point recognising that important parts of the CRPS pathophysiology are obviously located within the CNS.

There is much evidence that the changed somatosensory perceptions observed in CRPS patients are likely due to changes in the central representation in the thalamus and cortex (Maleki, J. *et al.*, 2000). Positron emission tomography (PET) studies demonstrated adaptive changes in the thalamus during the course of the disease (Fukumoto, M. *et al.*, 1999). Furthermore, recent magnetic encephalography (MEG) and functional MRI (fMRI) studies revealed a shortened distance between little finger and thumb representations in the primary somatosensory (S1) cortex on the painful side (Maihofner, C. *et al.*, 2003; Pleger, B. *et al.*, 2004; Maihofner, C. *et al.*, 2005a). The MEG SI responses were increased on the

affected side, indicating processes of central sensitization (Juottonen, K. *et al.*, 2002). fMRI studies indicate that prefrontal cortical networks are involved in SMP in CRPS patients. Furthermore, in one CRPS patient a traumatic cerebral contusion of the left temporal lobe resolved the symptoms (Shibata, M. *et al.*, 1999; Apkarian, A. V. *et al.*, 2001).

We do not know the extent to which these central changes depend on continuous nociceptive input from the affected extremity; however, it has been shown that these generalized sensory changes may disappear after successful treatment of the pain (Maihofner, C. *et al.*, 2004; Pleger, B. *et al.*, 2005). In the future, we will fully understand that CRPS is a neurological disease affecting several functional systems that are closely integrated. This will include centers for the processing of cognitive and affective information.

5.59.5.3 A Possible Link between Inflammation and the Sympathetic Nervous System

In some patients sympatholytic procedures can ameliorate pain as well as inflammation and edema. Accordingly, animal studies have demonstrated that the sympathetic nervous system can influence the intensity of an inflammatory process (Levine, J. D. *et al.*, 1985; Jänig, W. *et al.*, 1996; Miao, F. J. *et al.*, 1996a; 1996b; Perl, E. R., 1996). The question arises whether the sympathetic nervous system might be involved in the inflammatory process in CRPS and whether it might interact with immune cells.

Under normal conditions, catecholamines act via β2-adrenoceptors on immune cells to inhibit the production and release of proinflammatory cytokines. These cells do not express α-adrenoceptors under basal conditions. However, the situation can dramatically change in chronic inflammation. Now, immune cells downregulate their expression of β2-adrenoceptors and upregulate their expression of α1-adrenoceptors over time (Gazda, L. S. *et al.*, 2001). In contrast to β2-adrenoceptors, α1-adrenoceptors stimulate the production and release of proinflammatory cytokines. If α1-adrenoceptors were to become expressed by the resident and/or recruited immune or immunocompetent cells of the affected CRPS extremity, then sympathetic activation would be predicted to cause pain and other inflammatory signs via cytokine release.

Summarizing the hypothetical ideas described above Figure 1 illustrates the possible interactions between sympathetic fibers, afferent fibers, blood vessels, and nonneural cells related to the immune system (e.g., macrophages) leading theoretically to the inflammatory changes observed in CRPS patients.

5.59.5.4 Do the Genes Predispose for Complex Regional Pain Syndrome?

One of the unsolved features in human pain diseases is the fact that only a minority of patients develop chronic pain after identical inciting events. Similarly, in certain nerve lesion animal models, differences in pain susceptibility were found to be due genetic factors (Mogil, J. S. *et al.*, 1999). To address this question in CRPS patients, gene technology has been used to characterize the genetic pattern of patients at risk to develop CRPS (Mailis, A. and Wade, J., 1994; 2001). In a cohort of 52 CRPS patients, class I and II major histocompatibility antigens were typed. The frequency of HLA-DQ1 was found to be significantly increased compared with control frequencies (Kemler, M. A. *et al.*, 1999). In patients with CRPS who progressed towards multifocal or generalized tonic dystonia an association with HLA-DR13 was reported (van Hilten, J. J. *et al.*, 2000). Furthermore, a different locus, centromeric in HLA-class I, was found to be associated with spontaneous development of CRPS, suggesting an interaction between trauma severity and genetic factors that describe CRPS susceptibility (van de Beek, W. J. *et al.*, 2003).

5.59.5.5 The Future Need for Diagnostic Procedures

To design experiments in CRPS patients, it is important to define the population as precisely as possible. An exact diagnostic classification of the study cohort is essential to perform clinical treatment trials on a homogeneous group.

5.59.5.5.1 Validation of clinical diagnostic criteria

The definition of standardized diagnostic criteria for CRPS in 1995 was a major advance (Stanton-Hicks, M. *et al.*, 1995). However, these criteria were derived based upon the consensus opinion of a small group of expert clinicians. While this was an appropriate first step it is important to continuously improve the criteria, i.e., to validate and, if necessary, modify these initial consensus-based criteria based upon results of systematic validation research. The CRPS diagnostic criteria were adequately sensitive (i.e., rarely miss a case of actual CRPS). However, both internal and external

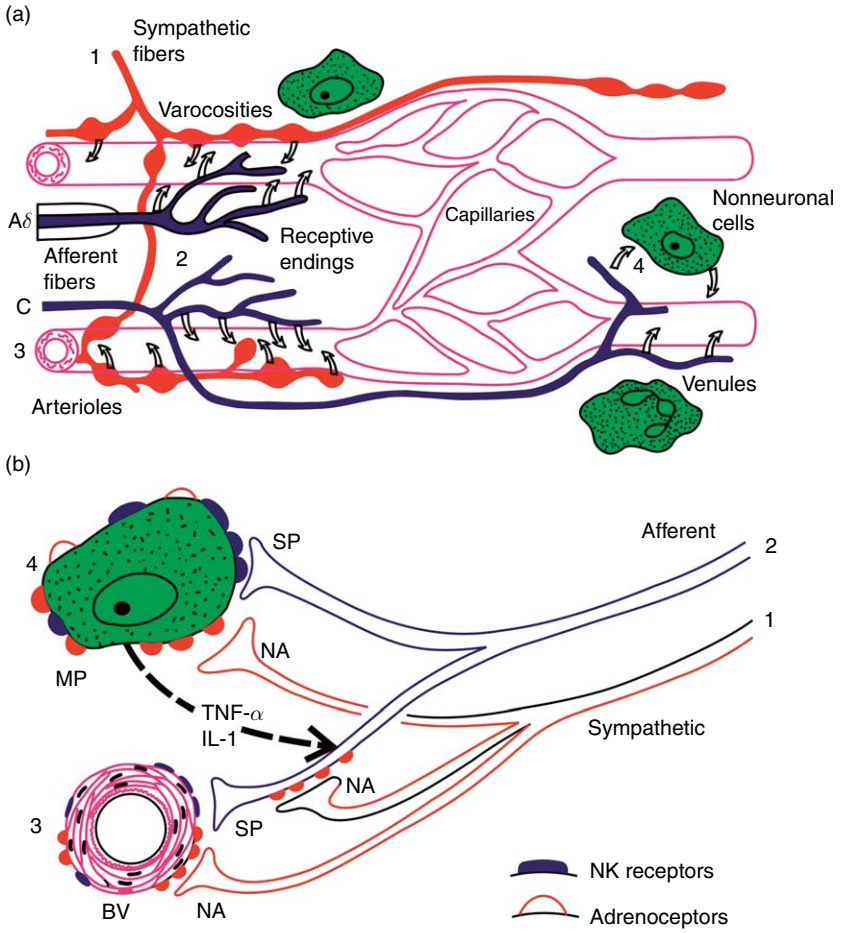

Figure 1 (a) The micromilieu of nociceptors. The microenvironment of primary afferents is thought to affect the properties of the receptive endings of myelinated (A) and unmyelinated (C) afferent fibers. This has been particularly documented for inflammatory processes, but one may speculate that pathological changes in the direct surroundings of primary afferents may contribute to other pain states as well. The vascular bed consists of arterioles (directly innervated by sympathetic and afferent fibers), capillaries (not innervated and not influenced by nerve fibers), and venules (not directly innervated but influenced by nerve fibers). The micromilieu depends on several interacting components: Neural activity in postganglionic noradrenergic fibers (1) supplying blood vessels (3, BV) causes release of noradrenaline (NA) and possibly other substances and vasoconstriction. Excitation of primary afferents (Aδ and C fibers) (2) causes vasodilation in precapillary arterioles and plasma extravasation in postcapillary venules (C fibers only) by the release of substance P (SP) and other vasoactive compounds (e.g., calcitonin gene-related peptide, CGRP). Some of these effects may be mediated by nonneuronal cells such as mast cells and macrophages (4). Other factors that affect the control of the microcirculation are the myogenic properties of arterioles (3) and more global environmental influences such as a change of the temperature and the metabolic state of the tissue. (b) Hypothetical relation between sympathetic noradrenergic nerve fibers (1), peptidergic afferent nerve fibers (2), blood vessels (3), and macrophages (4). The activated and sensitized afferent nerve fibers activate macrophages (MP) possibly via SP release. The immune cells start to release cytokines, such as tumor necrosis factor alpha (TNF-α) and interleukin-1 (IL-1), which further activate afferent fibers. SP (and CGRP) released from the afferent nerve fibers reacts with neurokinin 1 (NK1) receptors in the blood vessels (arteriolar vasodilation, venular plasma extravasation, neurogenic inflammation). The sympathetic nerve fibers interact with this system on three levels: (1) via adrenoceptors (mainly α) on the blood vessels (vasoconstriction); (2) via adrenoceptors (mainly β) on macrophages (further release of cytokines), and (3) via adrenoceptors (mainly α) on afferents (further sensitization of these fibers.) Adapted from Janig, W. and Baron, R. 2003. Complex regional pain syndrome: mystery explained? Lancet Neurol. 2, 687–697.

validation research suggests that CRPS was overdiagnosed (Bruehl, S. *et al.*, 1999; Harden, R. N. *et al.*, 1999). For example, an external validation of the International Association for the Study of Pain (IASP) criteria in 117 patients with CRPS and 43 patients with neuropathic pain without CRPS etiology demonstrated a sensitivity of 0.98 and a specificity of 0.36. The inclusion of a category motor and trophic signs and symptoms, for

Table 1 Revised diagnostic criteria for CRPS

A. Continuing pain, which is disproportionate to any inciting event
B. Categories of clinical signs/symptoms
1. Positive sensory abnormalities
2. Vascular abnormalities
Vasodilation
Vasoconstriction
Skin temperature asymmetries
Skin color changes
3. Edema, sweating abnormalities
Swelling
Hyperhidrosis
Hypohidrosis
4. Motor, trophic changes
Motor weakness
Tremor
Dystonia
Coordination deficits
Nail, hair changes
Skin atrophy
Joint stiffness
Soft tissue
Interpretation
Clinical use
≥1 Symptoms in ≥3 of the categories AND ≥1 signs at time of evaluation in ≥2 of the categories
Sensitivity = 0.85, specificity = 0.60
Research use
≥1 Symptoms in each of the categories each AND ≥1 signs at the time of evaluation in ≥2 of the categories each
Sensitivity = 0.70, specificity = 0.96

CRPS, complex regional pain syndrome.

example, improves specificity considerably without losing sensitivity (Bruehl, S. *et al*., 2002).

Based on this validation research a novel diagnostic algorithm was recently proposed (Table 1, Baron, R. and Janig, W., 2004; Burton, A. W. *et al*., 2005). In addition to the improved clinical categories, it became clear to distinguish between criteria for clinical use and a classification for research purposes. For the clinician and in particular for the patients, it is important to have a high sensitivity value combined with a fair specificity (e.g., 0.85 vs. 0.60, Table 1). For research purposes, however, it is much more important to have a high specificity in order to perform studies in a precisely diagnosed population (e.g., 0.7 vs. 0.96, Table 1).

5.59.5.5.2 Tests which aid the diagnosis of complex regional pain syndrome

Several diagnostic procedures have been evaluated in recent years (Table 2). New techniques to assess specific signs objectively are in the experimental testing phase. Cortical reorganization underlying somatosensory and motor abnormalities can be visualized using MEG and fMRI. Video-assisted kinematic analysis and tremor analysis is used to quantify and qualify motor abnormalities like weakness, coordination deficits and tremor. The acute inflammatory component of the disorder, in particular the role of specific inflammatory mediators, are explored using microdialysis techniques and analysing the content of suction blister fluid. These and other investigations will pave the way for a quantitative and objective analysis of these abnormalities. Furthermore, genetic patterns of patients at risk to develop CRPS have already been revealed and more genes determining the susceptible patient are to come.

Table 2 Diagnostic tests in CRPS

	Sensitivity	*Specificity*
Plain radiograph (only chronic stages)	73	57
Bone scan (only acute stages)	97	86
Quantitative sensory testing (QST)	High	Low
Temperature differences (during sympathetic stimulation)	76	93
MRI (skin, joint, etc.)	91	17

CRPS, complex regional pain syndrome; MRI, magnetic resonance imaging.

In summary, we have to stimulate researchers from various fields to unravel the diagnostic puzzle of the CRPS mystery using an interdisciplinary research approach.

Glossary

allodynia Pain due to a stimulus that does not normally provoke pain.

central pain Pain initiated or caused by a primary lesion or dysfunction in the central nervous system.

hyperalgesia An increased response to a stimulus that is normally painful.

5.60.1 Introduction

Central poststroke pain (PSP) is defined as pain directly caused by a cerebrovascular lesion, regardless of the anatomical location within the central nervous system (CNS).

Neuropathic pain has mainly been discussed in the context of peripheral neuropathic pain, that is, conditions where the injury or the dysfunction is located within the peripheral nervous system (Jensen, T. S. *et al.*, 2001b). Typical examples of diseases affecting the peripheral nervous system giving rise to pain are painful polyneuropathies, such as diabetic neuropathy and toxic neuropathies, postherpetic neuralgia, trigemenial neuralgia, and nerve injuries. Although probably less common and more complex in nature, central neuropathic pain conditions share some of the same phenomena seen in peripheral neuropathic pain, that is, sensory loss in part of the territory with pain, the paradoxical presence of lost sensibility, and hypersensitivity to one or several submodalities of pain (Tasker, R. R. *et al.*, 1991; Schott, G. D., 1995; Bowsher, D. *et al.*, 1998; Boivie, J., 1999). This chapter will briefly review central neuropathic pain after stroke: its underlying mechanisms, clinical picture, and management.

5.60.2 Characteristics of Central Pain After Stroke

Despite the heterogeneity in etiology and anatomical location, neuropathic pains share certain characteristics (Boivie, J., 1999; Woolf, C. J. and Mannion, R. J., 1999; Jensen, T. S. *et al.*, 2001b; Dworkin, R. H. *et al.*, 2003):

- Pain located in a neuroanatomically defined area with partial or complete sensory loss.

- Ongoing pain (stimulus independent).
- Evoked types of pain (stimulus dependent).
- Hypersensitivity.

These symptoms and signs may occur in various combinations but do not necessarily have to be present altogether at the same time and in all patients affected by the same disease. There are no universally accepted criteria for PSP, but the following seem to be minimal criteria:

- A confirmed cerebrovascular accident.
- Development of pain after stroke.
- Sensory abnormality (hypo- or hypersensitivity to temperature or pinprick) in a body area corresponding to the CNS region damaged by the stroke.
- Pain located within the body area of sensory abnormality.

5.60.2.1 Symptoms in Central Pain

As for peripheral neuropathic pain, central pains are characterized by the presence of spontaneous types of pain and various types of evoked pains (Boivie, J., 1999; Jensen, T. S. *et al.*, 2001b).

Ongoing pains. These pains are spontaneous and may be continuous or paroxysmal. The character differs, but they can be shooting, shock-like, aching, cramping, crushing, smarting, burning, etc. No specific pain character has been associated with PSP (Boivie, J., 1999).

Evoked pains. The stimulus-evoked pains are classified according to the type of stimulus that provokes them. Several types of evoked pains can be present; the most prominent types in PSP are mechanical and thermal.

In some patients ongoing pain is dominating, in others evoked pain. Some patients have several of these phenomena, others only one type of hyperalgesia. For example, in some patients with neuropathy, cold allodynia may be the only abnormality present. Therefore, a number of different stimuli have to be used to document or exclude abnormality. The evoked pains are usually brief, lasting only for the duration of stimulation, but sometimes they can persist even after cessation of stimulation causing aftersensations (see below), which can last for minutes, hours, or perhaps days. In such cases, the distinction between evoked and spontaneous pain can be difficult. Both evoked and spontaneous pains may be confined to deep structures.

5.60.2.2 Sensory Abnormalities

Sensory disturbances are key phenomena in patients with PSP and a variety of disturbances may be present.

Sensory deficit and pain. An essential part of neuropathic pain is a loss (partial or complete) of afferent sensory function. In some patients the sensory deficit may be gross, in others subtle and difficult to detect with bedside methods, but quantitative testing can usually disclose minor changes. The sensory loss may involve all sensory abnormalities, but a loss of spinothalamic functions (cold, warmth, and pinprick) appears to be crucial, and there is now some evidence to indicate that spinothalamic loss is a necessary, albeit not sufficient, requirement for the development and maintenance of pain (Andersen, G. *et al.*, 1995; Vestergaard, K. *et al.*, 1995). In the study by Andersen G. *et al.* (1995), decreased sensibility to all types of stimuli was seen in the same proportion of patients, regardless of the presence of pain. It can occasionally be difficult to document sensory loss because of the additional presence of hypersensitivity phenomena in the same area.

Sensory hypersensitivity and pain. Another characteristic of PSP is the paradoxical presence of hyperphenomena in the painful area. These hyperphenomena may be present as hypersensitivity, allodynia, or dysesthesia to one or several sensory modalities (touch, pinprick, cold, or warmth). Allodynia or hypersensitivity has mainly been noted as a cutaneous phenomenon, but it was originally suggested that allodynia could also be present in deep structures as a hyperalgesia to pressure (Vestergaard, K. *et al.*, 1995). Consistent with this observation, Bowsher D. *et al.* (1998) noted movement-induced allodynia in 9 of 73 patients, and in another study, 22% of 92 patients with central pain had movement-induced pain (Bowsher, D., 1996). A dissociation of cutaneous and deep sensibility has been noted in three case reports (Mailis, A. and Bennett, G. J., 2002). In the study by Andersen G. *et al.* (1995), cold allodynia/dysesthesia was present in 88% of PSP patients but only in 3% of stroke patients with nonpainful sensory abnormalities. Similarly, 75% had touch-evoked allodynia or dysesthesia while none in the group without pain had these abnormalities. In the study by Bowsher D. *et al.* (1998), 59% of the patients had allodynia mostly seen as a mechanical allodynia. Abnormal temperature and pain sensibility are the most consistent abnormalities in PSP. In two studies, it was found that 81%

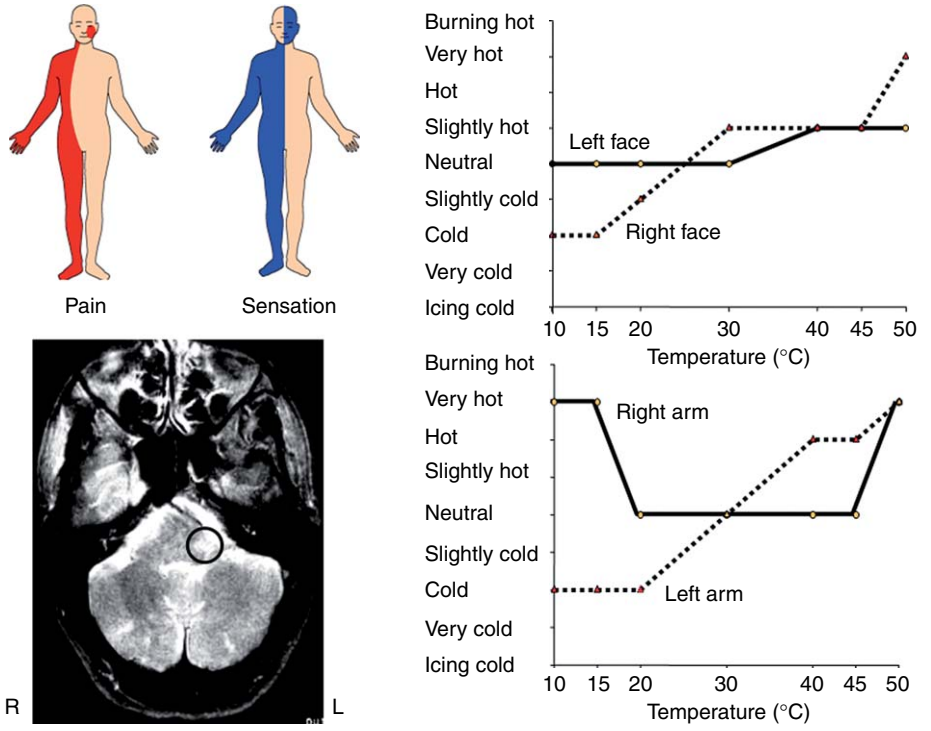

Figure 1 A case presenting a 75-year-old patient with lateral medullary infarction and central pain. At the age of 68, he experienced short-lasting vertigo. At the age of 72, he had a left brain infarction with left facial and right hemibody ongoing pain and burning pain evoked by touch. The magnetic resonance imaging (MRI) scan shows a left lateral medullary infarction. Stimulus–response functions of cold and warm stimuli in the patient using a thermotester showing decreased thermal sensation on the left side of the face and paradoxical sensitivity to cold on the left side of the body.

had reduced sensibility to temperature (Boivie, J., 1989; Andersen, G. *et al.*, 1995). In some studies, on the other hand, sensation to touch is only reduced in a smaller proportion of patients (Boivie, J., 1989).

Based on the observation that thermal sensation is also disturbed in a large proportion of stroke patients with no pain, it has been concluded that loss of spinothalamic function mediating thermal stimuli is a necessary, but probably not a sufficient condition for the development of PSP (Jensen, T. S. and Lenz, F. A., 1995). In addition to the sensory deficit, some patients may have a paradoxical sensitivity to cold and heat so that cold is perceived as hot and vice versa. An example of a patient with a lateral medullary infarction and such a sensory pattern is shown in Figure 1.

5.60.3 Epidemiology of Poststroke Pain

There is limited information on the frequency of PSP. A prospective study found that 8.4% of 191 unselected consecutive stroke patients developed PSP within the first year after stroke (Andersen, G. *et al.*, 1995). In an unpublished study from the UK, the frequency of PSP was found to be 11% in a group of stroke patients aged 80 years and above (Bowsher, D., personal communication).

In 63 patients with lateral medullary infarction, 16 (25%) developed central pain within 6 months after stroke. There was a significant relationship between the degree of sensory loss and the development of pain, suggesting to the authors that pain is a result of a lesion of the neospinothalamic system, which causes a denervation sensitivity of the paleospinothalamic system. In patients with sensory disturbances, the frequency of pain is much higher: thus 44% in one series (MacGowan, D. J. *et al.*, 1997) and 18% in another series (Andersen, G. *et al.*, 1995).

Stroke lesion. Both infarcts and hemorrhages may cause PSP (Andersen, G. *et al.*, 1995; Bowsher, D. *et al.*, 1998; Kim, J. S., 2003). Based on the fact that ischemic lesions are 7–8 times more frequent than are hemorrhages, infarction is the most common cause for PSP. Lesions are known to occur at any level of

the spinothalamic pathways and its cortical projection. Previous studies using computed tomography (CT) imaging show that the lesion involves the thalamus in one-fourth to one-third of cases (Bogousslavsky, J. *et al.*, 1988; Leijon, G. *et al.*, 1989; Andersen, G. *et al.*, 1995). In one study of PSP, more than 60% of patients had a lesion of the ventroposterior thalamic nucleus demonstrated by magnetic resonance imaging (MRI) (Bowsher, D. *et al.*, 1998). In a series of 63 patients with lateral medullary infarctions, it was found that 16 patients (25%) developed a PSP within 6 months after their stroke (MacGowan, D. J. *et al.*, 1997). In another series of 55 patients with medullary infarctions, 24 patients had sensory complaints from the face (Kim, J. S. and Choi-Kwon, S., 1999).

5.60.4 Mechanisms of Pain

The pathophysiological mechanisms underlying peripheral neuropathic pain have been reviewed extensively in recent years (Besson, J. M., 1999; Woolf, C. J. and Salter, M. W., 2000; Koltzenburg, M. and Scadding, J., 2001; Jensen, T. S. *et al.*, 2001a; Bolay, H. and Moskowitz, M. A., 2002).

Evidence from a large number of studies indicates that neuronal hyperexcitability, either at the level of the peripheral receptor or centrally, plays a key role in generating pain after nerve injury. The mechanisms responsible for central pain after stroke are much less clear. The combination of symptoms and signs is compatible with a general sensitization of second- or third-order neurons in the CNS that have lost part of their normal patterned input and are substituted by a changed afferent influx. In fact, sensitization is today considered to be an essential phenomenon behind persistent neuropathic pains (Woolf, C. J. and Salter, M. W., 2000; Woolf, C. J. and Max, M. B., 2001; Dworkin, R. H. *et al.*, 2003; Jensen, T. S. and Baron, R., 2003).

Patients with central pain display ongoing spontaneous pain and abnormally evoked pain with hypersensitivity to noxious and nonnoxious stimuli in the painful area. These findings suggest that hypersensitive pools of cells are present in the nervous system and that they probably are involved in generating pain (Tasker, R. R. *et al.*, 1991; Jensen, T. S. and Lenz, F. A., 1995; Schott, G. D., 1995). Several hypotheses have been forwarded. The most important ones are summarized briefly below:

Spinothalamic tract lesion. Sensory examination and more elaborative quantitative sensory analysis show that patients with PSP have abnormal temperature and pain sensitivity, but normal epicritic sensibility (touch, vibration, and pressure). In addition, it is well known that dorsolateral infarctions of the lower medulla and cordotomies, two conditions characterized by loss of spinothalamic but preservation of lemniscal pathways, cause central pain (Boivie, J. *et al.*, 1989; Vestergaard, K. *et al.*, 1995; Nathan, P. W. *et al.*, 2001).

Subsequent studies have indicated that while a spinothalamic tract lesion and its cortical projection is necessary for the development of pain, it is not sufficient for the development of central pain (Jensen, T. S. and Lenz, F. A., 1995) since similar somatosensory disturbances may occur in stroke patients without pain (Andersen, G. *et al.*, 1995; Vestergaard, K. *et al.*, 1995).

Lemniscal disinhibition. In their original description Head H. and Holmes G. (1911) suggested that injury to the lateral part of thalamus sets free a medial thalamic center and the result is allodynia to all types of stimuli. A consequence of this theory is that sensory modalities such as touch, vibration, and pressure conveyed by the lemniscal system exert a control over pain and temperature, so that sensory deficit in discrimination causes spontaneous pain and allodynia.

Loss of normal cold inhibition. On the basis of experimental studies in animals and in humans, Craig A. D. (2000) has suggested that central pain is due to loss of a normal inhibitory effect exerted by cool-signaling pathways from lamina I projecting to the thalamus and insula. According to this hypothesis, a lesion of the lateral cool projection system disinhibits the medial system of heat–pinch–cold neurons passing from lamina I to the medial part of the thalamus. This disinhibition then results in the release of cold allodynia and burning and ongoing pain (Craig, A. D. and Bushnell, M. C., 1994; Craig, A. D., 2000). Disruption of thermosensory integrations leads to a disinhibition of noxious responding thalamocortical neurons and a sensation of burning pain (Craig, A. D., 2000). The hypothesis and the processing of cold proposed by Craig has been criticized by Willis W. D. Jr. *et al.* (2002), and more recently, Greenspan J. D. *et al.* (2004) suggested, based on studies in 13 patients with PSP, that cold allodynia is not caused by loss of normal cold pathway but is rather due to input via an intact cold pathway driving nociceptive neurons in the thalamus. So it is still unclear whether and to what

extent an intact cold pathway plays a role for the cold allodynia seen in stroke patients.

Thalamus and PSP. In all instances of PSP, the thalamus is thought to play a role for the pain. The most critical parts of the thalamus are the ventroposterior part, the medial intralaminar nuclei, and the reticular nucleus, but the exact mechanisms of central pain are still unclear. Based on clinical and experimental observations, it has been suggested that the development of PSP may be related to an imbalance in the activity of the spinothalamic and reticulothalamic systems so that if the former is damaged, as for example in medullary infarction, this may result in pain from non-noxious stimuli via the reticulothalamic pathway (Tasker, R. R. *et al.*, 1991; MacGowan, D. J. *et al.*, 1997).

5.60.5 Treatment

There is limited amount of data on pharmacological treatment of PSP and no evidence to support treatment of the individual patient based on symptoms and signs. Pharmacological agents used to treat PSP share the ability to interfere with some of the processes involved in neuronal hyperexcitability either by decreasing excitatory or by increasing inhibitory transmission, thereby exerting a neuronal depressant effect.

5.60.5.1 Antidepressants

Tricyclic antidepressants inhibit the presynaptic reuptake of noradrenaline and serotonin and interfere with *N*-methyl-D-aspartate (NMDA) receptors and sodium channels (Sindrup, S. H. *et al.*, 2005). Amitriptyline 75 mg day^{-1} effectively relieved PSP (Leijon, G. and Boivie, J., 1989). The pain-relieving effect correlated with total plasma concentration, with a plasma concentration of amitriptyline and its metabolite nortriptyline exceeding the 300 nmol l^{-1} necessary for pain relief. Amitriptyline administered from the first day after a stroke and thereafter for 1 year in 39 stroke patients did not prevent PSP and allodynia (Lampl, C. *et al.*, 2002). Seven patients developed PSP (three receiving amitriptyline and four receiving placebo), and a large sample size is needed to exclude a type II error. Tricyclic antidepressants cannot be used in patients with heart failure, cardiac conduction disturbances, and epilepsy, and side effects including dry mouth, sweating, and sedation may limit their use. Recently, serotonin noradrenaline reuptake inhibitors with a better side-effect profile have been shown to relieve peripheral neuropathic pain, but these antidepressants are not yet studied in central pain conditions. Selective serotonin reuptake inhibitors are less effective in relieving neuropathic pain (Sindrup, S. H. *et al.*, 2005), and citalopram was found not to relieve PSP (Vestergaard, K. *et al.*, 1996).

5.60.5.2 Sodium Channel Blockers

In peripheral neuropathic pain, increased and abnormal sodium channels are known to be a source of neuronal hyperexcitability (Waxman, S. G. *et al.*, 2000). A role for such sodium channels and neuronal hyperexcitability in central pain in humans is supported by randomized controlled trials using sodium channel blockers. In 16 patients with central pain (six with PSP), lidocaine 5 mg kg^{-1} given intravenously over 30 min alleviated spontaneous ongoing pain, brush-induced allodynia, and mechanical hyperalgesia (Attal, N. *et al.*, 2000). This effect in central pain may be related to suppression of ectopic discharges from hyperexcitable central neurons. This is supported by a recent experimental study demonstrating increased expression of abnormal sodium channels functionally linked to neuronal hyperexcitability and central pain behaviors on second-order dorsal horn neurons close to a spinal cord lesion (Hains, B. C. *et al.*, 2003).

Along this line, the sodium channel blocker lamotrigine, at a relatively low dosage of 200 mg day^{-1}, reduced ongoing pain with a mean reduction of 30% and cold allodynia in PSP patients (Vestergaard, K. *et al.*, 2001). Lamotrigine was generally well tolerated. Side effects associated with the use of lamotrigine include dizziness, nausea, headache, and fatigue. Rash and potentially life-threatening hypersensitivity reactions are rare but potential risks, and slow dose escalation is recommended to minimize these risks. Carbamazepine 800 mg day^{-1} showed a statistically nonsignificant trend toward a pain-relieving effect in PSP (Leijon, G. and Boivie, J., 1989).

5.60.5.3 Opioids

Opioids seem to effectively relieve peripheral neuropathic pain with an effect size in line with tricyclic antidepressants and gabapentin/pregabalin (Finnerup, N. B. *et al.*, 2005) but seem to be less effective in PSP, although a subgroup of patients may respond well to opioids (Attal, N. *et al.*, 2002; Rowbotham, M. C. *et al.*, 2003).

5.60.5.4 Gabapentin

Gabapentin, which binds to the $\alpha_2\delta$ subunits of the voltage-dependent calcium channels, has not been studied in PSP but has been found to relieve spinal cord injury pain (Levendoglu, F. *et al.*, 2004), and given its tolerability, it is a treatment option in PSP.

5.60.5.5 GABA Agonists

Increasing γ-aminobutyric acid (GABA)-mediated inhibition using intravenous propofol is reported to relieve central pain including PSP (Canavero, S. and Bonicalzi, V., 2004), but propofol is very sedating and oral GABA agonists have not proven effective in neuropathic pain.

5.60.5.6 Treatment Option

Based on a few randomized controlled trials, an evidence-based treatment algorithm for PSP is not possible, but lamotrigine, gabapentin, tricyclic antidepressants, or serotonin noradrenaline reuptake inhibitors may be suggested as first choice.

5.61.1 Measuring the Single Dimension of Pain in the Laboratory and in the Clinic

To the layman, the pain threshold is often synonymous with the concept of pain sensitivity. It is used to describe individual differences, such as, "she has a high pain threshold." In pain research, the threshold describes a distinction between sensory qualities of nonpainful and painful. As the magnitude of a noxious stimulus is increased, the pain threshold marks the transition from the absence of pain sensation to the presence of pain sensation, and is quantified as the amount of stimulus intensity needed to evoke a painful sensation.

In the clinic, gross changes in pain threshold can be assessed in a qualitative way by administering a standard stimulus (e.g., safety pin, manual palpation) and by asking if the evoked sensation is painful (e.g., "does this hurt?"). More precise, quantitative methods increase the intensity of the stimulus until the evoked sensation is described as painful. The amount

of stimulus intensity at this point, or the average from a number of trials, is the pain threshold. Clinical examples of this method are the determination of the pain pressure threshold (PPT) to blunt pressure by mechanical or electrical dolorimeters for syndromes such as temporomandibular disorders or fibromyalgia (Petzke, F. *et al.*, 2003a; 2003b).

5.61.1.1 Measuring Pain in the Laboratory

In the laboratory, the pain threshold is determined by more extensive psychophysical procedures that are designed to control for a number of biases that may influence threshold assessments. These share a number of common features. They present a series of stimuli of varying intensity in a random sequence, or increasing from a randomly varied starting point. Subjects judge and rate the sensations evoked by each stimulus, and the different paradigms are designed to collect fresh judgments of the evoked sensations while minimizing extraneous information about stimulus intensity. They assume that the threshold is not succinct, but rather spans a range of stimulation in which painfulness is uncertain.

These laboratory methods include the classical Method of Limits, which uses alternating ascending and descending series of continuous or discrete stimuli, and the Method of Constant Stimuli that presents discrete stimuli of varying intensities that span the range from certain judgments of nonpainful to certain judgments of painful. Figure 1(a) shows an example of the method of limits. This method is usually modified for pain evaluation by using only ascending series to avoid the possibility of unacceptably painful stimulation at the beginning of a descending series. Biases are controlled by varying the starting point or step size, and traditionally in studies of nonpainful stimulation, the use of ascending and descending series to control for directional errors such as anticipation, of indicating the presence of pain before the sensation becomes painful, and errors of habituation, of continuing to use the nonpainful responses after the stimulus has become painful (Engen, T., 1971a). Figure 1(b) shows a histogram of a sequence of random stimuli that span the gray area between certain responding and an example of a probability function generated by this procedure. In addition to these classical methods, Figure 1(c) shows the logic of signal detection theory or sensory decision theory (SDT) evaluation, which can be conceptualized in sensory detection as a 2×2 table of the four possibilities of whether a particular stimulus value was delivered on a trial (versus delivery of nothing, termed a blank stimulus) and whether a sensation was detected or not. The common SDT terms for the four possibilities are a hit (correctly identifying a delivered stimulus), a correct rejection (correctly indicating that no stimulus was given) and the two errors of a miss (not identifying a stimulus when it was given), and a false alarm, indicating that a stimulus was given when it was not. The reader can appreciate that this 2×2 table is common in statistics, where the correct responses are referred to as accepting or rejecting the null hypothesis, and the errors are referred to as the α or type I error (labeling an effect as present when it is not, corresponding to a false alarm), and β or type II error (labeling something as absent when it is present, corresponding to a miss). Probably the most self-explanatory labels for the four outcomes are true positive, true negative, false-positive, and false-negative. While the classical methods consider the concept of a threshold to be fuzzy, and therefore best described by a mean or probability, SDT extends the concept to include two variables. One is a measure of sensitivity of the system, directly analogous to a statistic such as t or Z, which can be thought of as a distance between determinations of no detection and detection (or no pain and pain) divided by the variability of these judgments. The second refers to the labeling behavior, and is directly related to the α level (such as $p < 0.05$) arbitrarily set by an experimenter in statistics. It describes the willingness to use specific responses, and it can be liberal or conservative. As in statistics, this behavior divides the gray area of indecision into two types of error. For a given sensitivity, changing this behavior decreases one error only at the expense of increasing the other. For example, adapting a liberal criterion and calling uncertain sensations painful increases the false alarm error (or α, type I, or false-positive) while decreasing the miss error (or β, type II, or false-negative).

One of the first applications of SDT was to assess the performance of radar operators (Swets, J. A., 1964). In this context, the sensitivity parameter d' describes the overall sensitivity of the system, which includes the visual acuity of the human operator and the physical capabilities of the radar receiver. The response criterion parameter is set by the operator and in this case determined by the demand

characteristics. During wartime, operators must adapt a liberal criterion to label any suspicious blip as an enemy plane. This vigilant strategy minimizes the misses at the expense of increased false alarms. Other situations such as capital punishment must adapt the opposite conservative criterion, to be as sure as possible of a hit, minimizing false alarms at the expense of increased misses.

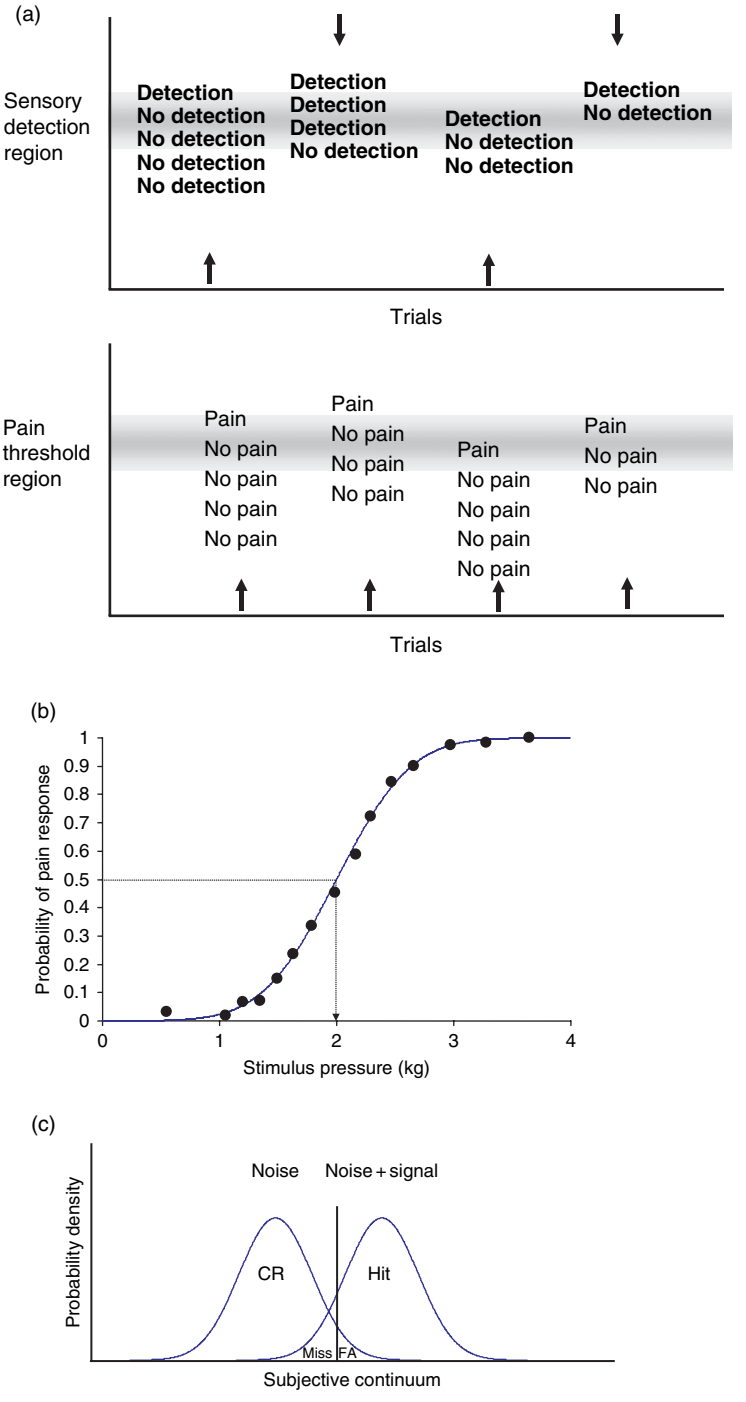

Figure 1 (Continued)

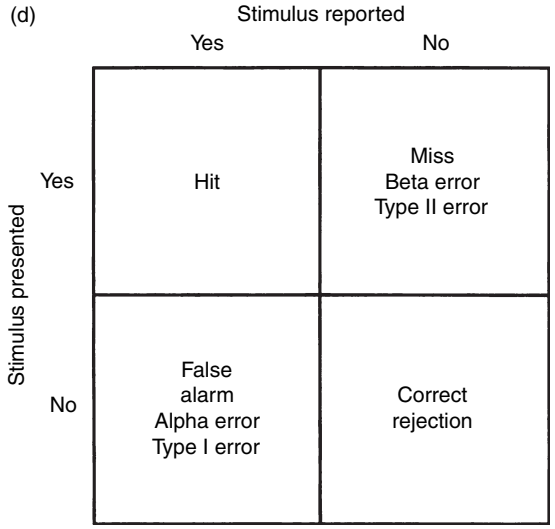

Figure 1 (a) The method of limits. Stimulus intensity is increased in successive discrete presentations on trial 1 until a positive response (yes) is made. Intensity is decreased on trial 2 until a negative response (no) is made. Several trials are run with varied initial starting intensities. The threshold is defined as the mean of the response transitions for each trial. A common modification of the method of limits to measure pain threshold delivers only ascending series to avoid excessively painful stimulation. (b and c) The method of constant stimuli. (b) Shows a range of stimulus intensities about the threshold that are presented in random sequence. (c) Shows the probability of a positive response over stimulus intensity. The result typically is an ogive shape (cumulative normal distribution) and the threshold is defined as the stimulus intensity corresponding to a specific response probability (in this case 0.5). This method emphasizes that the transition between no sensation, nonpainful sensation, and pain sensation shown in (a) is not distinct and varies over trials. (c and d) The logic of signal detection theory (SDT). (c) Shows the sensory distributions of a blank stimulus and an actual stimulus. Because of noise in the system, these distributions overlap. (d) Shows the four possibilities of signal presence and response choice. (d) This table is analyzed in terms of discrimination sensitivity and the relative frequency of the errors of false alarms or misses.

SDT methods are easily implemented by including the presentation of blank stimuli to determine the rate of false-positive errors. In addition to SDT, the robust method of two alternative forced choice (2ALFC) controls the labeling behavior rather than assessing it, while providing a measure of sensitivity similar to that provided by SDT. The 2ALFC is implemented by presenting two stimuli at the same time in different places (e.g., left and right hands) and asking which was the true stimulus or which had the greater sensation. The same method can also be used by applying two stimuli to the same (or different) place at different times and asking whether the first or second stimulus period contained the stimulus or had a greater sensation.

There are a number of issues that have been raised about the pain threshold, which assesses pain sensitivity only at the very bottom of the pain range. One issue is whether SDT methods are superior to the classical procedures. This is also an issue for suprathreshold scaling and this issue is presented below in the suprathreshold context. SDT methods usually require more trials than conventional procedures, which may be problematic if these trials are painful. Another issue is whether the pain threshold predicts suprathreshold sensitivity. Figure 2 shows that the answer is "not always." In the clinical condition of

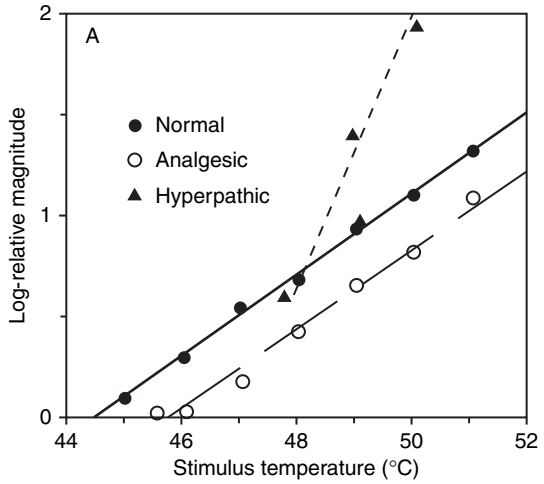

Figure 2 Pain thresholds may not indicate suprathreshold sensitivity. The triangles show the type of function that could be obtained in the clinical condition of hyperpathia in which the threshold is raised and suprathreshold sensitivity is increased.

hyperpathia, an elevated pain threshold (decreased pain sensitivity) is combined with significant suprathreshold sensitivity. Increasing the intensity of the stimulus does not evoke a sensation at usual levels and an explosive experience of pain at higher levels. In cases in which the pain threshold is predictive of suprathreshold sensitivity, an issue is whether it is more or less sensitive, and more or less responsive to pain interventions.

Another issue is the presence of prepain sensation. In studies of nonpainful modalities, the sensation is either not present or present, as shown in Figure 1(c). In pain studies, there are usually three alternatives: nothing, nonpainful sensation, and painful sensation. This leads to some operational difficulties with methods such as SDT, and changes detection tasks (with the control provided by blank stimulation) to rating tasks described below.

5.61.1.2 Measuring Pain in the Clinic

The requirements of clinical and laboratory assessments are usually quite different. Because of the limitations of time, the need to test multiple areas with multiple modalities, and the gross nature of many clinical abnormalities, clinical methods are necessarily brief and thus devoid of the protection against bias contained in the classical and more modern methods. This may not be an important issue in specific situations, but can significantly influence the outcome, especially when the comparisons are between individuals.

These issues of clinical versus laboratory methods were addressed in a recent study by Petzke F. *et al.* (2003a) that compared the influence of psychological distress on clinical and laboratory measures of the PPT in fibromyalgia. This study compared the methods described above. The qualitative clinical method is the manual tender point count, which applies a standard stimulus (4 kg of thumb pressure) to nine bilateral pairs of defined tender points defined by the American College Rheumatology (1990). The tenderness part of the diagnosis of fibromyalgia is satisfied if the standard stimulus evokes pain in at least 11 of the 18 tender point sites. The reader can appreciate that patients with fibromyalgia know about these points and criteria, and know what to say if they want to satisfy this aspect of the diagnosis.

The quantitative clinical measure used a standard commercial dolorimeter at the same 18 tender point sites, slowly increasing the pressure of a 1 cm diameter probe until the sensation is reported to be painful. The laboratory procedure used the multiple random staircase (MRS) method (see below) that uses a computerized interactive logic to determine the PTT and also pain sensitivity at more intense levels between pain threshold and tolerance (Petzke, F. *et al.*, 2003b).

Since one theory of tenderness in fibromyalgia is that it is the extreme tail of a normal distribution of tenderness, Petzke F. *et al.* (2003a) composed a group of 76 subjects that included both healthy controls and patients with fibromyalgia with a normally distributed range of PPTs determined by a dolorimeter. Table 1 shows the association of the different measures of pressure pain sensitivity with measures of psychological distress. The manual tender point count is significantly associated (23%) with distress, the more quantitative clinical dolorimeter is significantly but less associated (15% at tender points, 12% at thumb) with distress, while the random psychophysical method applied to the thumb is insignificantly associated with distress (4%).

Table 1 Results of regression analysis[a]

	R^2	*B*	*SE*	*Significance*
MTPC	0.23	0.24	0.06	0.001
DM-PT	0.15	−0.02	0.009	0.008
DM-THU	0.12	−0.08	0.033	0.019
RAN	0.04	0.59	0.42	0.169

[a]*R*-square, regression coefficient *B*, standard error of *B*, significance , for four dependent measures of tenderness measures with distress (GSI) as independent variable. MTPC is the manual tender point count, defined as the number of 18 predefined sites at which 4 kg of manual thumb pressure evokes pain. DM-PT is the mean of dolorimeter measures of the pain pressure threshold obtained at the 18 tender point sites. DM-THU is the dolorimeter-derived pain pressure threshold obtained at the left thumbnail. RAN is the pressure pain sensitivity at the left thumbnail determined by the multiple random staircase method. Adapted from Petzke, F., Gracely, R. H., Park, K. M., Ambrose, K., and Clauw, D. J. 2003b. What do tender points measure? Influence of distress on 4 measures of tenderness. J. Rheumatol. 30, 567–574.

5.61.1.2.1 Quantitative sensory testing methods

The influence of distress may be less of an issue in other clinical situations. In cases in which multiple determinations are made in a single individual and compared between sites, trait characteristics of individual response styles may cancel out. In addition, in many cases the abnormalities that are the target of the evaluations are so dramatic that they can be accurately assessed by a variety of methods. Indeed, simple threshold measures form the core of a set of procedures referred to as quantitative sensory testing (QST). After a considerable history in which clinicians applied pinpricks to patients in the clinic and psychologists applied electrical or thermal stimuli to healthy students in the laboratory, QST bridged the gap, applying an increasing number of stimulus methods and modalities to patients with a variety of pain complaints. The section below briefly summarizes these methods, and provides a few examples of studies in which pain psychophysical threshold procedures have elucidated mechanisms and aided diagnosis. It focuses on the pain in pain psychophysics.

The goal of sensory assessment is to obtain information from the neural system, which may help in diagnosis and treatment of disorders in the nervous system itself and in surrounding tissue. Traditionally, this examination included the response to a brush, a cotton swab, a warm or a cold object, and a pinprick (Hansson, P., 2002). QST extends these methods.

For clinical applications, the methods can be organized into a protocol that is applied routinely to all patients. Determination of an abnormality can be made on the basis of comparison to a set of standard control values, although comparison to a contralateral unaffected site in the same patient may be the best approach when available (Kemler, M. A. *et al.*, 2000).

Common stimulus modalities used to assess the function of specific nerve fibers are:

1. Touch, electrical, and vibratory stimuli for the evaluation of the function of the thickly myelinated Aβ fibers.
2. Cold detection threshold for the assessment of thinly myelinated Aδ fibers.
3. Heat detection threshold for the assessment of thin unmyelinated C-fibers.

Touch and vibration sensitivity is usually determined by the detection and pain thresholds to both calibrated monofilaments and a vibrating probe. Four different thermal parameters (thresholds to warm and cold stimuli, heat pain, and cold pain) are typically assessed by Peltier element-based thermal stimulators. The cold pain threshold is a specific test for cold allodynia, a common finding in conditions involving nerve injury. Altered heat pain thresholds can reflect either the function of myelinated Aδ fibers or unmyelinated C-fibers, depending on the rate, location, and sequence of stimulation (Collins, W. R. *et al.*, 1960; Price, D. D. *et al.*, 1989; Andersen, O. K. *et al.*, 1995; Koltzenburg, M., 1997).

Tests of the area of abnormality assess the threshold for sensory detection, and usually a higher threshold for pain. In some cases both may be altered, or the sensory detection threshold may be absent, and stimulation evokes only pain. The profile of altered sensory and pain thresholds across mechanical and thermal modalities provides information about the type of nerve abnormality, and can be supplemented by additional tests that examine pain processing at levels above the pain threshold (Hansson, P., 2002). Since it is important to ascertain whether the distribution of sensory abnormalities match the damaged nerve's dermatome, the borders of sensory dysfunction area should be carefully determined using the different modalities. The finding of extraterritorial pain that extends beyond the border of a dermatome is discussed below.

The response to electrical stimulation is usually not included in standard QST assessments, and several studies have found conflicting and inconsistent results using electrical tests (Hagberg, C. *et al.*, 1990; Vecchiet, L. *et al.*, 1991; Bendtsen, L. *et al.*, 1997). However, recent studies demonstrate a number of unique features of electrical stimulation. Unlike the other methods, which naturally stimulate nerve receptors, electrical stimuli may bypass the receptor to stimulate the axon of the primary afferent. Due to this property, electrical stimulation does not show the same temporal profile of sensitization, suppression, or fatigue as found in natural stimulation of receptors. In addition, at the threshold for detection, electrical stimuli exclusively activate the thickly myelinated Aβ fibers. Thus, a comparison of the detection threshold to both mechanical and electrical stimuli can provide a differential method that isolates receptor and postreceptor processes of Aβ fibers. Changes in both or in only electrical detection indicate a postreceptor process, while changes in only the results of mechanical stimulation indicate a receptor process. Thus, altered electrical sensitivity alone indicates a postreceptor process in large myelinated fibers. A single electrical test can identify a number of central processes, including spinal sensitization resulting in Aβ-mediated allodynia, and inflammatory processes that include the nerve in passage. One

problem with electrical sensory assessment is interpatient variability. This inconsistency can be reduced by expressing the electrical detection thresholds as the ratio between the pathological and the contralateral side, that is, the healthy side used as a control for the pathological side (Kemler, M. A. *et al.*, 2000).

The results of QST methods help distinguish between nociceptive and neuropathic pain, which differ significantly in etiology, mechanism, and effective treatment. Nociceptive pain is the normal condition in which actual or impending tissue damage is sensed by the receptor organs, nociceptors, resulting in a range of normal pain conditions that may be treated with conventional (e.g., NSAID, opioids) analgesics. Neuropathic pain describes a special condition in which the sensing neural apparatus is damaged, leading to a variety of pain sensations with unnatural characteristics of quality and distribution. Neuropathic pain can be particularly difficult to treat, and successful agents include drugs such as anticonvulsants that modify neural function.

5.61.1.2.2 Quantitative sensory testing signatures of pathological conditions

Mechanical nerve damage or total nerve transection is characterized by myelinated and unmyelinated nerve fiber hyposensitivity reflected in elevated detection thresholds to heat, electrical, and mechanical stimulation (Dao, T. T. and Mellor, A., 1998). Partial damage may be followed by either hypo- or hypersensitivity accompanied by ongoing neuropathic pain (Benoliel, R. *et al.*, 2001; 2002).

In contrast to the neuropathic process of mechanical nerve damage, specific nociceptive processes may provide a different, identifiable sensory signature. For example, early perineural inflammation produces short-lasting large myelinated nerve fiber hypersensitivity that results in reduced detection to electrical and mechanical stimuli. This increased detection sensitivity has been demonstrated in clinical studies and in animal spinal nerve models (Eliav, E. and Gracely, R. H., 1998; Eliav, E. *et al.*, 1999; Chacur, M. *et al.*, 2001; Eliav, E. *et al.*, 2001; 2003) and reproduced in a model of inflammatory trigeminal nerve neuropathy (Benoliel, R. *et al.*, 2002).

Although the mechanisms are not clear, muscle-induced pain may result in the opposite effect, that is, reduced large nerve fiber sensitivity reflected by elevated electrical or mechanical detection thresholds (Stohler, C. S. *et al.*, 2001; Eliav, E. *et al.*, 2003). In the orofacial region, there is both experimental and clinical evidence for this effect. Following injection of hypertonic saline to the masseter muscle, mechanical stimuli applied into the overlying skin induced significant increases in the verbal rating score (Svensson, P. *et al.*, 1998), and lowered pain thresholds to this type of stimulation have been found in patients with orofacial myofascial pain (Svensson, P. *et al.*, 1998; 2001).

Both neuropathic and intense nociceptive pain can initiate and maintain a condition of spinal central sensitization (CS). CS is characterized by spontaneous pain and evoked pain abnormalities that can cross dermatomes. One striking abnormality is dynamic mechanical allodynia, pain to light brushing of the skin. Theoretically, this can be mediated by either sensitized pain fibers or a functional change in large-diameter Aβ fibers that usually only mediate the sense of touch. Mechanical stimulation cannot distinguish between these alternatives, but recent evidence shows that a ratio between the electrical pain and the detection threshold of <2.0 may indicate altered central nervous system processing of Aβ fiber input (Sang, C. N. *et al.*, 2003). This result is strong evidence of altered central pain modulation and CS.

Combining the above procedures into one methodological approach provides a clinical decision-making tool that facilitates diagnosis and choice of treatment. The following section illustrates how these tests have helped identify the underlying mechanisms of three painful syndromes.

5.61.1.2.3 Clinical studies

5.61.1.2.3.(i) Burning mouth syndrome Burning mouth syndrome (BMS) is a putative centrally mediated pain that is poorly understood and treated. BMS is diagnosed only when the burning sensation is not associated with a local or systemic pathology. In contrast, burning mouth symptoms (BMST) is diagnosed in the presence of a known etiology for the altered sensation. BMS is an intraoral disorder most prevalent in postmenopausal women (Grushka, M., 1987; Grushka, M. *et al.*, 2002), characterized by a burning mucosal pain without major visible physical signs. Altered taste sensations have long been associated with BMS and nearly 70% of the patients complain of accompanying dysguesia (altered taste sensation) (Ship, J. A. *et al.*, 1995). Conventional QST in BMS patients identified defects in pain tolerance, altered chemosensory function, increased pain threshold to laser stimulation, and hypoesthesia of large and small nerves (Grushka, M. and Sessle, B., 1988; Grushka, M. and Sessle, B. J., 1991; Mott, A. E. *et al.*, 1993; Formaker, B. K. and Frank, M. E., 2000). Accumulating evidence suggests that BMS involves

central and peripheral nervous system pathologies induced by the damage to the taste system at the level of the chorda tympani nerve. This damage results in reduced trigeminal inhibition that in turn leads to an intensified response to oral irritants and eventually to oral phantom pain (i.e., BMS) (Grushka, M. *et al.*, 2003).

Recent studies of BMS show how electrical tests can enhance a QST examination. Electrical stimulation of the tongue can provoke two different sensations; one is described as itch (tingling) and the other as an electrical taste (Bujas, Z. *et al.*, 1979; Lindemann, B., 1996). The electrical taste threshold in the tongue is easily recognized as a sensation usually described as a battery-like or sour taste. The taste sensation is assumed to be conducted via the chorda tympani nerve and the itch sensation via the lingual nerve. Thus electrical detection thresholds of the anterior two thirds of the tongue likely evaluate the role of chorda tympani and lingual nerve function in BMS.

Eliav E. *et al.* (2007) found no difference between electrical taste and electrical detection thresholds among 23 BMS patients, 14 BMS patients, or 10 asymptomatic controls at extraoral nerve mental and infraorbital control sites. In the control and BMST patients, the ratio between the electrical taste and the itch sensation on the tongue was <0.7, while this ratio was significantly higher (1.4) in the BMS patients. This result is consistent with the hypothesis that BMS is an oral phantom-type pain induced by damage to the taste system (Grushka, M. *et al.*, 2003), and suggests that the electrical taste and itch ratio may be a useful diagnostic test for BMS.

5.61.1.2.3.(ii) Painful temporomandibular disorder Painful temporomandibular disorder (TMD) can be due to arthralgia in the temporomandibular joint or from processes in nearby muscle. Eliav E. *et al.* (2003) classified a cohort of patients as suffering from joint arthralgia ($n = 44$) or myalgia ($n = 28$). Electrical thresholds for Aβ fibers and heat thresholds for C-fibers were assessed in these patients and in 33 healthy control subjects. These tests were performed bilaterally in three trigeminal nerve sites: the auriculotemporal nerve territory, the buccal nerve territory, and the mental nerve territory.

Electrical detection threshold ratios were calculated by dividing the affected side by the control side; thus reduced ratios indicate hypersensitivity of the affected side. In control patients, ratios obtained at all sites did not vary significantly from the expected value of one. In arthralgia patients, the mean ratio obtained for the auriculotemporal nerve territory (0.63) was significantly lower than the ratio for the mental nerve (1.02) and buccal nerve (0.96) territories in patients and lower than the auriculotemporal nerve ratios in myalgia (1.27) and control subjects (1.00). In the myalgia group, the electrical detection threshold ratios in the auriculotemporal nerve territory were significantly elevated compared to the auriculotemporal nerve ratios in control subjects. There were no significant differences between and within the groups for electrical detection threshold ratios in the buccal and the mental nerve territories, and for the heat detection thresholds in all tested sites. Following arthrocentesis (fluid draining) delivered to 10 arthralgia patients, mean electrical detection threshold ratios in the auriculotemporal nerve territory were significantly elevated from 0.64 to 0.99, indicating resolution of the hypersensitivity. Thus, electrical stimulation distinguished between joint and muscle-related facial pain, and monitored the time course of the joint pain.

5.61.1.2.3.(iii) Sinusitis Sinusitis can be classified as acute (<1 month) or chronic (>3 months). The transition from acute to chronic likely involves a shift from acute inflammation to more persistent mechanisms that may involve nerve damage, changes that should be detectable by QST. In a pilot study by Eliav and coworkers (personal communication), neurosensory function was evaluated in seven patients and eight control subjects by measuring the electrical detection threshold for large myelinated nerve fibers and heat detection thresholds for the assessment of thinly myelinated nerve fibers. The sensory tests were conducted in the region of the infraorbital, supraorbital, and mental nerve distributions. Nine acute and five chronic sinusitis were diagnosed. Acute sinusitis was associated with bilateral large myelinated nerve hypersensitivity (to electrical stimulation) compared to healthy controls with no significant change in the unmyelinated nerve fiber detection threshold (to heat). Chronic sinusitis resulted in a large myelinated fiber hyposensitivity and a thin myelinated fiber bilateral hyposensitivity compared to healthy controls. These preliminary results suggest that QST may distinguish between an early inflammatory neuritis and a chronic condition likely accompanied by nerve damage.

5.61.1.2.3.(iv) Malignancy The ability of electrical stimulation to detect inflammation along the course of the nerve has also been applied to the

detection of malignancy. Eliav E. *et al.* (2002) assessed the sensitivity of Aβ primary afferents to weak electrical currents applied bilaterally to regions innervated by three peripheral branches of the trigeminal nerve. For dermatomes containing lesions, ratios of electrical detection thresholds (affected/unaffected side) were <0.8 in 12 patients. Biopsy showed that the lesions in 10 of these 12 patients were malignant. No malignancy was found in the remaining 11 patients. These results suggest that Aβ primary afferent hypersensitivity is observed to occur in nerves exposed to early soft tissue oral malignancies, and that a simple electrical test may provide a nonivasive and inexpensive method of early detection.

5.61.1.3 Suprathreshold Pain Sensation

Although the pain threshold is very useful in QST examinations, in some cases it may be necessary to assess pain sensitivity at higher, suprathreshold levels. As shown in Figure 2, in conditions such as hyperpathia the pain threshold may not predict suprathreshold sensitivity. In this case the psychophysical function rotates; decreased sensitivity at threshold levels is accompanied by increased sensitivity at suprathreshold levels. In addition, suprathreshold pain stimulation is important for goals outside of QST testing in which the painful stimulus is designed to simulate some aspects of spontaneous pain. In the clinical situation, threshold-level pain sensations are less relevant and the focus is on treatment of intense acute pain following injury or medical procedures, and the management of relentless chronic pain.

The psychophysical scaling techniques used to evaluate suprathreshold sensations are reviewed in a number of sources (Torgerson, W. S., 1958; Bock, R. D. and Jones, L. V., 1968; Engen, T., 1971b; Anderson, N. H. *et al.*, 1974; Marks, L. E., 1974; Stevens, S. S., 1975; Gescheider, G. A., 1985; Falmagne, J. C., 1986; Bolanowski, S. J. and Gescheider, G. A., 1991; Atkinson, R. C. *et al.*, 1998). In terms of the task performed by the subjects, these methods can be divided into three classes: discrete numerical or verbal category scales, bounded or confined continuous-measure equivalents of bounded scales such as the 10 cm visual analog scale (VAS), and unbounded scales such as the well-known method of magnitude estimation (using any number).

These methods also differ in analysis, with some common rating tasks analyzed by distinctly different procedures. For example, discrete numerical or verbal category scales can be analyzed by considering the distances between categories to be psychologically equal (formally titled as the method of equal appearing intervals (Engen, E., 1971b). Many pain studies have used discrete category scales such as the 0–10 numerical scale (Brennum, J. *et al.*, 1992), the four-point category scales of pain (none, mild, moderate, severe) or pain relief (none, some, lots, complete) (Gracely, R. H. and Naliboff, B. D., 1996). The most widely used McGill Pain Questionnaire (MPQ) (Melzack, R., 1975) is usually analyzed by assigning integer ranks to each category subscale.

The actual category values can be determined by the response behavior of the subjects as they use the scale. Thurstone L. I. (1959) developed a number of methods that use this approach, in which the spacing of two categories is inversely related to the extent that they are confused, such as the relative proportion that each response is used to describe the same stimulus intensity. The method of successive categories (Thurstone, L. I., 1959; Engen, E., 1971b) is applied to category scaling data and a related analysis is used for the simpler task of paired comparisons, in which subjects are presented a series of stimulus pairs and they indicate which of the pair is more intense. Thurstone analyses are rarely applied to pain assessment (LaMotte, R. H. and Campbell, J. N., 1978), but could be applied to many more studies currently using the method of equal appearing intervals to analyze categorical data. A comparison of the two methods can actually be performed post hoc, either validating the assumption of equal intervals or providing an alternative that more closely resembles the values of the category responses.

Methods that use response distributions can also be applied to clinical pain ratings, when the underlying stimulus intensities are not known. An example is Rasch analysis, which has been applied to the assessment of low back pain. The results can be used for item weighting or for item selection during further scale development (McArthur, D. J. *et al.*, 1991).

A third class of methods also determine the appropriate value for each category response. However, in contrast to the Thurstone methods of determining these values simultaneous with scaling, these methods quantify category values in a separate procedure. The scales can be used for both experimental and clinical pain assessment. A notable example of this approach is the MPQ. The 2–6 items within each of the 20 subscales were quantified during the development of the scale (Melzack, R. and Torgerson, W. S., 1971). One of

the most sophisticated examples of determining category scale values was performed by Tursky B. (1976), who requantified some of the MPQ items using a ratio-scaling paradigm advocated by Stevens S. S. (1975). The details of this method are described in Section 5.61.1.3.3.

Once category values are quantified, the issue is how these categories should be used to measure pain. Categorical scales can be presented in ordered sequences as a simple checklist such as the MPQ, or be placed at the appropriate locations on a spatial continuum to form a graphic rating scale (Heft, M. W. and Parker, S. R., 1984; Gracely, R. H., 1991). This continuum can be some type of VAS discussed below (Lembo, A. *et al.*, 2000). Figure 3 shows an example of an alternative format in which descriptors are placed at the appropriate locations along a higher-resolution numerical category scale. This type of scale is useful in situations in which the subjects cannot mark a line, such as in neuroimaging experiments or in telephone assessments.

A novel method presents the categories in random order and subjects rate experimental or clinical pain magnitude by choosing a category from the randomized list (Gracely, R. H. *et al.*, 1978a). This method is unique since it forces category choices based on the semantic content of the item rather than on its spatial location in a list. This method has two prominent advantages. First, basing choices on the meaning of a word or phrase may help subjects distinguish between different dimensions of pain experience (see below). Second, choices from a randomized list may be free of the rating biases associated with choosing responses from a bounded scale. These biases relate to the subject's tendency to spread repeated responses evenly over a category scale. This tendency results in scale responses that are influenced by the distribution of delivered stimulus intensities, including range, spacing, and frequency of presentation (Parducci, A., 1974). Varying these parameters distorts the resultant scale. Methodological improvements may reduce the effects of these distortions, such as iterative scaling techniques that systematically eliminate distortions (Pollack, I., 1965), and the use of open-ended scales described below (Stevens, S. S., 1975). The randomized descriptor method is likely the best improvement, since it eliminates the scaling space that forms the basis for the response spreading. The disadvantages of the random method is that resolution is limited to the number of categories (in contrast to a graphic rating scale) and that the task may be more difficult than scaling with an ordered set of categories.

Figure 3 Box scale of pain intensity. This scale combines a spatial range of verbal descriptors previously quantified and position on a logarithmic scale adjacent to a 0–20 category numerical category scale. Subjects use the descriptor space to determine an appropriate amount of intensity and to then choose the nearest numbered box to express this magnitude of pain intensity. This method increases the resolution beyond the number of descriptors, allows for semantic gaps such as mild to moderate, adds additional scaling space at the top, is used also for a scale of unpleasantness, does not require a motor response, and can be used for applications such as telephone surveys.

Although an undistorted scale is desirable for pain measurement, applied studies of pain may be more concerned with how these response behaviors adversely affect the evaluation of changes in pain sensitivity such as the effect of analgesic interventions. In this situation, the tendency to produce a uniform response distribution tends to diminish the response to a real pain treatment effect, reducing assay sensitivity. This is one of several normalizing effects; others include regression to the mean and the physiological

effect termed the law of initial values, together forming a group of effects informally called floor-ceiling effects. For example, study using a 0–6 category scale showed a reduced response range immediately after a pain-reducing intervention, which quickly spread to the previous response distribution, diminishing the effect. In contrast, a randomized verbal descriptor scale, with no spatial response range, showed a persistent reduction (Gracely, R. H. *et al.*, 1984).

5.61.1.3.1 Advantages of multiple category items

In contrast to scaling methods that average a large number of ratings, many clinical pain scales are based on a single score or only a few scores. One advantage of verbal categories is that they describe different magnitudes of similar or different pain dimensions, and a scale can consist of a number of items. Both the long (Melzack, R., 1975) and the short (Melzack, R., 1987) forms of the MPQ take advantage of this property. The use of composite scores from a number of items decreases the influence of random scaling errors. For example, the reliability and homogeneity of the overall score of the descriptor differential scale (DDS) is greater than the mean score obtained from each individual item (Gracely, R. H. and Kwilosz, D. M., 1988). This improvement obtained from the use of multiple items at a single testing time is similar to the improvement noted with repeated use of single items; averages of multiple responses to a single-item pain diary are superior to single responses or to the mean of only a few responses (Jensen, M. P. and McFarland, C. A., 1993). Multiple measures delivered at the same time must use different items, a requirement naturally filled by the use of verbal categories. The DDS uses this approach by presenting 12 quantified descriptors and instructing subjects to rate if their clinical pain is equal to that implied descriptors, or how much less or greater on a +10 to −10 scale. The DDS has been administered to patients in acute or chronic pain in several studies, revealing adequate reliability, internal consistency, validity, and sensitivity (Hargreaves, K. M. *et al.*, 1986; Kwilosz, D. M. *et al.*, 1986; Gracely, R. H. and Kwilosz, D. M., 1988; Doctor, J. N. *et al.*, 1995).

In these applications, the different categories must describe different amounts or aspects of pain, but do not have to be quantified. Quantifying these verbal categories provides additional advantages. Comparisons between the pattern of item responses and the previously determined descriptor values provide a measure of scaling consistency. The DDS shows high consistency that improves from the first to the second administration (Gracely, R. H. and Kwilosz, D. M., 1988). These consistency measures can be used at screening, or over the course of a study to identify subjects who obviously are not attending to the scaling task. Eliminating these subjects may improve psychometric properties and increase the sensitivity of an analgesic assay.

The use of multiple, quantified items also allows the construction of alternative forms, each with different descriptor items, that are theoretically equivalent. Kwilosz D. M. *et al.* (1984) validated such forms and used them to evaluate the accuracy of memory of acute postsurgical pain over a 1-week period. The use of alternative forms is critical in such studies. Without alternative forms, memory for pain cannot be distinguished from an alternative explanation, that it represents only the memory of a previous pain rating.

Finally, the methods used to quantify verbal categories can provide information about the stability of the meanings attached to the words, and the consistency for these meanings over the general population. The exact procedures used for the quantification are described in Section 5.61.1.3.3. The overall approach uses methods that reduce bias. Each subject uses two independent methods to rate the words and the comparison of these methods provides a check of internal consistency. The similarity of these scales validates both the methods and the general concept that verbal descriptors, with no physical metric of their own, can be rated as reliably as physical stimuli. After scales produced by different response methods are shown to be similar, they are combined into an overall scale of magnitude. Figure 4 shows an example of these separate and combined scales for descriptors of pain intensity (Gracely, R. H. *et al.*, 1978a).

In addition to these measures of internal consistency, comparisons among individuals evaluate common usage. The Gracely R. H. *et al.* (1978a) quantification of pain sensory intensity descriptors found evidence for common usage, expressed as objectivity. Mean individual reliabilities were 0.96 over 1 week, and the mean of correlations between each individual's scale and mean scale from the remaining subjects in a group were also 0.96. The equivalence of these correlations indicates very high objectivity; an individual's quantification of the verbal descriptors was predicted equally well by that individual or by a group norm. This objectivity indicated general agreement about the ordering and spacing of English words describing magnitudes of sensory

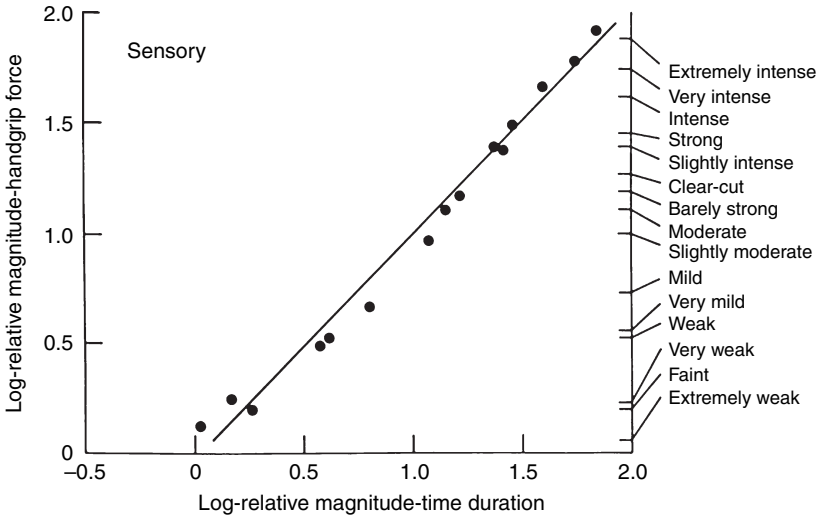

Figure 4 Relative magnitude of sensory intensity verbal descriptors derived from cross-modality matching to handgrip force (ordinate) and to time duration (abscissa). Each point is the geometric mean of 80 responses of 40 subjects to a single descriptor. The mean of the two magnitudes for each descriptor is shown on the right vertical axis. From Gracely, R. H., McGrath, P. A., and Dubner, R 1978a. Ratio scales of sensory and affective verbal pain descriptors. Pain 5, 5–18.

intensity, validating the use of a group normative scale. The results of these pain-related investigations were in general agreement with previous psychological studies of semantic meaning. For example, the adverbs very and slightly, when used to modify adjectives of pain magnitude (Gracely, R. H. and Dubner, R., 1987) or pain unpleasantness (Walther, D. J. and Gracely, R. H., 1986), appear to serve as multiplicative modifiers independent of the adjective modified (e.g., pain, distressing, unpleasantness). This property was described by Cliff N. (1959) and the constants found in that study using a Thurstone analysis of paired comparisons (1.30 for very, 0.55 for slightly) are in general agreement with those found with ratio-scaling procedures (1.44 for very, 0.42 for slightly; Gracely, R. H. and Dubner, R., 1987).

5.61.1.3.2 Bounded continuous scales: the visual analog scale

The VAS is likely the most widely used pain measurement tool. As shown in Figure 5, the VAS is usually a 10-cm line labeled at the ends with descriptors such as no pain and worst pain imaginable. Subjects indicate pain magnitude by marking the line, and a ruler is used to quantify the measurement on a 0- to 100-mm scale. Variations include vertical or horizontal alignments, placing descriptors along the scale, scales of different lengths, use of mechanical devices, and presentation on a computer or small

Figure 5 A typical visual analog scale (VAS). A horizontal 10-cm line is labeled with extremes of no pain and pain as bad as it could be. Subjects indicate pain magnitude by a mark on the line. Other formats use vertical orientations, plastic slide rules, presentations on a computer screen or handheld PDA, with different or more numerous verbal labels.

personal digital assistant (PDS) device (Jensen, M. P. *et al.*, 1986; Price, D. D., 1988; Jamison, R. N. *et al.*, 2002).

The popularity of the VAS is due to its ease of use and evidence to support the reliability and validity of this method. It has become a standard in clinical pharmacology, a field long dominated by the consistent use of four-point categorical scales of pain intensity and pain relief. The continuous nature of the VAS provides a 0–100 response resolution, limited by the observer's discriminative capacity rather than by the scale. It also allows for increased independence of multiple responses in designs requiring repeated measures, since subjects cannot remember previous responses as well as with category scales.

Other bounded continuous scales have been applied to pain assessment, usually requiring some form of apparatus. These include squeezing a handgrip dynamometer (Gracely, R. H. *et al.*, 1978b) using

a finger span device (Cooper, B. Y. *et al.*, 1986), a mechanical slide rule (Price, D. D., 1988), a slider along the back of a meter stick (McGrath, P. A. *et al.*, 1983), and a VAS presented on a PDA (Jamison, R. N. *et al.*, 2002).

Since the VAS and similar scales are bounded, representing a confined response space, they should be vulnerable to the same spatial rating biases demonstrated with category scales. They should be sensitive to stimulus range, spacing, and frequency of presentation. Subjects may spread out their responses after an analgesic intervention, reducing sensitivity. A few studies have addressed these biases and limitations of the VAS (Fernandez, E. *et al.*, 1991; Yarnitsky, D. *et al.*, 1996), but generally these effects have not been investigated in any detail.

5.61.1.3.3 Unbounded scales: ratio-scaling methods

Ratio scales are defined as having both a true zero point and a defined interval, corresponding to physical scales such as length and mass. In contrast, interval scales have a defined unit but no true zero point (Fahrenheit temperature scale). Other scales are classified as ordinal, ranks with no information about distances between values, as finishing first, second, and third in a race. The use of numbers to connote identity without order, such a sport jersey numbers, is referred to as nominal. These distinctions were emphasized by the late Stevens S. S. (1975), who promoted the use of ratio scales and developed a set of methods to produce scales with ratio properties (Engen, E., 1971b; Carterette, E. C. and Friedman, M. P., 1974; Marks, L. E., 1974; Stevens, S. S., 1975; Gescheider, G. A., 1985; Falmagne, J. C., 1986; Bolanowski, S. J. and Gescheider, G. A., 1991).

The ratio-scaling methods advocated by Stevens used instructions to rate stimulus-evoked sensations in a proportional or ratio manner. In the most commonly used ratio method of magnitude estimation, subjects used any number to rate the sensations produced by a series of stimuli. The instructions emphasized ratios or proportions, such as if a subsequent stimulus-evoked sensation felt twice as intense as a previous sensation, it should be rated by a number twice that used to describe the previous sensation. Ratio scaling avoided the biases of a bounded scale described above by offering an unlimited response continuum. This is literally true for measures such as magnitude estimation (number choice) and time duration, and virtually true for brightness (13 log unit range). Other ratio responses, which can be any adjustable continuum, may be relatively unbounded in practice but ultimately bounded due to physical (handgrip force) or safety (loudness) limitations (Gracely, R. H. and Naliboff, B. D., 1996).

The use of responses other than magnitude estimation is referred to as cross-modality matching, which describes the general case in which any adjustable response is used to match responses to any controllable stimulus modality. Magnitude estimation itself can be thought of cross-modality matching to number use.

The characteristic feature of the ratio-scaling methods advocated by Stevens S. S. (1975) is that the relationship between a particular response and a stimulus modality is described by a power function of the form $R = S^n$ in which R is the response, S the stimulus, and n the power function exponent (ignoring additive constants). This function is expressed conveniently in a logarithmic plot ($\log R = n + \log S$) since this format is linear and the exponent is equal to the slope of the function. The value of this slope, or exponent, is related to both the stimulus and the response modalities. Each modality is associated with its own specific exponent, and the theoretical exponent is the ratio of the response-specific exponent divided by the stimulus-specific exponent. Since the exponent for the very common response modality of magnitude estimation is 1, the theoretical exponent for any stimulus modality assessed by magnitude estimation would be equal to the reciprocal of the exponent of the psychophysical function, since the function exponent is equal to the response exponent (1) divided by the stimulus exponent.

The theoretical value computed from the modality-specific exponents will likely not be exactly the same since the empirical exponent is influenced by a number of other factors, including the influence of regression bias, which is a tendency to contract the response continuum, resulting in an empirical exponent always less than the theoretical exponent computed from the ratio of the response and stimulus-specific exponents. Other factors may also influence the empirical exponent. Although the open-ended nature of ratio-scaling methods such as magnitude estimation have been shown to reduce biases due to stimulus range, frequency, and spacing, there is considerable evidence that power function exponents can be influenced by factors such as stimulus range (Poulton, E. C., 1979), although the variation can be viewed as the factor that actually

determines the modality-specific exponent (Teghtsoonian, R., 1971).

Ratio-scaling methods have been applied to experimental pain assessment, with resulting power function exponents of 1.0 for radiant heat, 2.1–2.2 for contact heat, and 1.8 for electrical skin stimulation (Hardy, J. D. *et al.*, 1952; Tursky, B., 1974; Gracely, R. H., 1977; Price, D. D., 1988). However, theses applications provide examples of how experimental parameters may influence the size of the exponent. For example, the stimulus range is usually restricted in pain studies to avoid excessively high levels of pain. This restriction will tend to increase the value of the exponent. Similarly, constriction of the response scale, such as using a bounded VAS scale, will usually lower the exponent by about 50%. These lowered exponents are termed virtual exponents, since they reflect both the exponent of the underlying unrestrained continuum and the compressive effect of limiting the response range (Stevens, S. S., 1975). Price and coworkers (Price, D. D. *et al.*, 1983; Price, D. D., 1988) obtained exponents for VAS measures of thermal pain intensity (2.1–2.2) that were similar to those found with line production. However, the compressive effect should have resulted in a VAS exponent that was reduced to approximately one-half of that observed for line production. Price D. D. *et al.* (1983) posit that this lack of reduced exponent was due to specific instruction to subjects, to the use of the longer (15 versus 10 cm) scales, and experience with the range of stimuli. According to the investigators, this training essentially converts the bounded VAS to a line production response. Whatever the mechanism, the results of Price D. D. *et al.* (1983) serve as an excellent example of how the power function exponent may be manipulated by subject instructions. This is a critical issue when exponents are compared across studies that differ in instructions and scale formats.

5.61.1.4 The Different Goals of Traditional and Pain Psychophysics

Traditional Steven's psychophysics and other scaling methods have been concerned primarily with the shape of the function relating sensory magnitude to stimulus intensity. Steven's ratio-scaling methods focus on the magnitude of the slope (in log coordinates), which describes the rate-perceived intensity increases with a given increase in stimulus intensity. Most studies using these methods focus on the variation of slope with different stimulus modalities or response procedures. In addition, the function derived from ratio-scaling methods is compared to the functions obtained with different methods such as category scales in an effort to find the true function relating stimulus intensity to the magnitude of evoked sensation.

In contrast to the research focus of traditional psychophysical studies, pain psychophysics is necessarily concerned with the absolute level of sensation, addressing questions such as, "does this group experience greater pain than this group?" or "does this treatment reduce pain magnitude in comparison to a sham treatment?"

Since psychophysical methods generally focus on the shape and slope of the psychophysical function, they usually provide little information about the height of the function. In certain methods this height has little meaning. In the common use of a free modulus in ratio scaling, subjects choose their own personal unit of measurement, which arbitrarily determines the height of the psychophysical function. In another option in ratio scaling, the initial stimulus is described by a fixed response value (modulus) such as 10. The use of a modulus equalizes the units among subjects, eliminating differences in absolute magnitude between these subjects.

The emphasis on the shape of the function pervades much of the psychophysical literature, including comparisons of the different functions generated by bounded category scales and unbounded ratio-scaling procedures. Because of this emphasis on height rather than slope, much of this literature may have little applied utility to pain evaluation.

5.61.1.4.1 Adapting psychophysical methods to pain assessment

To provide absolute measurement useful for pain assessment, scales must be anchored to a subjective standard. Bounded scales include a degree of anchoring. In the bounded VAS scale, the possible range of pain from threshold to worst imaginable is represented by a short line. Thus a mark of 3 cm on a 10-cm scale represents a moderate amount of pain, a mark of 5 cm represents greater pain, and a mark of 6.7 cm represents more intense pain. Numerical category scales represent the range of possible pain magnitude in a similar response continuum. Verbal categories also present a limited response range; however, the use of verbal categories further defines

subjective standards along the scale. In a sense, verbal categories provide the anchoring of a response space in a manner similar to VAS and numerical categories, and in addition add a second anchoring system defined by the meanings of the words along the category. Subjects could conceivably use only one of these systems; they could use the meaning of the words irrespective of the number or spacing of the categories or alternatively treat the scale as a numerical scale without attending to the meaning of the words. Studies of the relative contribution of these two sources of subjective standard suggest that subjects use both sources of information in making judgments. Shifting the position of quantified descriptors from an arithmetic to a logarithmic spacing changes the scale, but not enough to suggest that subjects are only attending to word values (Gracely, unpublished observations). One feature of randomized scales discussed above is that this ambiguity is reduced, since information provided by spatial location in a list is purposefully omitted.

The anchoring provided by the limited range of bounded scales is absent in conventional ratio scaling, but can be included in several ways. In one approach, a subjective standard is used in conjunction with a modulus. Hilgard, in a study of hypnotic modification of cold pressor pain, instructed subjects to use the modulus 10 to describe a critical level of pain, one that "they would very much wish to terminate" (Hildard, E. R., 1975). In a second approach, subjects rate both pain stimuli and intermingled verbal stimuli that anchor responses, such as moderate or intense, like childbirth or headache, or pain severe enough to require medication. This second paradigm simultaneously scales the stimuli, the subjective standards, and anchors the pain responses (Gracely, R. H. and Wolskee, P. J., 1983).

A third approach uses verbal categories quantified by ratio methods. This method combines the anchoring provided by category scales with the advantages of ratio scaling, for example, permitting inferences such as, "this drug reduced pain by 36%." In this method the subjective anchors are quantified in a session separate from scaling pain sensations. The descriptors are used directly to measure pain sensations, effectively anchoring each judgment to a subjective standard. The second and third approaches are functionally similar, each with specific advantages. Pain scaling with the third, descriptor method, is efficient, with each response providing a subjective anchor. However, choosing specific descriptors forces each response into a discrete category. This method is also vulnerable to poor response behaviors, such as perseverance or use of a limited number of descriptors. Although longer, the use of the second approach that collects ratio-scaled responses to both pain and verbal stimuli may provide greater resolution and eliminate problems with the second approach.

5.61.1.5 Using Experimental Stimulation as an Anchor for Experimental and Clinical Pain Assessment

This approach uses evoked sensations as a standard anchor. Rather than match pain to a category or response space, pain is matched to pain evoked by methods such as contact heat, or matched to the intensity of a nonpainful stimulus such as the brightness of a light (Duncan, G. H. *et al.*, 1988). Another approach for clinical pain assessment anchors judgments by using the same pain rating scale to rate both clinical and experimental pain sensations (Gracely, R. H., 1979; Heft, M. W. *et al.*, 1980). The validity of these methods is dependent on little variance in experimental pain sensitivity across the population. Heat pain approaches this ideal. Other stimuli such as electrical tooth pulp stimuli are extremely variable. However, even in the case of heat there is considerable variation due to genetic (Kim, H. *et al.*, 2004; Mogil, J. S. *et al.*, 2005) and other factors. At this point it appears that the validity of an absolute pain scale must rely on the face validity of the meaning of words within a language and other scale properties such as number use and anchoring in a response space such as the VAS.

5.61.1.6 Other Suprathreshold Scaling Techniques: Discrimination and Single-Stimulus, Single-Response Designs in General

5.61.1.6.1 Discrimination

SDT evaluation of painful stimulation was presented in Section 5.61.1. Although usually used to assess detection, the applications to pain measurement have modified the procedure to assess category ratings of suprathreshold painful stimulation. In the usual detection paradigm, binary responses (detected, not detected) are made to random sequences of two stimulus conditions (present, blank). These stimulus and response pairs form a 2×2 table, with each of the four cells representing the outcomes (hit, miss, false alarm, and correct

rejection) used in the analysis. The analysis of detection examines the proportion of positive and negative responses to the presentations of a stimulus and blank stimulus, that is, between a stimulus pair and a response pair. The suprathreshold modification uses this set of stimuli and responses, and in addition, many more 2×2 tables formed from possible pairs of two stimuli and two category responses. In these cases, the lesser stimulus serves as a blank in the analysis, and the lesser response serves as a not detected. Among all of the stimulus and response possibilities, this analysis can be performed on any 2×2 table with sufficient responses in all four cells, that is, an adequate number of hits, misses, false alarms, and misses. Widely separated stimuli and response categories will usually not meet these criteria because of insufficient false alarms or misses.

The differences between direct scaling and SDT scaling are primarily in the analysis. A subject may not perceive any difference; both methods require category responses to randomly presented stimulus intensities. Each method presents multiple blocks of stimuli that vary in the number of stimuli, stimulus repetitions, and response categories. The two methods are actually similar in many respects. Direct scaling and SDT can be described as single-stimulus, single-response (SSSR) methods (Gracely, R. H. and Naliboff, B. D., 1996). All SSSR designs provide a mean response to each stimulus, and a measure of stimulus discrimination. It is clear that a mean response can be determined from any of the methods. Similarly, the evaluation of discrimination is not limited to the traditional SDT method of using a small number of stimulus intensities (e.g., four) and a large number of response categories (e.g., 12–14). A nonparametric pain-rating paradigm developed by Richard Coppola (Buchsbaum, M. S. *et al.*, 1981) uses the opposite approach; 4 responses categories are available to describe 31 stimulus intensities.

Discrimination can also be computed from the standard direct scaling paradigm in which any number of response formats are used to describe five to seven stimulus intensities presented two to four times each. The discrimination between any two stimulus pairs can be computed by parametric or nonparametric tests such as the *t*-test or the Mann–Whitney *U* test. This measure is similar to d'; both represent the ratio of difference in means of distributions and the variability of these distributions. All of the data can be used to compute overall discrimination by a parametric or nonparametric one-way analysis of variance with the stimuli as the factors and the repetitions as pseudosubjects. The resultant statistic is related to discrimination; high slopes and/or small standard errors around each stimulus will produce a large value of the statistic (e.g., *F*), while low slopes and/or large standard errors will result in small values of the statistic. This method has been applied to a study of the effect of naloxone (Gracely, R. H. *et al.*, 1987) on pain evoked by electrical tooth pulp stimulation using an analysis of variance and the *F* statistic, and to taste discrimination using the interclass correlation coefficient (ICC) as the measure of discrimination (Weiffenbach, J. M. *et al.*, 1986).

5.61.1.6.2 Sensory decision theory applications to pain assessment

A person suffering from acute or chronic pain lives with a burden that is difficult to understand unless it has been experienced. The burden is augmented by the fact that pain has no physical correlate; it is only defined and communicated by self-report. Mistrust of such reports adds to the burden of having pain; patients must fight for credibility as well as relief. Even in the laboratory, in which the level of a painful stimulus can be controlled, measures of pain are based on subjective reports. Although conventional psychophysical methods control for many biases, there is general agreement that any measure of pain can be clouded by extraneous factors that augment or reduce reported pain.

SDT was introduced to pain assessment as means of solving this problem, of separating out extraneous factors from a measure of actual pain. The method was used in studies examining the influence of placebo, nitrous oxide, the minor tranquilizer diazepam, the narcotic analgesic morphine, acupuncture, and transcutaneous electrical nerve stimulation (TENS) (Feather, B. W. *et al.*, 1972; Chapman, C. R. and Feather, B. W., 1973; Chapman, C. R. *et al.*, 1973; Clark, W. C. and Yang, Y. C., 1974; Chapman, C. R. *et al.*, 1975; Chapman, C. R. *et al.*, 1976; Yang, J. C. *et al.*, 1979). Subjects in these studies used category scales to rate the pain evoked by either electrical stimulation of the tooth pulp or heat applied to the skin. These investigations assumed that discriminative sensitivity, assessed by parameters such as d', represented true pain sensitivity, and a change in this parameter after an analgesic intervention would represent actual analgesia. Similarly, the response criterion parameter was assumed to represent response bias, and a change in only this parameter would represent a nonphysiological effect in which subjects changed the labels to describe the evoked pain sensation without any real

physiological change in this sensation. The results of these initial studies were consistent with this interpretation. Administration of placebo resulted in only a shift in the response criterion without a change in d', while the active interventions reduced d' with variable effects on the response criterion.

These results focused attention on the issues of pain measurement and generated additional studies and a lively dialog between proponents of the SDT method and critics who questioned the interpretation of the SDT variables in terms of pain sensitivity and labeling bias (Chapman, C. R., 1977; Rollman, G. B., 1977; Clark, W. C. and Yang, Y. C., 1983; Coppola, R. and Gracely, R. H., 1983). This focus identified at least three theoretical issues that potentially limit the interpretation of SDT parameters for pain evaluation (Gracely, R. H. and Naliboff, B. D., 1996). First, discriminability among sensations is not equivalent to sensory magnitude (Rollman, G. B., 1977; Coppola, R. and Gracely, R. H., 1983). It is also influenced by variability in the afferent system from receptor to brain, and cognitive variability in choosing labels to describe evoked sensations. Second, discriminability between sensations could be based on sensory qualities unrelated to pain magnitude (Gracely, R. H., 1994) such as radiation or temporal characteristics. Third, a change in the response criterion may represent analgesia. Pain is defined as a feeling of hurt with both sensory and affective components. An analgesic intervention that reduces the affective, unpleasant aspect of a pain sensation could conceivably result in a change in the response criterion without a change in the discriminability of the stimulus-evoked sensations.

The extent to which these theoretical limitations apply in practice is not known. At present, these issues can be considered to be working hypotheses to be addressed by further studies. Additional issues include the role of prepain sensation in the determination of sensitivity, and the negative influence of pain unpleasantness on discrimination of painful or nonpainful sensations. Until disproved, it may be best to assume that the influence of extraneous biases cannot be eliminated by analytical method but rather controlled as in other psychophysical experiments, through careful experimental designs that consider the many factors that can influence response behavior.

5.61.1.6.3 Pragmatic problems with a fixed set of stimulus intensities

Both direct scaling and SDT methods deliver a predetermined set of fixed stimulus values in a randomized sequence. These methods are easily applied to the evaluation of nonpainful stimuli, but become problematic when evaluating pain. Care must be taken to avoid delivering unacceptable stimulation to any person. This unacceptable level varies between healthy control subjects. One method simply limits the maximum stimulus to a value that is tolerated by the most sensitive subject. A problem with this approach is that the least sensitive individuals will not experience the same level of subjective pain as experienced by the more sensitive individuals. Another problem is that in studies of analgesia, an active drug may be identified by the effects on stimulus range; a wide range before the intervention may be contracted afterward, providing a clue that an active treatment had been administered. In addition, insensitive subjects may show no effect, since the stimuli evoked minimal pain sensations before the intervention.

These effects are observed in a group of homogenous subjects and pronounced in comparisons between normal and hypersensitive groups. The obvious solution to this problem is to determine ranges of tolerable stimulation for each individual and compute separate stimulus sets for each individual. This can be done once or possibly a second time after an analgesic intervention. This method has implications for the analysis. Rather than use parametric t-tests or analyses of variance, the analysis must use multivariate or regression methods to evaluate both the response and the subject-specific stimulus intensity associated with the response.

Direct scaling and SDT methods share another common feature. Both procedures were developed prior to laboratory computers and performed using pencil and paper methodology. Adaptations to computer administration simply automated the paper and pencil process.

5.61.1.6.4 Utility of interactive adaptive methods

A relatively recent set of procedures solves the problems with fixed stimulus sets by using interactive, computerized paradigms. These adaptive methods extend a concept developed by Cornsweet T. N. (1962), in which the stimulus series is based on the behavior of the subject. In its simplest form, this method is a tracking task in which a response of painful would lower the intensity of the next presented stimulus while a response of not painful would increase the intensity of the next presented stimulus. However, since the next stimulus is always response-

contingent, subjects, or even pigeons in the case of Cornsweet T. N. (1962), can become aware of the staircase rule and adapt simple strategies to reduce the painful stimulus (humans) or maximize positive reward (pigeons). Cornsweet's innovation minimized the contingency between the response and the change in the stimulus intensity by using two different and independent tracking paradigms and randomly alternating between them. This method of double random staircases was used in conjunction with a light detection task to demonstrate dark adaptation curves in the pigeon (Cornsweet, T. N., 1962). This method formed the basis for the method of MRS scaling of pain sensation. The MRS expanded on the double random staircase method in three ways. First, it increased the number of independent staircases, with the initial application using six staircases. Second, rather than assess only detection, the method was expanded to evaluate both detection-level and suprathreshold pain sensations. Third, the paradigm took advantage of computerization to become more interactive, with a dynamically changing amount of stimulus step size to match the method's performance to the discriminative ability of the subject.

Each staircase in the MRS is associated with a response interval between two categories or between two alternatives of a continuous rating scale (e.g., 20.5 mm on a 0- to 100-mm VAS scale). On each trial, a staircase is randomly chosen and stimulus intensity is delivered to the subject. The response determines the new stimulus intensity to be delivered the next time that particular staircase is again chosen. Different decision rules are possible; in the simplest, any response above the associated stimulus level reduces the intensity of the next delivered stimulus, while any response below the associated level increases the intensity of the next delivered stimulus. The amount the stimulus changes, the step size, is a dynamic variable particular to each staircase. It is usually large in the beginning and reduces if the direction of the response change (increase or decrease) changes too frequently (e.g., a very large step size that would administer either nonpainful or very painful stimuli). It can increase if the direction of the response change is the same over a large number of trials (e.g., an increment that is so small that the staircase never becomes painful).

The MRS method solves the problem of choosing appropriate stimulus ranges for each subject since it adjusts the range automatically. The initial stimulus values can be either set low for all staircases or set near the appropriate value by using the results of a simple ascending series. The method has a number of additional potential advantages (Gracely, R. H., 1988; Gracely, R. H., *et al.*, 1988). The results of the independent staircases can be compared to assess reliable scaling performance. Poor subject ability or compliance results in random walks for each staircase, while consistent responding produces characteristic response patterns. The method expresses the results in units of stimulus intensity, permitting simple comparisons across subjects or time. Figure 6 shows that the method can tract sensitivity over small intervals of time, demonstrating analgesia to fast-acting agents such as nitrous oxide or narcotic analgesics. Most importantly, the method results in a similar subjective range of pain in each subject regardless of individual pain sensitivities. This reduces confounds in which more sensitive subjects experience greater subjective levels of pain. In studies of pain control interventions, subjects experience the same level of pain before and after the intervention (i.e., after an efficacious analgesic the computer increases the stimulus intensities to evoke the previously experienced pain level). This minimizes biases associated with analgesic-induced reduction of the range

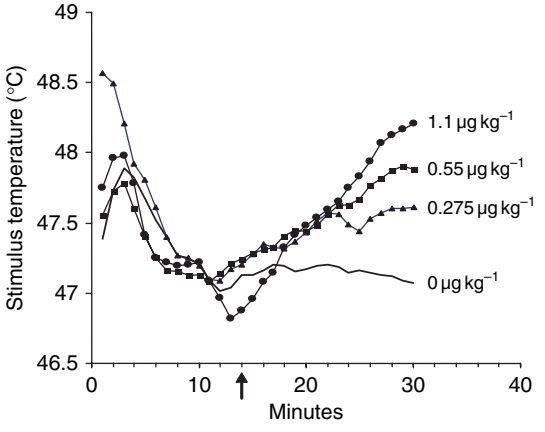

Figure 6 Fentanyl analgesia. The figure shows the effect of dose of the opioid fentanyl for the staircases titrated between moderate and intense. The double-random staircases titrated at this interval were combined into one mean staircase to show the results of four groups ($n = 16$ each). Stimulus intensity is shown on the ordinate, and time before, during, and after a 2-min double-blind intravenous infusion administered at 10 min (arrow) is shown on the abscissa. Subjects received either placebo, shown by solid line, or 0.275, 0.55, or 1.1 µg kg^{-1}fentanyl shown respectively by the triangles, squares, and circles. Fentanyl significantly increased staircase temperatures, indicating analgesia. Both rate of onset and final temperature were dose-related.

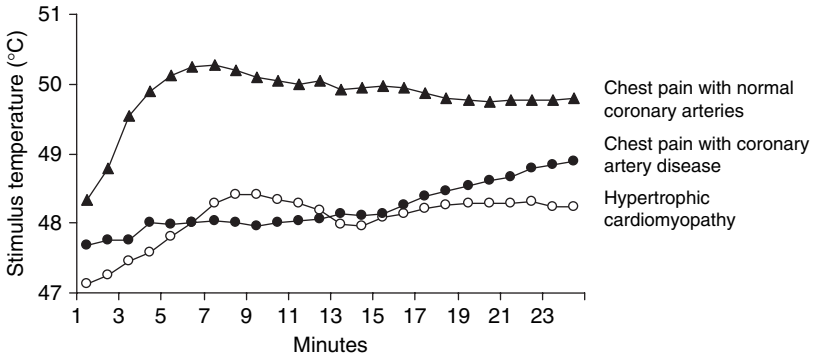

Figure 7 Multiple random staircase evaluation of thermal cutaneous pain sensitivity in cardiac patients. Threshold and suprathreshold values determined over a 34-min period are plotted for patients with chest pain and normal coronary arteries (triangles), hypertrophic cardiomyopathy (open circles), or coronary artery disease (closed circles). Stimulus temperatures required to produce these three subjective levels of pain sensation are plotted against time. These temperature differences indicate decreased cutaneous pain sensitivity in the chest pain, normal coronary artery group, suggesting that their chest pain does not result from a generalized pain sensitivity. Adapted from Cannon, R. C., Quyyumi, A. A., Schenke, W. H., Fananapazir, L., Tucker, E. E., Gaughan, A. M., Gracely, R. H., Cattan, E. L., and Epstein, S. 1990. Abnormal Cardiac Sensitivity in Patients with Chest Pain and Normal Coronary Arteries. J. Am. Coll. Cardiol. 16, 1359–1366.

of pain sensations that plagues methods that used fixed sets of stimulus intensities. Figure 7 suggests that the reductions of biases is also useful for the determination of stable values that can be compared among different groups. This figure shows the comparison of cutaneous pain sensitivity of patients suffering from angina pain, suggesting that patients with coronary artery disease are generally more sensitive than patients with pain but no evidence of coronary pathology (Cannon, R. C. *et al.*, 1990).

The last advantage is an ethical one; studies of analgesia at high stimulus intensities are achieved with less pain using the MRS method. For a simplistic example, that is, to study the analgesic effect at 10 kg of pressure, a conventional method delivers 10 kg, and an analgesic reduces the response to what would be evoked by 8 kg before the analgesic was administered. With the MRS, 8 kg is administered, which evokes a specific response. After the analgesic, the computer raises the pressure to 10 kg to evoke the same response. With the conventional method, the evaluation of the analgesic effect at 10 kg requires the subjects to experience the pain evoked by 10 kg. With the MRS method, the subjects only experience the pain produced by 8 kg of pressure.

The main principle of adaptive methods is that the intensity of stimulation delivered to the subjects is adjusted based on the subject's ratings of the sensations evoked by the stimulation. In addition to the staircase algorithm described above, which bases response change primarily on the immediate response history, an alternative method that computes probabilities from past responses provides a current best estimate of the stimulus–response function (Duncan, G. H. *et al.*, 1992). This method provides an excellent estimate of unvarying sensitivity, since all responses are used in the computation. However, these methods may not be optimal for the assessment of pain sensitivity that naturally varies, or is reduced by an analgesic intervention. In their present form, each of these procedures may be ideal for different purposes: the staircase algorithm for tracking changing pain sensitivity and the probability algorithm for evaluating unchanging sensitivity. However, the algorithm of each can be altered to approach the characteristic of the other. The sensitivity of probability methods to varying pain sensitivity can be increased by decreasing the time interval used for the computation of probabilities, while the use of a dynamic increment in staircase paradigms provides an influence of response history.

SSSR designs share common features and provide (1) information about the mean response applied to a stimulus and (2) the ability to discriminate stimulus-evoked sensations. The limitations of these parameters have been discussed above in Sensory Decision Theory Applications to Pain Assessment. The first parameter is a measure of perceived pain magnitude, influenced by a subject's response criterion. The second parameter is a measure of the intensity of the pain sensation, noise in the neural afferent system, and, most importantly, general

cognitive ability in consistently choosing the same labels to describe the same sensory magnitude. Neither is a pure measure of pain magnitude.

5.61.1.6.5 Stimulus integration: double-stimulus, single response methods

In contrast to SSSR methods in which subjects make a single response to a single stimulus, another family of methods presents two or more stimuli and collects a single response. Usually two stimuli are delivered, which could be termed a double-stimulus, single-response (DSSR) design. In the usual case, a pair of stimuli is administered on each trial and the subject chooses a single response to describe some integrated impression of the two stimuli. The analysis produces an independent scale for each stimulus set. The statistical interaction between these two scales can be used to assess both individual and group scaling performance. This evaluation of performance is a unique feature of these methods. Rather than passively collect responses to stimuli and accept the resultant scale, these procedures treat the processes as an experiment that either fails or succeeds. If successful, the separate scales are accepted. A negative outcome indicates a failure in one or more of the three operations involved in the task: scaling, integrating, or choosing a response. Two different methods have been used, differing primarily in the analysis. Functional measurement treats the responses as interval-level data and performs a parametric analysis. Conjoint measurement assumes only ordinal properties in the responses, and performs a nonparametric analysis.

This description and the term DSSR are oversimplified. In most applications to pain measurement, a subject provides a single response to two stimuli using a specified integrating operation such as averaging. The subjects could also be asked to respond to ratios, subtract or summate the sensations evoked by the two different stimuli. In other applications, two attributes of a single stimulus, rather than two separate stimuli, are assessed. In this case the integration is implicit. For example, subjects may rate the heaviness of weights varying independently in size and mass, and the analysis assesses the separate influence of mass and size without specific instructions. Applications to painful stimuli could vary both intensity and another attribute such as stimulation site, area, or stimulus duration. The design is not limited to two stimulus sets or two attributes. Subjects may integrate any number of delivered stimuli or stimulus attributes.

The literature on these DSSR methods includes a few studies that integrated pain sensations. One of the first presented all possible pairs of two identical sets of four electrocutaneous stimuli varying from 1 to 4 mA (Jones, B., 1980). Responses to the average painfulness of these stimuli were analyzed by functional measurement. A two-way analysis of variance (ANOVA) validated the method by showing two main effects and no interaction. Algom D. *et al.*, (1986) varied this design by asking subjects to integrate sensations evoked by painful and, aversive but not painful, stimuli. Subjects rated overall aversiveness of all possible pairs of six electrical stimuli and six loud auditory stimuli. Gracely R. H. and Wolskee P. J. (1983) extended the generality of this method for pain assessment (1983) by asking subjects to integrate the magnitude of pain sensations with the magnitude implied by a verbal descriptor. Subjects matched handgrip force to the average intensity of pain sensations produced by all possible pairs of five electrical tooth pulp stimuli and five verbal descriptors (weak, mild, moderate, strong, and intense). A functional measurement ANOVA analysis showed significant main effects for the tooth pulp and the verbal stimuli and a nonsignificant interaction, validating the method. This integration of somatic and verbal stimuli was replicated by Heft M. W. and Parker S. R. (1984) using electrical skin stimulation and a conjoint measurement analysis.

To summarize evaluation of a single pain dimension, SSSR methods that deliver single stimulus and collect a single response on each of multiple trials contain similar information regardless of how the response is analyzed. The responses contain information about the mean value of the stimulus and about the variability in response to the same stimulus and between different stimulus intensities. These are the most common methods for the evaluation of suprathreshold pain sensation. Measures of discrimination and response magnitude do not provide pure measures of analgesia, but are influenced by other factors such as cognitive ability and variable response criterion. These factors cannot be isolated by a SSSR method, but rather must be controlled by careful experimental design. Preliminary results with other procedures such as DSSR methods, however, may be capable of providing more information than SSSR methods, although the capabilities and limitations of these methods have not been examined in detail. Measures such as performance in DSSR designs or sensitivity measures in SDT designs may be considered as measures of performance, which may be

independent of pain or provide a behavioral measure of pain. Measures in which subjects judge intensity or some other aspect of a sensation must rely on the reduction of biases through adequate experimental control, and the anchoring of judgments to a standard. Choice of anchoring method may be based in part on which method has greater face validity: a mark on a VAS scale, a numerical category scale on a scale of 1 to 10 or 20, or the use of language and the commonalities inherent in language.

5.61.2 Pain as Dual Variables of Intensity and Unpleasantness

Pain is usually treated as a single dimension of intensity, such as heaviness. However, the history of pain literature emphasizes a second dimension. Aristotle and Plato described pain as a "passion of the soul," and contemporary science has used terms such as the reaction component, unpleasantness, discomfort, distress, affective, or evaluative.

5.61.2.1 Psychophysical Studies of Feeling States: Hedonics

Pain shares this feeling state with other sensory systems. Modalities involved with maintaining homeostatic equilibrium such as temperature and the chemical senses of taste and olfaction possess two distinct dimensions. The first is a dimension of sensory intensity that is shared with all other senses and that has been the focus of the discussion of pain measurement above. The second is a feeling state that for most homeostatic modalities can be either pleasant or unpleasant. Together, these bivalent feeling states have been described as hedonic. Generally, departures from homeostatic neutrality result in an unpleasant hedonic for sensations consistent with that departure; warm water is unpleasant if one is overheated, that is, hyperthermic. Sensations associated with the restoration of homeostatic are usually pleasant. Cool objects, air, or water feel pleasant when overheated. Thus, sensations of sensory intensity can be associated with either pleasant or unpleasant feelings; these sensations are characterized by bivalent hedonics. Hedonic ratings of sugar solutions are initially pleasant with increasing concentrations, then decline and become unpleasant at very high concentrations. Extreme temperatures are unpleasant, while more moderate departures from thermal neutrality can be pleasant. In addition to this bivalent nature, the examples above indicate that the sign and magnitude of the hedonic depends on the internal state. Hunger shifts the hedonic function for sugar solutions so that the formerly moderately pleasant concentrations become more pleasant, and formerly unpleasant concentrations become pleasant (Mower, G. *et al.*, 1977). Satiety has the opposite effect. After overeating at a buffet table, even favorite deserts lose their appeal. Similarly, thermal pleasantness or unpleasantness depends on core temperature. Water of a specific temperature can feel either pleasant or unpleasant, depending if one is hypothermic or hyperthermic (Mower, G., 1976).

In contrast to these bivalent hedonics, a number of sensations appear to be associated with only unpleasant feelings. Vertigo, nausea, and tinnitus do not usually have a positive counterpart, and of course pain is a prime example of an unpleasant sensation. This group of sensations can be characterized as having a univalent hedonic; they are unpleasant throughout the range of sensory intensity.

Although pain does not parallel the homeostatic regulatory functions of hunger, thirst, or temperature regulation, it does serve to protect the integrity of the organism by both avoiding or minimizing injurious stimulation, and once injured, to promote behaviors that maximize recuperation.

While the distinction between the sensory intensity and the hedonic dimension is readily apparent for modalities that can feel either good or bad, this distinction is less obvious for modalities such as pain that have only a univalent hedonic. Pain unpleasantness increases with intensity, and the intertwined nature may make it difficult to distinguish between these dimensions. VAS or cross-modality scales have used different sets of instructions with mixed results. Extensive instructions have been sufficient to facilitate the distinction between intensity and unpleasantness (Price, D. D., 1988), while instructions to cross-modality match or use magnitude estimation to rate unpleasantness appeared to result in scales only of the salient dimension of sensory intensity (Gracely, R. H. and Naliboff, B. D., 1996).

One tactic to avoid the influence of variable instructions is to build in the instruction by using verbal categories. The most popular example of using language to facilitate the discrimination of unpleasantness and other qualitative dimensions was initiated by Melzack R. and Torgerson W. S. (1971), who quantified a list of words compiled by Dallenbach K. M. (1939). In this study, the verbal stimuli were first sorted into discrete categories of qualitative meaning. For each category, the values of

the words within the category were computed using a Thurstone L. I. (1959) scaling analysis of stimulus rankings. The results of this study provided the core of the subsequent MPQ, which is undoubtedly the most widely used multidimensional pain assessment instrument (Melzack, R., 1975). This questionnaire and a short version are described more fully in The Need for Scaling Multiple Pain Dimensions.

Tursky B. (1976) applied Steven's ratio-scaling methods to a subset of the MPQ words. The selection of the specific words reduced the large number of categories of the Melzack and Torgerson study and the subsequent MPQ to a few dimensions common to all of pain experience. Gracely R. H. *et al.* (1978a; 1979) refined Tursky's methods by reducing the number of words further to describe two dimensions of sensory intensity and unpleasantness, and by omitting ambiguous descriptors (e.g., severe) to satisfy the criterion that the sensory intensity class could be used to described the intensity of any sensation. Initial studies demonstrated reliability and scaling consistency (Gracely, R. H., 1978a; 1978b) and subsequent studies evaluated the modulation of experimentally evoked pain sensations evoked by analgesic interventions.

5.61.2.2 Validity of Hedonic Scales

Development of separate scales to assess sensory intensity and hedonic tone does not ensure that such scales will actually assess these dimensions. It is conceivable that, regardless of the scale used, subjects may literally or figuratively take off their glasses and use the spatial properties of the scale to make responses. These responses may be made to the most salient dimension, perhaps the dimension of sensory intensity for a study assessing responses to experimental stimulation in healthy subjects and the dimension of unpleasantness for patients rating the magnitude of persistent chronic pain. This possibility must always be considered when a study finds that scales of sensory intensity and unpleasantness yield essentially the same result. Does such a finding indicate that the scales are indeed the same, or that they fail to discriminate between these dimensions?

Studies of hedonic scales establish validity in two ways. First, validity is assumed if the scales of sensory intensity and unpleasantness result in different psychophysical functions. The finding of similar functions does not invalidate the scales since the functions could be similar; thus similar scales are ambiguous for purposes of demonstrating validity. A related issue is that separate scales of intensity and hedonics should be physically similar, such as category scales or labeled VAS scales. Using different formats introduces method variance such that a finding of different psychophysical functions could represent the different scale formats and not the different subjective dimensions.

The second line of evidence for validity is that sensory and hedonic ratings are altered appropriately by interventions targeted at one or the other dimension. In the examples of temperature and taste described above, the validity of the scales is supported if manipulations that alter homeostasis alter hedonic ratings without changing ratings of sensory intensity.

Both types of evidence have been found for nonpainful modalities such as temperature, taste, and olfaction. The hedonic functions are different than ratings of sensory intensity, and are shifted by changes in internal state by manipulation of core temperature or hunger (Mower, G., 1976; Mower, G. *et al.*, 1977).

5.61.2.3 Validity of Scales of Pain Unpleasantness

Similar types of evidence have also been shown for ratings of painful stimulation. Evidence for different functions is shown in Figure 8, which summarizes the results of studies that assessed pain sensations evoked by electrical stimulation by choosing quantified descriptors of sensory intensity or unpleasantness. The result was significantly different functions. In contrast, instructions to use cross-modality matching to rate either dimensions resulted in the same function that was coincident with the verbal descriptor function of sensory intensity. This result suggests that the instructions alone were not sufficient to discriminate between these dimensions, and subjects rated the salient dimension of sensory intensity regardless of instructions to rate either sensory intensity or unpleasantness.

The second line of evidence for the validity of scales of pain unpleasantness, differential and appropriate response to an intervention, has been demonstrated in a study in which different groups of healthy controls used randomized lists of verbal descriptors to rate either the intensity or the unpleasantness of sensations evoked by electrocutaneous stimuli before and after the intravenous

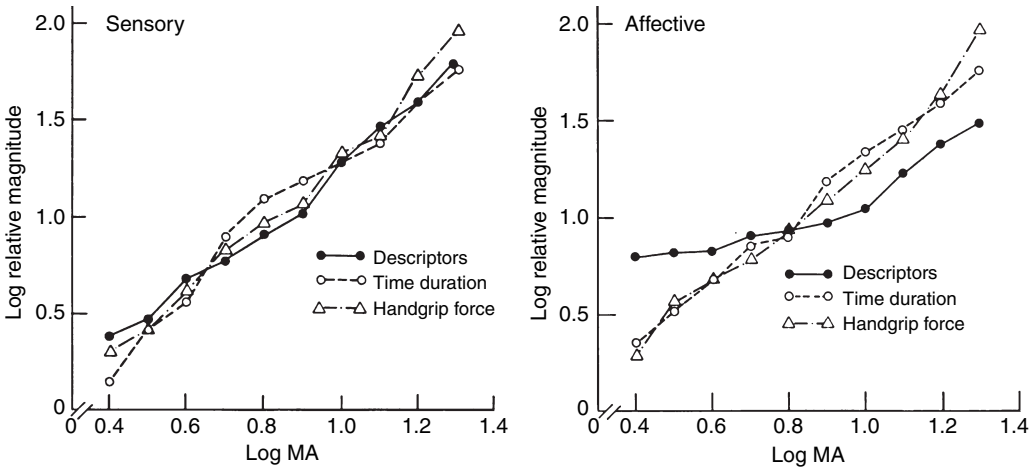

Figure 8 Verbal descriptor and cross-modality matching functions for sensory intensity and affective/unpleasantness responses. Log relative magnitude is plotted against stimulus intensity in log milliamperes. The *left graph* shows psychophysical functions derived from choosing sensory descriptors from a random list and from cross-modality matching time duration and handgrip force to the intensity of the pain sensations evoked by the stimuli. The *right graph* shows psychophysical functions derived from choosing unpleasantness descriptors from random lists and from cross-modality matching of time duration and handgrip force to the unpleasantness of the stimulus-evoked sensations. Each point is the mean of 4 observations from each of 16 subjects. All of the functions are similar except for the unpleasantness descriptor responses.

administration of the minor tranquilizer diazepam. Unpleasantness responses were reduced following diazepam while sensory intensity responses were not altered (Gracely, R. H. *et al.*, 1978b). Subsequent studies have demonstrated different functions for sensory intensity and unpleasantness (Greenspan, J. D. *et al.*, 2003) and differential effects following administration of the opioid fentanyl (Gracely, R. H. *et al.*, 1979), hypnosis (Malone, M. D., 1989; Rainville, P. *et al.*, 1997; Hofbauer, R. K. *et al.*, 2001), conditioning (Wunsh, A. *et al* 2003), and different experimental pain modalities (Rainville, P. *et al.*, 1992; Strigo, I. A. *et al.*, 2002; Dunckley, P. *et al.*, 2005). Tasks such as attending to either the localization or the unpleasantness of evoked pain have shown differential activation of lateral and medial structures, respectively (Bentley, D. E. *et al.*, 2004; Kulkarni, B. *et al.*, 2005).

5.61.2.4 The Concept of Affective Gain

Recent studies of supraspinal structures involved in sensory discrimination and unpleasantness may ultimately provide support for models of pain unpleasantness that posit an affective system that depends both on sensory input and what can be simply considered as the gain of the affective processing system (Gracely, R. H., 1992a; Price, D. D. and Harkins, S. W. 1992). Affective gain can be expressed as the amount of unpleasantness associated with a specific sensory pain intensity. Interventions that reduce the amount of unpleasantness without altering sensory intensity can be considered to reduce affective gain, while interventions that reduce both sensory intensity and unpleasantness equally can be considered to reduce only sensory input. In this case affective gain has not been changed, only the input to the affective gain system.

One result of this affective gain system is that in studies in which clinical pain varies or experimental pain is varied, there is an expected correlation between sensory intensity and unpleasantness. This correlation has led to the suggestion that the concepts of sensory intensity and unpleasantness are not independent and should be simply combined into a measure of overall pain magnitude (Gracely, R. H., 1992b). However, the affective gain, which has been expressed as the ratio of unpleasantness to sensory intensity ratings, is relatively independent of sensory intensity and a meaningful variable that has been specifically altered by pharmacological and cognitive interventions (Gracely, R. H. *et al.*, 1978b; Gracely, R. H., 1979; Malone, M. D. *et al.*, 1989; Rainville, P. *et al.*, 1997; Wunsh, A. *et al.*, 2003; Bentley, D. E. *et al.*, 2004; Kulkarni, B. *et al.*, 2005) and it varies widely over the type of experimental or clinical pain (Price, D. D. *et al.*, 1987; Rainville, P. *et al.*, 1992).

It is interesting to note that interventions can reduce only the affective gain in both pain modalities (e.g., hypnosis) and nonpainful modalities (core temperature, satiety) such as taste or temperature. This selective attenuation of affect may be only one of the few options available for intractable pain syndromes such as poststroke pain that currently are not adequately managed by available treatments. The aversive aspect of pain is not a unitary construct and includes multiple levels of distress. The term unpleasantness has been used to refer to the immediate disagreeable nature of pain that prompts withdrawal and other avoidance and escape behaviors. This conceptualization is similar to the homeostatic feelings of hunger, thirst, and hypo- or hyperthermia; all are negative feeling states that prompt behaviors that reduce the negative feeling. They are present in both animals and man. In addition to this immediate feeling state of unpleasantness, pain is also associated with an emotional or affective state that includes cognitive appraisals (thought) and described in terms of distress, hopelessness, and despair (Gracely, R. H., 1992a; Price, D. D. and Harkins S. W., 1992). Implicit in this view is an emotional state resulting from thoughts about both the present and the future consequences. While the presence of this level in animals is at least debatable, it is clear that the human ability to think about the future contributes to this secondary level of pain affect. In addition to these levels is a tertiary level that is not specific to pain (Gracely, R. H., 1992a). It is shared by all medical conditions and results from the presence of a condition, interaction with the health care system, and general concern about the present and future.

In addition to the hedonic and affective dimensions, pain varies in locus and spatial extent, and in sensory quality. Pain can be experienced in mechanical terms of pulling, squeezing, pressing, and tearing. It can be sharp or dull, deep or superficial, and localized or diffuse. Pain can burn, throb, or ache. Pain can be localized to one constant site, or spread or move. The following section describes methods that extend the measurement of pain sensation and unpleasantness to consider all secondary levels of pain affect and all of these sensory dimensions.

5.61.3 Multidimensional Pain Assessment

Sensations can be described by four attributes: location, duration, intensity, and quality. Pain can be localized and its presence or absence simply noted. Location and duration are recognized as important aspects of the pain experience, and while they are not always easily quantifiable, they are at least conceptually straightforward. In most situations, pain is treated as a single dimension of sensory intensity, although there is increasing recognition of the need to also assess pain unpleasantness. A number of approaches have extended the evaluation of pain to include all of the qualitative dimensions, affective dimensions, and in some cases the reaction to pain, including emotions, cognitions, behaviors, and neural and autonomic responses.

5.61.3.1 The Need for Scaling Multiple Pain Dimensions

The utility of extending pain measurement beyond a single dimension depends on the incremental value of the increased information in terms of diagnosis, choice of treatment, evaluation of treatment efficacy, or investigation of underlying mechanisms. In the case in which multiple pain qualities are assessed, multidimensional pain scales that determined the mixture of pain qualities present, similar to a color mixture for house paint, must demonstrate incremental utility over the assignment of a single dimension, or in the case of paint, a primary color such as blue, red, or yellow (Gracely, R. H. and Naliboff, B. D., 1996).

Clark W.C. *et al.* (1989)distinguish between restrictive and nonrestrictive measurement. Restricted measurement systems determine the number of dimensions *a priori*, while nonrestrictive systems discover the number and type of dimensions for a particular type of subject and pain condition. Naliboff points out that this distinction becomes blurred as results of these methods accumulate (Gracely, R. H. and Naliboff, B. D., 1996), "In actuality this differentiation in approach is not so clear since the objective of even 'unrestrictive' methods is to discover the real pain dimensions and therefore lead to restrictive measurement. Conversely, the system of sensory and affective dimensions was at least in part 'discovered' through empirical categorizing of reports."

Multidimensional scaling can be applied to any scale of pain intensity, and, similar to quantified category scales described above, can be used to evaluate verbal response items independent of pain experience. The most popular and widely used multidimensional pain instrument is the MPQ. The MPQ presents 20 categories of verbal descriptors with 2 to 6 descriptors per category for a total of 78

Sensory

1.	2.	3.	4.	5.
Flickering	Jumping	Pricking	Sharp	Pinching

Unbearable		Tearing		Torturing

Figure 9 Pain descriptors from the McGill Pain Questionnaire (MPQ). The 20 word sets are grouped into 4 major classes; 1–10 are sensory descriptors, 11–15 are affective descriptors, 16 is evaluative, and 17–20 are miscellaneous. Descriptors are ordered within each set based on increasing intensity of the particular pain quality. (McGill Pain Questionnaire, copyright, Ronald Melzack, 1975.)

pain-related descriptors (Figure 9). The MPQ is based on the pioneering study of Melzack R. and Togerson W. S. (1971), which used physician and nonphysician groups that classified a list of 102 pain descriptors in terms of similarity of pain quality. The words were grouped into three general classes of sensory words describing pain in terms of temporal, spacial, pressure, and thermal features, affective words describing tension, fear, and autonomic qualities, and evaluative words describing the general intensity of the pain experience. The result included 16 subclasses. In the second step, the words of each subclass where scaled for intensity. Ultimately, four additional miscellaneous categories were added for descriptors that were not adequately described by the three general categories. In theory, a patient's pain can be described by a profile of the 20 subclasses although in practice the results of the MPQ are usually expressed by the three general dimensions (sensory, affective, and evaluative) by summing the scores of the respective subclasses.

One psychometric property of the MPQ scoring system is that a general score such as the sensory class, or the overall score, can be obtained by either relatively high scores on a few subclasses or lower scores on a larger number of subclasses. This system equates a low-intensity pain with many qualities with a higher-intensity pain described by one or only a few qualities. Scaling verbosity, the tendency to choose many categories, inflates the scores. The subsequent short form of the MPQ avoids these issues by requiring a rating response to each verbal item from a subset of the MPQ items (Melzack, R., 1987).

Responses from the two forms of the MPQ and other multidimensional pain scales can be analyzed by several methods, including factor analysis, ideal

type analysis, and individual differences scaling (INDSCAL) (Gracely, R. H. and Naliboff, B. D., 1996). The factor analytic methods refine items into separate dimensions with maximal attainable internal consistency. These methods have been used to confirm 3D MPQ, and also in studies that aim to identify the true number of relevant pain dimensions (Melzack, R. and Katz, J., 1992; Holroyd, K. A. *et al.*, 1992).

However, there is an important distinction between studies that use factor analysis to analyze items in a questionnaire (the items are presented as stimuli and rated) and studies that use factor analysis to evaluate patients' actual use of a questionnaire. The analysis of items is a standard psychometric technique that indicates the number and homogeneity of the subscales in an instrument. Like the MPQ, the result is similar items grouped together by semantic similarity. In contrast, factor analysis of patient responses evaluates associative similarity (Torgerson, W. S. *et al.* 1988; Gracely, R. H., 1992b; Gracely, R. H. and Naliboff, B. D., 1996). These identify symptoms that coalesce in specific pain syndromes such as deep and throbbing or superficial and burning. They identify the constellation of symptoms found with the particular pain disorders present in the population using the scale. As Torgerson (private communication) has pointed out using a food analogy, factor analysis of items groups butter and margarine together and bread and cake together, but a factor analysis of responses to such a food scale would provide associate similarities, such as grouping bread and butter.

When factor analysis is used appropriately, the item analyses can also eliminate important information in the combinations of correlated items into a scale. For example, measures of both height and weight could be highly correlated in a sample of subjects and it might seem reasonable to combine these into an overall scale of body size. However, a consideration of the difference between the two yields potentially medically important information about conditions of overweight or underweight that would be missed by combining the similar items of height and weight into a single scale (Gracely, R. H., 1992b; Gracely, R. H. and Naliboff, B. D., 1996). Attempts to combine the correlated pain dimensions of intensity and unpleasantness into a single scale are similarly problematic because important information, the amount of unpleasantness associated with a particular pain intensity (affective gain), is lost in the process (Gracely, R. H., 1992b).

In addition to these issues, Naliboff notes that almost all factor analytic studies are based on the data collected at a single point in time and thus do not evaluate temporal properties of pain dimensions (Gracely, R. H. and Naliboff, B. D., 1996). Circadian and hormonal rhythms, pain interventions, behavioral patterns, and fluctuations in specific disease symptoms may alter the compositions of the multidimensional experience of pain that as yet is not captured by these instruments.

The subclass structure of the MPQ assumes that each descriptor represents a magnitude of a specific quality, for example that flickering, throbbing, and pounding represent different degrees of temporal variation. Torgerson and coworkers developed an alternative approach in which a descriptor could represent different amounts of various qualities (Torgerson, W. S. *et al.*, 1988). A specific descriptor could represent a pure quality, but this approach assumes that many of the pure qualities are not represented by a single word. These specific qualities were referred to as ideal types.

Torgerson's method required subjects to scale each descriptor by both its similarity to a set of ideal types and a quantitative dimension of magnitude, a study of 17 stimuli (16 from the original Melzack–Torgerson set), and identified four ideal types: bright, slow/rhythmic, thermal, and vibratory-arrhythmic. Figure 10 shows the results of studies using either sensory or affective descriptors, each in relation to three ideal types (Torgerson, W. S., 1988). Torgerson W. S. *et al.* (1988) used overlapping subsets of the original Melzack and Torgerson descriptors and ultimately derived 19 ideal types. Pain qualities as well as an overall quantitative pain intensity scale were obtained. The results generally confirmed the sensory intensity dimension of the MPQ organization with some refinement such as dividing the punctuate pressure MPQ class into separate dimensions of pricking, stabbing and drilling, boring, acknowledging the rotational character of the latter group. Words that closely matched the sensory ideal types include sharp, tugging, and pounding, and close affective types words included frightful, sickening, and cruel. Figure 11 shows the two pain descriptors closest to each of the 19 ideal types. Use of these descriptors to assess low back pain found an association between sensory qualities and diagnosis, and between the affective qualities and the psychological distress (BenDebba, M. *et al.*, 1993).

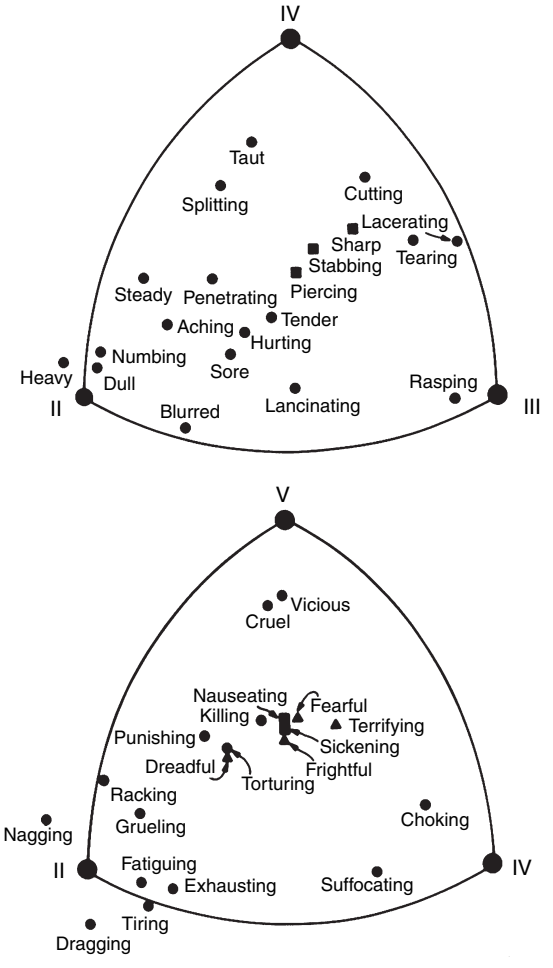

Figure 10 Surface plots illustrating the ideal type structures obtained from a set of sensory (*top*) and affective (*bottom*) words. The numbers at the vertices of the hyperspherical triangle correspond to three of the ideal types identified in each analysis. A total of four ideal types were identified for the sensory words and five for the affective words. From Torgerson, W. S., BenDebba, M., and Mason, K. J. 1988. Varieties of Pain. In: Proceedings of the Vth World Congress on Pain (*eds*. R. Dubner, G. R. Gebhart. and M. R. Bond), p. 368. Elsevier.

A third major approach to scaling multidimensional pain descriptors uses software developed to scale any type of multidimensional modality. Clark and coworkers use INDSCAL procedures combined with preference mapping (PREMAP) to define a multidimensional pain coordinate system and to place a particular judgment within this system. These software programs use judgments of proximity (sameness) to identify the number and type of dimensions inherent in the responses. As with other techniques, the meaning of the dimensions must be inferred from the configuration of the results, especially at the poles of the dimension. The PREMAP model aids in this process by having judges rate each stimuli on bipolar property scales, which are used to help interpret the meaning of the dimensions from the INDSCL analysis. This combination of INDSCAL/PREMAP method also provides a measure of the importance of each dimension to individual subjects.

Clark and coworkers have applied the INDSCAL/PREMAP method to judgments of pain descriptors, clinical pain ratings, and experimental pain stimuli. In the study of pain descriptors, 9 descriptors (mild pain, annoying, cramping, sickening, miserable, burning, unbearable pain, intense pain, and shooting) were presented to subjects in all 36 possible pairs and subjects judged the similarity of each pair of descriptors. The INDSCAL/PREMAP analysis resulted in three dimensions. Clark W. C. *et al.* (1989) labeled these three dimensions as evaluative, aversive, and somatosensory, although Syrjala K. (1989) raises issues about this interpretation. The evaluative dimension includes both pain magnitude and affective qualities. The aversive dimension also contains descriptors of pain magnitude combined with affective descriptor of sickening and shooting. The somatosensory dimension described two qualities related to depth and temporal qualities of pain.

Clark W. C. *et al.* (1989) also collected ratings from a group of patients with cancer and a control group. Interestingly, the cancer group found the affective descriptors to be less important than did the control group. Analysis of the importance of the affective variation within the patient group revealed variability in the importance of the affective descriptors, suggesting the possibility that those who found the affective dimensions to be important might be responding to interventions targeting affect such as antianxiety agents, while those assigning more importance to the somatosensory dimension might be more responsive to analgesics.

The INDSCAL/PREMAP method has also been used to assess the perceptual dimensions of pain evoked by experimental stimulation (Figure 12). Janal M. N. *et al.* (1991; 1993)delivered electrocutaneous and thermal stimuli in pairs and subjects rated the similarity of the pairs. The software identified a robust dimension of intensity and additional stimulus-specific dimensions: a frequency dimension for the electrical stimuli and a warm–hot dimension for the thermal stimuli. The intensity dimension for the

In: Proceedings of the Vth World Congress on Pain (*eds*. R. Dubner, G. R. Gebhart. and M. R. Bond), p. 368. Elsevier.

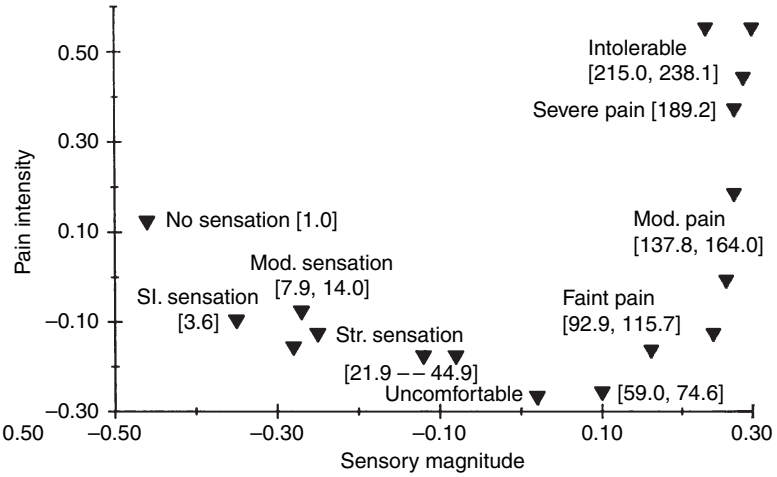

Figure 12 Sensory magnitude versus pain intensity dimensions from individual differences scaling (INDSCAL) analysis of electrocutaneous stimuli. Category labels for each stimulus are determined from the mean response from a method of limits procedure. Numbers in brackets refer to the mean power (mW) of the stimulus. Note that the stimuli labeled no sensation to faint pain order well on the abscissa (sensory magnitude dimension). Higher intensities are clustered together on the sensory magnitude dimension but separate out on the pain intensity dimension (the ordinate) from faint pain to intolerable. From Janal, M. N., Clark, W. C., and Carroll, J. D. 1991. Multidimensional scaling of painful and innocuous electrocutaneous stimuli: reliability and individual differences. Percept. Psychophys. 50, 108–116.

electrical stimuli distinguished between nonpainful and painful electrical stimulation. Together, these results suggest that this scaling approach scales the common dimension of intensity present for all stimuli and in addition produces separate scales specific to the unique characteristics of each stimulus modality.

5.61.3.2 Issues Concerning Multidimensional Scaling

The complex methods of multidimensional scaling have been shown to provide a sensitive assessment of common and stimulus-specific pain dimensions. When is this extra effort warranted? Naliboff

(Gracely, R. H. and Naliboff, B. D., 1996) identified four criteria: increase in reliability or accuracy, diagnostic sensitivity, improved evaluation of psychological and other variables that lead to improved treatment, and increasing basic knowledge of pain mechanisms.

There is at present little empirical evidence that the extra dimensions provided by these measures increase either reliability or accuracy. In most cases, the extra dimensions describe how different stimulus modalities are different, and add little to the dimensions common to all stimuli that are already adequately described by simple measures of pain intensity or possibly dual scales of pain intensity and unpleasantness. However, in certain instances, the distinction between different qualities may be important to describe pain changes in this quality (efficacy of nerve block, spontaneous change in pain qualities).

The use of these methods to determine pain quality as an aid to diagnosis has immediate face appeal. Current diagnostic decision making is based in large part on qualitative dimensions. Although these methods are promising, there are little data linking the outcome of these scales with diagnostic pain groupings. Studies have discriminated between heterogeneous groups such as back pain or headache. However, there is no evidence that these approaches provide any increase in utility over simple diagnostic tests and simple scales of one or two pain dimensions. Such evidence would have to be substantial, satisfying standard psychometric criteria for reliability, cross-validation in different setting, sensitivity, specificity, and predictive utility in relation to prevalence (Anastasi, A., 1968). If utility is demonstrated by these methods, it is likely to be in specific situations. One of the best examples of a more difficult discrimination aided by these methods is the study by Grushka M. and Sessle B. J. (1984)in which the MPQ distinguished a tooth with a reversibly inflamed pulp and a tooth in which the pulp inflammation was irreversible based on verbal pain reports.

Multidimensional analysis of pain ratings have also been proposed as a way to assess broader issues of psychological functioning in pain patients. Clark and coworkers have even suggested that questions such as "Is this patient really in pain or merely depressed?" can be addressed by an analysis of "What are the patient's coordinates in the multidimensional global pain space and which dimensions are most relevant for him?" The extension of this view is that treatment would follow from an analysis of an individual multidimensional diagnosis. A patient rating clinical pain high on a somatosensory burning dimension would receive a different medication than one with a similar pathophysiology but a greater score on a somatosensory tingling dimension or an affective dimension. To date there is no empirical support for the validity of using pain reports in this manner or for the assumption that assessment of subjective pain quality offers a more accurate and useful assessment of psychological functioning than more traditional mood or personality instruments.

Improved quantification of a patient's pain report might also increase health providers' ability to communicate, express empathy, and enlist cooperation from a suffering patient. Patients often complain that their pain report is misunderstood or dismissed by providers and perhaps a better common language could help this process. This may be especially relevant for changes in pain over the course of treatment and adjustment of pharmacological interventions. A potential difficulty with the current approach to multidimensional scaling is that the dimensions are often difficult for even the researcher to interpret. Application to the clinical setting requires translation into language with face validity for both clinicians and patients. This application of multidimensional assessment reinforces the need to examine pain as a dynamic process and to validate the ability of any multidimensional framework to monitor pain as it changes with time and treatment. In addition, the multidimensional analytical techniques applied to pain have to date emphasized the discovery and validation of painfulness dimensions, and not analytical tools for assessing pain in a clinical situation over time.

Perhaps the most promising area for application of multidimensional pain assessment is in basic research on neurophysiology and neuroanatomy of pain. There has been and will continue to be rapid growth in techniques for the study of ongoing central nervous system (CNS) processes such as functional brain imaging and CNS stimulation and recording techniques. Better quantification of a subject's subjective experience along with multiple dimensions may allow for specificity in the psychological domain corresponding to specific neurophysiological processes. For example, Lenz F. A. *et al.* (1993; 1994) have found that electrical stimulation of the thalamus in patients undergoing stereotactic neurosurgery evokes sensations that can be referred to distinct body locations. When these locations coincide with the locus of a chronic pain syndrome, the quality of the evoked pain is similar to

the quality of the pain experienced chronically by the patient. Evoked sensations located at other locations either were not painful or did not resemble the patient's clinical pain. These studies rely heavily on valid multidimensional pain assessment. In this case, the investigators used a tree-branching questionnaire that efficiently evaluated pain quality in an intraoperative environment.

5.61.4 Conclusion

Pain is in part a sensory experience that can be assessed by the methods used to evaluate other sensory modalities. While the concept of pain threshold is well known and often used to imply pain sensitivity, adequate evaluation of pain sensitivity must include the range of pain from threshold to tolerable suprathreshold intensities. While many traditional psychophysical methods focus on the relation between different stimulus intensities, pain measures strive to provide absolute pain assessment that facilitates evaluation of slow-acting analgesics or comparing pain levels between groups. Pain also varies greatly in quality, and in temporal and spatial characteristics. New measures employing multidimensional scaling and other novel methods continue to address these dimensions. Finally, similar to some modalities, pain motivates behaviors of avoidance, escape, guarding, and recuperation. It is immediately unpleasant and commands attention. If pain persists, it is associated with both plastic changes in the nervous systems and secondary affective components associated with cognitions of distress and despair. Assessment of sensory function provides an important part of the evaluation, and the application of psychophysical methods continues to increase the understanding of pain mechanisms and provide diagnostic information in individual patients. This realm of pain assessment provides necessary information, but no single approach is completely sufficient. In the clinic, measures of pain sensation and unpleasantness must be supplemented by measures from other branches of psychology and medicine, including cognitive style, personality, mood, beliefs, and function.

Glossary

the hard problem Mechanism or algorithm that accounts for the emergence of conscious experience and willed action from neural activity. The expression was coined by Chalmers D. (1995).

locked in Neurological condition, usually due to severe brain injury, in which an individual is awake and alert but completely paralyzed and unable to express himself with words or movement.

MPTA (mesopontine tegmental anesthesia area) Restricted location in the reticular formation bordering the brainstem mesencephalon and pons at which microinjection of minute quantities of pentobarbital, and other $GABA_A$-receptor active drugs, induces a brief period of general anesthesia.

nocifensive response Adaptive behavioral responses intended to avoid, minimize, or escape from noxious, tissue-threatening stimuli. Examples are the flexor reflex as well as more complex escape, distress vocalization, and avoidance behaviors. The term nocifensive does not necessarily imply a reasoned, intentional response.

stress-induced analgesia The observation that stressful events such as electrical shock or forced cold-water swim may be followed by a period of reduced pain sensitivity.

5.62.1 Introduction

Pain is a sensory and emotional experience, a mental state (Merskey, H., 1986). As such, it cannot be properly addressed without reference to the conscious brain. Analysis of skin receptors, spinal pathways, and other substrates of pain without considering the resulting conscious experience is analysis of nociception, not pain *per se* (see below). The hard problem of how neural activity gives rise to conscious experience and willed action is probably intractable as a subject of philosophical analysis (McGinn, C., 1999). However, despite alleged semantic proofs to the contrary, it should ultimately be amenable to solution using neurobiological tools. Just as life is now understood without reference to supernatural vital spirits, the proposition that consciousness is a bodiless ghost temporarily resident in the gray matter is implausible. It is too obviously subject to conventional neurobiological variables such as circadian

rhythmicity, pharmacological modifiers of membrane excitability and synaptic action, blood glucose levels, and so forth. Consciousness is a product of neural activity; there is nothing spooky about it (Searle, J. R., 1992). And while new principles might have to emerge before we fully understand it, they will be natural ones that play out within the cranial vault.

At present we do not know whether the hard problem is hard because of intrinsic complexity (like decoding the genome) or hard only because nobody has yet had the flash of insight necessary to see the essence of the problem and its simple solution. Think of a puzzle many of us faced as kids where six toothpicks were laid on the table and we were challenged to use them to construct four equilateral triangles. You can spend a lifetime working on this one, or solve it in a second by raising the toothpicks off the plane of the table to form a pyramid. Knowledge that the problem has a solution can help keep you from giving up, but it does not provide hints as to how to proceed, nor does it let you know in which of these two senses the problem is hard.

5.62.2 Definitions

Like alert awareness in general, the experience of pain is a causal consequence of neural activity in the brain – the execution of a neural algorithm. Unfortunately, we do not have the foggiest idea of how this algorithm operates, nor can we even conceive of an algorithm whose output would constitute pain experience. This is the reason that current attempts to define consciousness are basically futile. The numerous definitions that have been proposed are not definitions at all, but either metaphors (spotlight, stage, narrator, multiple drafts, etc.) or semantic restatements (e.g., alertness, subjective experience, self). Imagine some large-headed extraterrestrial arriving on earth and delivering the pain algorithm in the form of compiled code ready to run on a Pentium IV. He assures us that the computer is now conscious and experiences pain given an appropriate input signal. But would we have any way of knowing if this was in fact so unless he were willing to explain the principle in a way we could grasp? The red flashing icon that hurts would clearly prove nothing . . . you don't need a large head to make a computer do that. The computer analogy itself may be flawed . . . perhaps an entirely different sort of physical architecture is required to implement the algorithm.

The erstwhile conscious Pentium is not unlike humans who become locked in due to central nervous system (CNS) damage and are unable to feel, move, or communicate. However, reports of locked-in patients who found a way to make themselves understood (e.g., by an eye-blink code) leave no doubt that one can be fully awake and aware despite having no way of letting others know (Bauby, J.-D., 1997). Pain is subjective, inaccessible to others, not in its essence but because we do not yet know how to assess it objectively. This may change as noninvasive brain imaging technologies improve. It is important to realize that our inability to conceive of an algorithm that generates awareness in no way undermines the fact that such an algorithm is running in my brain right now, and in yours. To insist that research on the biology of consciousness must begin with a definition is misguided. It stymies research on the subject unnecessarily, before it has begun. The definition is the algorithm; it is the endpoint of the research, not the starting point. But where to begin?

5.62.3 Pain and the Neurobiology of Consciousness

Although they are private, first-person experiences, we can usually detect whether a person or an animal is conscious or unconscious, or in pain, by simple observations of behavior. This is enough to provide operational definitions for research. True, there may be gray areas (and deceit), but the problem is minor as long as one avoids subtle distinctions and sticks to major effects (see below). Thus, even without knowing the computation that generates conscious experience, practical experiments should be able to uncover some of its general characteristics. For example, it might be possible to learn whether the computation is carried out in a distributed manner or focally, and if focally, in what part of the brain. Beyond that, simply engaging in relevant biological research holds out the prospect that the imagination might be primed, increasing the likelihood of an intuitive leap taking place. Six toothpicks a pyramid makes.

Pain is a favorable point of entry into the neurobiology of consciousness for several reasons. First among them is its immediacy. In the visual system, extensive computation is required to extract meaning from contrasts falling on the retina. Is it a cloud

passing by or a rhinoceros charging? Only after this image analysis is completed does the visual scene become a useful object of attention. We do not have conscious access to the intermediate stages of visual image analysis just as we are not aware of the detailed command sequences sent spinally by our motor cortex, or the workings of our autonomic nervous system. The system delivers to a conscious brain the end product of the analysis, a meaningful visual scene, smooth gait, or a feeling of wellness. Output of the analysis is input to the consciousness algorithm. Injury to image analysis or motor sequencing functions of the brain may be crippling, but they cause blindness and spasticity, not obtunded consciousness or coma. Essential meaning in the pain system is an answer to the question: "Is it good for me or bad for me?" But unlike in vision, this information is available without extensive signal processing. Entry into the circuitry of consciousness via the pain system probably takes place within a synapse or two of the dorsal horn. A painful stimulus captures attention like no other.

A second advantageous feature of the pain system is the variable relation between provoking stimuli and the resulting percept. Photons of 450 nm invariably evoke blue, but 48 °C heat pulses do not necessarily evoke pain. The stimulus-color response function adjusts somewhat to environmental contingencies (e.g., color constancy despite variable illumination), but not nearly so robustly as the stimulus-pain response function. For example, at times of danger, pain normally evoked by an intense noxious stimulus, for example, an injury, may be completely suppressed (Melzack, R. *et al.*, 1982). It is generally presumed that this stress-induced analgesia evolved to increase the likelihood of successful fight or flight. Intense pain captures attention, occupying cerebral resources and degrading performance in other spheres. In an existential emergency, performance is critical; the wound can wait. In effect, the pain system disconnects the signal analysis (nociception) from the percept (pain). How is this done?

Most data suggest that the disconnect between injury and pain is executed primarily in the spinal cord. This is unlike color constancy, which is a cortical function. Disconnect reflects, at least in part, the operation of a specific neural circuit with a nodal point in the midbrain periaqueductal gray (PAG) and a variety of defined efferent effector pathways that employ known neurotransmitters, including bioamines and endogenous opiates (Fields, H. L. and Basbaum, A. I., 1999). The intrinsic descending pain control system(s), or something like it, is probably also engaged in other situations of noxious stimulus-pain disconnect such as the placebo effect, distracted attention, and hypnosis (Rainville, P. *et al.*, 1997; Benedetti, F. *et al.*, 1999). Appreciation of behavioral context (danger, anticipation, belief, and distraction) is a complex, multisensory, cortical function to be sure, but the actual pain disconnect appears to be carried out in the spinal cord or brainstem. Situations in which defined stimulus configurations yield alternative percepts, for example, ambiguous figures like the Necker cube, are fascinating grist for consciousness research. But in the pain system some of the actual neural pathways that implement flip-flop between alternative percepts (viz pain or no pain to a fixed noxious stimulus) have been worked out. For example, under some circumstances pharmacological blockade of enkephalinergic synapses can block the effect of placebos (Benedetti, F. *et al.*, 1999; Skoubis, P. D. *et al.*, 2005). We are talking here about the neural circuitry of belief and anticipation.

A third salient feature of the pain system is that a qualitative, emotional vector is an essential feature of the sensory experience. Authorities on pain psychophysics insist that people can assign a separate value to pain intensity and pain unpleasantness (Rainville, P. *et al.*, 1997). Moreover, drugs and lesions are said to be capable of dissociating between the two: "It hurts just as much as before, but it no longer bothers me" (i.e., no longer causes suffering). This is reflected in extensive involvement of the limbic system in functional brain imaging activations as well as in neuroanatomical connectivity (Peyron, R. *et al.*, 2000). A surprisingly large fraction of the human brain, including extensive regions of the frontal neocortex, appears to be devoted to limbic functions. Affect is undoubtedly an essential, if enigmatic, part of the circuitry of consciousness.

Finally, assuming a willingness to grant that animals, mammals at least, have mental states and neural mechanisms homologous to those that subserve conscious experience in man, the analysis of pain in animals offers a useful experimental shortcut. Present a red triangle to a monkey and it undoubtedly has a corresponding visual percept. To be certain, however (the beast may be daydreaming), and to know that both color and shape information were perceived, it is usually necessary to train the monkey beforehand in order to get an informative behavioral response. In the pain system behavioral responses that mark pain perception, nocifensive

responses, are built in, at least partly circumventing the need for extensive operant conditioning. Such responses include reflexes as well as complex escape behavior, distress vocalization, avoidance, and other such nonreflexive nocifensive behaviors. Granted, inferences about conscious perception in animals will always include an element of uncertainty. But progress can be made by taking as a given that mental states are present, and then later verifying in humans conclusions derived about biological mechanisms.

5.62.4 Pain versus Nociception

Nocifensive responses and avoidance learning could indicate the presence of perceived pain, or they could reflect automatic machine-like reactions of a nonconscious zombie (Woolf, C. J., 1984; Giacino, J. T. *et al.*, 2002; Kobylarz, E. J. and Schiff, N. D., 2004). Since Sherrington C. S. (1904) pain researchers have been trained to use the term nociception rather than pain when there is uncertainty that a conscious percept accompanies the nocifensive response. Nociception may occur when a person is unconscious, but by definition, pain cannot (Merskey, H., 1986). It is not obvious why conscious registration of noxious stimuli (i.e., pain) needs to occur at all. However, under normal circumstances nocifensive responses and pain experience go hand in hand. More than that, the pain system goes out of its way to ensure that noxious stimuli overcome distraction, and even arouse the individual from sleep and sedation. The experience of pain must have survival benefits that unconsciousness nociception cannot provide, perhaps in the realm of optimizing performance, learning, or empathy.

Investigators of other senses have not adopted a mnemonic equivalent to the pain–nociception dichotomy, but this distinction is not unique to pain. The monkey who responded to the red triangle could be machine-like, without awareness, like the door-opener mechanism in a supermarket. Monotonous visual or auditory impressions often do not register in awareness during routine tasks like driving. A particularly striking example is sensory processing during sleep. We toss and turn during sleep, unconscious, but continuously monitor the edge of the bed, and almost never fall out. Complex behavior does not necessarily require attention. And yet, despite periods on autopilot, most of the time we are aware and act with intent.

5.62.5 Neural Correlates of Pain Perception

5.62.5.1 Central Nervous System Activation

A noxious stimulus applied to the paw of an animal activates a large number of neurons in the spinal cord, many of which send ascending axons to the brain. A small minority, cells located in the most superficial layers of the dorsal horn, are nociceptive-selective in their responses. Most, however, have a wide dynamic range (WDR), and respond to weak as well as strong cutaneous stimuli. Still others show WDR responses combined with input from proprioceptive and visceral afferents (multireceptive neurons). The nociceptive-selective neurons have attracted the most attention, with some investigators insisting that their projections alone define the brain's pain-processing network (Craig, A. D., 2003). However, there is no rational basis for denying a role for the WDR and multireceptive neurons. These could well deliver a specific pain signal after extraction from the multiplexed mix (Price, D. D. *et al.*, 2003).

The spinal cord and corresponding brainstem trigeminal areas are sufficient alone to sustain simple nocifensive responses, and they play an important role in the early stages of pain processing. But it is a safe bet that the algorithm of conscious pain perception does not run in the spinal cord on the grounds that paraplegics are fully conscious, and may even report pain in their (phantom) legs. Pain happens supraspinally. Microelectrode recordings in animals and noninvasive functional imaging in humans show excitations in many brain areas following pain-provoking stimulation of the skin and internal organs (Peyron, R. *et al.*, 2000). These include structures that are well-known parts of the somatosensory system, such as the ventrobasal thalamus and the primary (S1) and secondary (S2) somatosensory cortices, as well as areas not classically thought of as somatosensory processors, such as the cerebellar cortex and the corpus striatum. Curiously, the classical somatosensory cortex (S1, S2) tends to show less robust and reliable activations than limbic cortical areas such as the anterior cingulate cortex (ACC), the insula, and parts of the frontal lobe. Noxious stimulation of different organs, skin versus viscera for example, reveals different if overlapping patterns of cortical activation appropriate to the different feels evoked (Rainville, P. *et al.*, 1997; Strigo, I. A. *et al.*, 2003). It is likely that

intensity, affect, localization, and other aspects of sensory quality are processed as a mosaic, in distinct brain areas. But this does not necessarily mean that perception is a mosaic. The various outputs of cortical processing may be bound in a central location.

5.62.5.2 Central Nervous System Lesions

Lesions in the primary visual cortex cause perceptual blindness although some visual performance persists based on subcortical and extrastriate pathways (blindsight, Poppel, E. *et al.*, 1973). In contrast, no cerebral area has been discovered in which lesions reliably produce analgesia or provide relief from ongoing pathophysiological pain. Even in the occasional case report of stroke or surgery relieving a preexisting chronic pain, pain typically returns. Indeed, cortical lesions frequently trigger chronic pain (Boivie, J. *et al.*, 1989; Gybels, J. M. and Sweet, W. H., 1990).

Large right parietal lesions can evoke a state of mind (anosognosia) where the individual denies that a body part belongs to him or her despite the obvious visual evidence to the contrary ("Whose leg is it that you put into my bed!"). The leg is no longer an integral part of the body schema, the inverse, as it were, of an amputation phantom. Nonetheless, pain is registered when the leg is pinched; only the source of the pain is denied. Prolonged anoxia, for example, in drowning victims, can cause still more extensive cortical lesions destroying essentially all of the cerebral cortex. If the patient survives, he or she may be left in a persistent vegetative state (PVS). In PVS the patient is eyes-open awake (with retained sleep–wake cycles), but largely unresponsive, and with massive loss of cognitive function and self-initiated movement. However, he or she typically continues to show appropriate, adaptive nocifensive responses, for example, to pinch stimuli (Plum, F. and Posner, J. B., 1980; Kinney, H. C. and Samuels, M. A., 1994; Kobylarz, E. J. and Schiff, N. D., 2004). With no possibility of communicating, reasonable people can differ over whether the patient has any residual conscious pain experience. Some authorities are sufficiently confident that pain is absent in PVS that once the decision is made to permit ending life, they see it as ethically acceptable to withdraw feeding and end life by slow starvation, rather than by painless injection.

The unexpected preservation of pain response following cortical lesions in S1, S2, and beyond can be interpreted in a number of ways: redundancy of cortical areas that support pain perception, a distributed architecture, or functional organization that is entirely different from the other senses. A final possibility, bordering on heresy, is that fundamental pain perception might not require the cerebral cortex (Dover, M., 2007).

5.62.5.3 Central Nervous System Stimulation

Expectations based on vision are violated even more dramatically in trials of direct cortical excitation. If pain function is multiply represented (redundant) focal lesions might not produce analgesia, but focal stimulation should nonetheless evoke pain. In fact, it has remained a mystery since the classic experiments of Penfield W. and Rasmussen T. (1955) why pain is rarely if ever evoked by stimulation of the cortical convexity (also see Libet, B., 1973), while visual, auditory, and (nonpainful) somatosensory percepts readily are. It may be argued that the relevant structures are buried in the midsagittal (cingulate gyrus) or Sylvian sulci (insula), or that unlike the other senses, multiple cortical areas must be activated simultaneously. However, it is very rare for epileptic seizures to include auras that are painful even though the underlying cortical discharge is frequently widespread and includes these buried cortices. Recent observations of pain evoked in a small number of epilepsy patients by depth electrodes on the insular cortex is a potential exception (Mazzola, L. *et al.*, 2006), but this needs detailed presentation and replication.

If not for the deeply held conviction that conscious perception is a high cortical function, the foregoing observations might have led to the tentative conclusion that the neural computations that generate pain experience do not, in fact, occur in or require the cortex. In contrast to the cortex, pain is readily evoked by focal (microelectrode) stimulation in areas of the thalamus and brainstem (Dostrovsky, J. O., 2000). Of course, this may simply reflect activation of ascending pathways, as for nerve or spinal cord stimulation. On the other hand, it might mean that the algorithm of pain experience runs subcortically. If this were the case, cortical (like cerebellar) activations evoked by noxious stimuli could reflect the contribution of noxious signals to functions such as memory formation, arousal, or the generation of motor sequences, rather than pain perception. Alternatively, the cortex could contribute qualitative detail to the pain percept such as precise localization and dynamics, which are not required for the raw feel

of pain. Indeed, given the high prevalence of chronic poststroke pain (Boivie, J. *et al.*, 1989), it is even possible that overall, cortical activity modulates pain by means of inhibitory control of subcortical circuitry.

5.62.6 Contents of Consciousness versus Its Presence

5.62.6.1 Contents

Much research on the neural correlates of perceptual states focuses on the contents of ongoing narrative. For example, an investigator may ask whether cerebral activation (or synchronization) in response to a fixed stimulus configuration changes when the resulting percept changes (e.g., at state transitions of ambiguous figures). In the realm of pain, many studies have shown that certain cortical activations in response to fixed noxious stimuli change when the resulting percept changes, say as a result of hypnotic suggestion or placebo/expectation (Rainville, P. *et al.*, 1999; Wager, T. D. *et al.*, 2004; Raij, T. T. *et al.*, 2005). An optimistic inference is that the altered neural activity correlates with the pain percept because it actually constitutes the pain percept. An alternative possibility, however, is that the change in the percept and in the underlying neural activity both occur subcortically, with the change in the cortex only secondary reflecting the fundamental subcortical change.

5.62.6.2 Pain and Loss of Consciousness

Compared to contents (states) of consciousness, much less research is done on the transition from consciousness to unconsciousness. By unconscious, I refer to the absence of consciousness, as in coma, not subconscious material that may be inaccessible. This more basic transition may sound mundane, but it is probably a more practical entry point into the underlying neural circuitry. Without question the most potent modality of pain suppression is general anesthesia. Shortly after adequate numbers of anesthetic molecules are inhaled or injected systemically, the most extreme of noxious stimuli can be delivered with no pain sensation at all. It might be argued that this is not analgesia at all as sensory experience is eliminated globally. Of course one might equally say that with loss of consciousness, analgesia is present, and that it is accompanied by blindness, deafness, and anosmia. Aspects of unconscious nociception may persist during anesthesia, such as cardiovascular and some spinal reflex response. Moreover, neurons at many levels of the neuraxis, from spinal cord to cerebral cortex, continue to respond to sensory input. This includes cortical responses to noxious and nonnoxious somatosensory stimuli. Indeed, nearly all of classical cortical neurophysiology was carried out in anesthetized animals. One could even make the case that consciousness is the thing that is lost by the action of general anesthetics. The mechanism of action of anesthetics is therefore of substantial interest with respect to pain – a unique experimental lead.

How do anesthetics obtund consciousness? The most widely held theory is that anesthetic agents distributed by the circulatory system directly access neurons throughout the CNS where they bind to membrane receptors and suppress either electrical excitability or synaptic action. For example, the anesthetic ketamine suppresses glutamatergic excitation while barbiturates such as pentobarbital enhance GABAergic inhibition. By this model, CNS suppression is global, quenched as if by a wet blanket. Anesthetics, however, can also act in a very different way. Microinjection of minute quantities of pentobarbital into a highly localized region of the mesopontine tegmentum, a region termed the mesopontine tegmental anesthesia area (MPTA), can induce all of the indicators of lost consciousness, assessed behaviorally and by electroencephalography. The same dose injected anywhere else in the brain has minimal or no effects (Devor, M. and Zalkind, V., 2001).

The discovery of the MPTA as a nodal site capable of switching the brain rapidly between alertness and unconsciousness is of considerable interest. Among other things, it indicates that neural circuitry exists that is capable of accessing and switching off pain perception, motor control, and consciousness. The difference between the wet blanket hypothesis and the MPTA circuit hypothesis is not in the molecular agents and receptors involved but in the system architecture. Tracing the connectivity of MPTA neurons provides a practical experimental avenue into the neural circuitry of pain as a conscious experience (Sukhotinsky, I. *et al.*, 2005; 2007). Are motor suppression, analgesia, and cognitive collapse inseparable consequences of loss of consciousness, or are these independent functions with independent circuitries that just happen to merge in the MPTA? Does loss of consciousness from fainting (syncope), concussion, and coma also involve MPTA circuitry?

Such questions have ceased to be topics for armchair speculation and can now be investigated using conventional neurobiological tools.

5.62.7 Conclusion

Pain is neither a noxious stimulus nor an adaptive nocifensive response. It is a mental state, a sensory and emotional percept experienced by a conscious brain by virtue of the operation of a neural algorithm, which is, in principle, knowable. Adaptive nocifensive responses and avoidance learning may occur in the absence of consciousness, but pain experience cannot. The pain system offers many advantages for the experimental discovery and analysis of the neural circuitry that subserves conscious perception.

Glossary

anthropomorphism The tendency to attribute human motivations, characteristics, or other attributes to nonhuman things including inanimate objects, the weather and, especially, animals.

cortex The outer layer of an organ. Thus, cerebral cortex: the layers of nerve cells at the outer part of the brain.

nociception The biological response to a noxious stimulus or other stimulus that threatens tissue damage if prolonged.

pain The subjective experience that often, but not always, accompanies nociception in socially conscious beings.

representational memory Memories of a particular event or thing with explicit representational content that can be consciously accessed.

5.63.1 Introduction

There are few living creatures that cannot respond to a noxious stimulus such as a pinch or a burning flame. Strike a match next to the humble *Drosophila* (fruit fly) larvae, for example, and it will bend and roll away (Goodman, M. B., 2003). Responses such as these are dependent upon specialized sensory neurons that preferentially respond to stimuli with the potential to cause tissue damage. These sensory neurons can be found in most animals, including fishes (Sneddon, L. U. *et al.*, 2003a; 2003b), as well as human beings and larvae. Clearly, then, all of these creatures have the apparatus to detect and respond to potentially dangerous stimulation, but can they all be said to feel pain?

If we define pain as the response to noxious stimulation then the answer must be yes, the larvae, fishes, and human being all feel pain. This definition, however, would also mean that a thermostat feels pain because it responds to excessive heat by changing its internal state. Similarly, even rocks must feel pain as they respond to excessive force by shattering. Such a definition seems much too permissive, but it is also flawed because it leads to a tautological understanding of pain. Pain is defined in terms of a stimulus that is deemed to be painful because it elicits the pain response. To put that more simply, pain is defined as pain (Derbyshire, S. W. G., 1999a). To escape from this tautology, a deeper examination of both the biology and the psychology of pain is required. Understanding the minimal necessary biology for pain will enable us to eliminate those animals that lack that biology from being able to experience pain. Similarly, understanding the psychological structure of pain will enable us to eliminate those animals that lack that structure from being able to experience pain.

5.63.2 The Biology of Pain

Modern imaging techniques have allowed unprecedented access to the workings of the brain and over the past decade a series of researchers have examined brain responses during pain experience (e.g., Craig,

A. D. *et al.*, 1996; Rosen, S. D. *et al.*, 1996; Coghill, R. C. *et al.*, 2003; Derbyshire, S. W. G. *et al.*, 2004). These studies have not identified a single center responsible for pain processing but have instead revealed a network or matrix of brain areas (see reviews by Treede, R. D. *et al.*, 1999; Derbyshire, S. W. G., 2000; Peyron, R. *et al.*, 2000; Vogt, B. A. *et al.*, 2003). This matrix includes subcortical structures, such as the thalamus, as well as cortical regions widely believed to be responsible for the higher processes of thought and feeling (Baars, B. J. *et al.*, 2003). The major areas of the cortex now demonstrated to be involved in pain processing include the anterior cingulate cortex, insular cortex, primary and secondary somatosensory cortices, and the prefrontal cortex (Treede, R. D. *et al.*, 1999; Derbyshire, S. W. G. 2000; Peyron, R. *et al.*, 2000; Vogt, B. A. *et al.*, 2003).

Evidence for the direct generation of pain by the cortex comes from an imaging study involving the so-called thermal grill illusion (Craig, A. D. *et al.*, 1996). The thermal grill illusion is the experience of a cold burn produced by interleaving bars that are cool (20 °C) and warm (40 °C) onto the palm of the hand. Instead of experiencing interleaved warmth and coolness, which is the actual stimulus being applied to the hand, the subject will report a feeling of pain that is similar to a cold burn. Explanation for this paradox rests upon the fact that the mammalian nervous system is generally designed to process warmth and coolness separately. Detection of coolness is suggested to proceed via the inhibition or deactivation of an intense cold pathway combined with the activation of a cool channel to produce the experience of coolness. The warm bars, however, act to inhibit the cool channel resulting in a net flow of information through the intense cold channel and the paradoxical experience of a burning cold (Casey, K. L., 1996). The nervous system is tricked, so to speak, into the experience of a burning cold pain sensation, and this trick results in the activation of anterior cingulate cortex and insular cortex. Thus, this activation of the cortex is directly associated with an experience of pain in the absence of an actual noxious stimulus.

In our laboratory, we have completed a study that also provides evidence for the direct involvement of the cortex in the generation of pain experience (Derbyshire, S. W. G. *et al.*, 2004). Eight subjects were selected for their ability to be hypnotized and to experience pain in the absence of any stimulation via hypnotic suggestion. Images of brain activation were recorded when actual noxious stimulation was provided to the subjects and when the pain was suggested in the absence of any stimulation. We demonstrated significant changes during this hypnotically induced pain experience within the anterior cingulate, insular, prefrontal, and parietal cortices. These findings compare well with the activation patterns during pain from an actual noxious source and provide direct experimental evidence in humans linking specific cortical activity with the immediate generation of a pain experience.

Thus, imaging studies demonstrate that the cortex is necessary for pain experience and, as rocks and thermostats do not have a cortex, they are excluded from the world of pain. The same is also true of fruit fly larvae. Other animals, however, are much more likely to share with humans the necessary biology for pain experience.

5.63.3 Animal Biology

In terms of gross anatomy and surface features, human cortex shares many features with the higher primates including the presence of neural structures widely associated with the pain neuromatrix. These similarities have facilitated the investigation of animal nociceptive systems with application to the human species (Vogt, B. A. *et al.*, 1987; Apkarian, A. V. and Hodge, C. J., 1989). At the same time, differences across species include how much the brain, and its constituent parts, weigh; the appearance of the individual cells in various brain regions; the destinations of axons from these cells; and the extent to which brain cells respond electrically when the sense organs are experimentally activated or when the animal is behaving. A review of each of these areas for all animals would be obviously vast and beyond the scope of this chapter (see Dehaene, S. *et al.*, 2005 for extensive comparison of humans and primates). For the purposes of expediency, I will focus only upon the higher primates and will consider only the comparative size and cytoarchitecture of the frontal cortex, which is often activated during pain and is more broadly involved in higher-cognitive abilities including the organization of mental contents that control creative thinking and language, and the artistic expression and planning of future actions (Damasio, A. R., 1985).

Human frontal cortex ranges in size from 239 to 330 cm^3, the range in the great apes is from 50 cm^3 (in a chimpanzee) to 112 cm^3 (in an orangutan) (Semendeferi, K. *et al.*, 2002). Within area 10 of the dorsolateral prefrontal cortex, the right human hemisphere has an estimated 254 million neurons, while

the great apes have less than one-third of that amount (Semendeferi, K. *et al.*, 2001). Although human area 10 has more neurons, it is less densely packed than in the apes such that the supragranular layers (layers II and III) stand out more in the human brain compared to apes. Consequently, humans have more space available for extrinsic and intrinsic connections, which may indicate increased communication within and between area 10 and other higher-order association cortices. The relative volume of white matter underlying prefrontal association cortices is also larger in humans than in apes, compatible with the idea that neural connectivity is increased in the human brain (Zhang, K. and Sejnowski, T. J., 2000).

We cannot replace psychological investigations by the examination of brain tissue (Walker, S. F., 1983; Derbyshire, S. W. G., 2000), but if the assumption that mental states reflect brain activation is to be taken seriously, then it is clear that the physical structure of animal brains must be taken into account when considering mental activity in animals. The similarities in structure between the brains of apes and humans suggest some commonality of function, but the differences in size, connectivity, and cytoarchitecture equally suggest important diversion of function. Until the relationship between the structure of the brain and function is fully realized, it will remain unclear what the differences in neural biology between humans and animals mean in terms of perception and experience, but further examination of the similarities in experience can proceed via comparative investigation of the psychology of animals and humans.

5.63.4 The Psychology of Pain, the Psychology of Humans and the Psychology of Animals

To avoid the tautological use of the term pain, we need some sort of definition of what pain is. In the absence of a definition, pain is ascribed when there are pain behaviors or pain stimuli or, more simply, pain is present when there is pain. The circularity arises because the description of behaviors that follow noxious insult and the psychological description of pain experience are at two different levels: the link between them is at the heart of the problem of understanding animal suffering or other types of animal experience (Nagel, T., 1974).

To escape the inherent tautology of describing pain as the result of painful stimuli, pain is generally defined as a sort of amalgam of cognition, sensation, and affective processes, commonly described under the rubric of the biopsychosocial model of pain (Waddell, G., 1987). Pain is no longer regarded as merely a physical sensation of noxious stimulus and disease, but is seen as a conscious experience that includes mental, emotional, and sensory mechanisms. This understanding is reflected in the current International Association for the Study of Pain (IASP) definition of pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage" (Merskey, H., 1991).

By this definition, pain is a high-level process that makes no sense in the absence of sentience; pain accompanies injury in minds that are capable of subjectivity or consciousness. Without consciousness, there can be the response to noxious stimulation, technically referred to as nociception, but there cannot be pain. Thus, to understand how pain experience in particular becomes possible, it is necessary to understand the origin and course of development of conscious experience in general.

I suggest that the origin of human subjectivity lies within development. Before an infant can think about objects or events, or experience sensations and emotion, elements of thought must have their own independent existence in the infant's mind. This is something that is achieved via continued brain development in conjunction with discoveries made in action and in patterns of mutual adjustment and interactions with the infant's caregiver. For example, an important step toward subjectivity is the development of representational memory, allowing responses to learned information as well as material directly available. Representational memory begins to emerge as the frontal cortex develops between 2 and 4 months of age. From this point on, there is the possibility of tagging in memory, or labeling as a something, all the objects, emotions, and sensations that appear or are felt. When a primary caregiver points to a spot on the body and asks, "does that hurt?" she is providing content and enabling an internal discrimination. This type of interaction provides for content and symbols allowing the infant to locate and anchor emotions and sensations and to arrive at a particular state of being within her own mind. Although pain experience is clearly individual, it is created by a process that extends beyond the individual. If pain were an entirely private affair, no words would be able to express it because no external frame of reference would be comparable and therefore

adequate to express the sensation. Pain is not like this because clearly human beings do express their painful experiences and these expressions have meaning that allow for diagnosis and treatment. In so far as human beings live in a community of thinking, feeling, talking beings, the privacy of experience is broken down and externalized for further analysis. As we are able to externalize our inner world, so we are able to reflect upon that world and become self-aware or self-conscious. Thus, the contents of our inner world come to mean something to us only in so far as they mean something to others, and the realization of that meaning occurs through a developmental process that is social as well as natural (Derbyshire, S. W. G., 1999b; Malik, K., 2000).

The evidence for this type of self-awareness within the animal world is limited and controversial (Heyes, C. M., 1993; Vauclair, J., 1997). There is some evidence of potentially reflective consciousness from behaviors such as giving of alarm calls and the use of deception, but any awareness or insight that these behaviors may indicate is heavily circumscribed and does not generalize. There is no evidence that the awareness, however defined or understood, provides any transformative impact within the individual animal or group. A chimpanzee, for example, behaves today in the same way as a chimpanzee did 100 000 years ago. When chimps forage for food, they do not ask themselves why or consider better alternatives any more than does a beaver consider better ways of building dams. When swallows fly south in the winter, they do not ask why it is hotter in Africa or what would happen if they flew further south or whether they could stay by creating warmth in the north. Humans do ask these kinds of questions and do engage in behavior that transforms their circumstances. We are not trapped inside a purely personal, solipsistic view of the world. We have a conscious insight that makes pain and all other experiences possible.

Pain is much more than working nociceptors connected to a brain. When we feel pain, it is an experience we have spent a good portion of our psychological development learning to recognize. This feeling is not given directly by our brain, but is made through repeated experience, categorization, memory, and reconnection. This development is obviously dependent upon the presence of a sufficiently developed neural system, the human brain, but the content of that experience is dependent upon elements that lie outside the human brain. Animals do not have a human brain and do not share in the psychological development of humans. Animal pain is therefore dependent upon a false equivalence of both biology and psychology and can be rejected.

5.63.5 Conclusion

The fact that some animal behaviors are specific to noxious stimulation and are particular defensive reactions driven by homologous neuronal centers is a long way from demonstrating pain experience. In their report on fishes, Sneddon L. U. *et al.* (2003a) concede that what a fish feels "is possibly nothing like the experience of humans" but is nevertheless "no less important in terms of biology or ethics" than human pain. This is similar to the argument of Beckoff M. (2002) who has suggested, "even though the experience of pain might not be the same across species, individuals of different species can still suffer their own type or version of pain."

It is not obvious why, if the experience is nothing like our experience, it still retains the same moral dimension and should still be called pain. Equally, there is no description of what the pain experience is like for the animals, beyond it being nothing like the human experience but still being important. What is perhaps being argued is that while animals are incapable of a broad awareness they are capable of experiencing something like pain or a narrow awareness. Whereas human awareness is a general phenomenon, carried along with every experience we have, from hitting ourselves with a hammer to enjoying a sunny day, that of the animals might be piecemeal with the individual pieces, including pain, available whole and fully formed.

What remains unexplained is how the animal can be aware of that particular piece of experience. As discussed, humans use symbolic labeling to differentiate pain, red, and so forth, and it is through this public process of externalizing our thoughts and feelings that those thoughts and feelings come to have meaning to us (Malik, K., 2000). We become conscious (Hobson, P., 2002).

As a subjective experience, pain is one of the many exceptional properties of human existence. Belief in the exceptional properties of human beings, however, is not currently popular. John Gray, professor of European thought at the London School of Economics, for example, has coined the phrase Homo rapiens to describe the human race, which he presents as no better than bacteria (Gray, J., 2002). Although certainly an extreme view, Gray is not alone in comparing humanity to bacteria (Fernandez-

Armesto, F., 2004), or in suggesting the planet would do well to rid itself of our existence (Preston, P., 1993).

Even though many will likely reject the extreme antihumanism of Gray and others, far fewer will reject the notion that animals are ultimately quite similar to us. Almost every day, we are presented with new revelations about how animals are more like us than we ever imagined. A selection of news headlines includes: "How animals kiss and make up"; "Male birds punish unfaithful females"; "Dogs experience stress at Christmas"; "Capuchin monkeys demand equal rights"; "Scientists prove fish intelligence"; "Birds going through divorce proceedings"; "Bees can think say scientists"; "Chimpanzees are cultured creatures"; "Psychic' parrot expected to ruffle scientific feathers"; and, "They're in love. They're gay. They're penguins."

While this kind of anthropomorphism can seem harmless and is often amusing, the ultimate effect is similar to that of the frank antihumanists: to denigrate human abilities (Schwab, A., 2003; Guldberg, H., 2004). The sheer staggering scale and richness of human culture are unlike anything in any other species. The development of medicine, industry, transportation, communication, clean water, a stable food supply, warm habitats, and so on, are the discernible signs of culture and progress that are evidently absent from the nonhuman world.

This does not mean we should ignore issues of animal welfare, but it does mean that any discussion of animal welfare is a human debate and is fundamentally about what it means to be human (Engelhardt, T. H., 2001; Derbyshire, S. W. G., 2002). The self-reflective ability of humans, which encapsulates feelings and experience and which made tangible material and cultural progress possible, has moral and political consequences. Humans are free agents, within the limits of any given political system, and organize their behavior according to rights and customs that they create, which includes weighing and judging the life of humans or animals (Engelhardt, T. H., 2001).

Human beings take a central moral position, not via some act of special pleading, but as a function of their exceptional and special abilities (Engelhardt, T. H., 2001). We have an unavoidable moral centrality that places us into a position of authority over animals and at liberty to do with our own animals whatever we wish. Arguably, where the aim is one of frank malevolence, the agents involved have rejected morality itself and are acting in an antisocial manner worthy of sanction. It is probably appropriate to distinguish between practices aimed at cruelty and those motivated by a scientific, educational, or cultural practice. Such distinction will lead to a condemnation of some animal uses but will not count against those that are part of sport, consumption, or research (Engelhardt, T. H., 2001).

For researchers involved in understanding pain, there is a simple message. The use of animals has application to human welfare because of the similarities between the nociceptive system of animals and humans. There is the real possibility of discovering new ways of preventing noxious transmission, and the processing of noxious information, in humans through the use of animal models. At the same time, the use of animals is morally acceptable, because animals precisely lack the insight and conscious appreciation that makes pain, moral agency, and personhood possible.

5.64.1 Overview of Pain

5.64.1.1 Overview of Stages/Dimensions of Pain

5.64.1.1.1 Psychological stages of pain processing

As a preliminary foundation for these discussions, this chapter begins with very general and somewhat simplified psychological and neurophysiological overviews of pain processing mechanisms. As a starting point for discussion, one can think of pain modulatory mechanisms as those that can intervene in the pathways outlined in Figures 1 and 2. Pain contains both sensory and emotional dimensions and is often accompanied by desires to terminate, reduce, or escape its presence (Buytendyck, F. J. J., 1961; Melzack, R. and Casey, K. L., 1968). By definition, pain is unpleasant and contains emotional feelings. This is largely due to the fact that the sensory qualities of physical pain dispose us to feel unpleasantness in most contexts. Thus, sensory qualities associated with pain are usually unpleasant for the same reasons that nausea and air hunger are perceived as unpleasant, as indicated by the path from nociceptive sensations to unpleasantness in Figure 1. In addition, there are parallel contributions to pain unpleasantness because the meaning of these sensory qualities is shaped by context and by a person's ongoing anticipations and attitudes. These contextual and cognitive factors are partly the result of the fact that pain often occurs within a situation that is threatening, such as during physical trauma or disease. Part of the affective dimension of pain is the moment-by-moment unpleasantness of pain, comprised of emotional feelings that pertain to the present or short-term future, such as annoyance, fear, or distress. Pain-unpleasantness is often though not always closely linked to both the intensity and unique qualities of the painful sensation. Another component of pain affect, secondary pain affect, includes emotional feelings directed toward long term implications of having pain (e.g., suffering), as shown in Figure 1 by the path extending from pain unpleasantness to secondary pain affect.

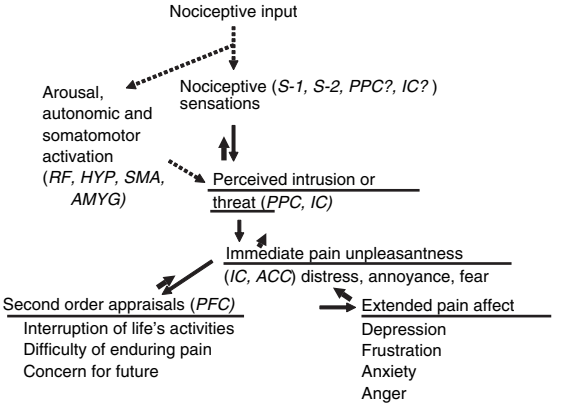

Figure 1 Schematic used to illustrate interactions between pain sensation, pain unpleasantness, and secondary pain affect (solid arrows). Neural structures likely to have a role in these dimensions are shown by abbreviations in adjacent parentheses and their full names are given in the legend of Figure 2. Dashed arrows indicate nociceptive or endogenous physiological factors that influence pain sensation and unpleasantness. From Price, D. D. and Bushnell, M. C. (*eds*.) 2004. Psychological Methods of Pain Control: Basic Science and Clinical Perspectives, pp. 322. IASP Press.

5.64.1.1.2 Factors contributing to pain unpleasantness

Multiple factors contribute to pain unpleasantness. Several sensory attributes of pain dispose unpleasant emotional feelings. The foremost among these is that sensations of pain are often, though not necessarily, more intense than other types of somatic sensations. Similar to other sensory modalities, it is commonly accepted that perceived intensity is a salient factor that contributes to the unpleasantness of pain. It may be the reason that very bright lights and loud sounds are sometimes metaphorically referred to as "painful". Qualities of sensations evoked by tissue damaging stimuli or stimuli that would produce tissue damage if maintained dispose us to perceive pain as invasive and intrusive for both the body and consciousness (Buytendyck, F. J. J., 1961; Price, D. D., 1999; 2000). Both neural and psychological processes related to sensory qualities of pain can be conceived as important causal links in the production of pain-related emotional disturbance. The persistence of these sensory qualities over time enhances unpleasantness. Thus, there exists a serial interaction between pain sensation intensity and pain unpleasantness.

Nociceptive, exteroceptive (e.g., sight, sound), and interoceptive sensory processes (e.g., startle, increased visceral responses) may provide parallel contributions to pain affect (Price, D. D., 1999). Pain itself can be conceptualized as both an exteroceptive and interoceptive phenomenon depending on the type of tissue that is stimulated and/or the types of sensory qualities that are present during pain. Consistent with Damasio's (Damasio, A., 1994) neurological view of emotion mechanisms, pain unpleasantness reflects the

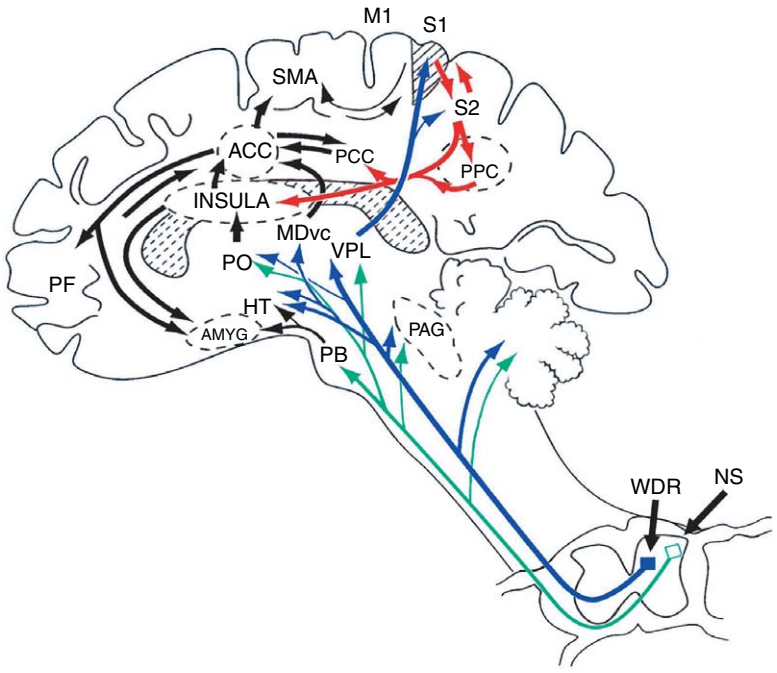

Figure 2 Schematic of ascending pathways, subcortical structures, and cerebral cortical structures involved in processing pain. PAG, periaqueductal gray; PB, parabrachial nucleus of the dorsolateral pons; VMpo, ventromedial part of the posterior nuclear complex; MDvc, ventrocaudal part of the medial dorsal nucleus; VPL, ventroposterior lateral nucleus; ACC, anterior cingulate cortex; PCC, posterior cingulate cortex; HY, hypothalamus; S-1 and S-2, first and second somatosensory cortical areas; PPC, posterior parietal complex; SMA, supplementary motor area; AMYG, amygdala; PF, prefrontal cortex. contribution of several sources, including pain sensory qualities, arousal, visceral, and somatomotor responses. Thus, these psychophysiological sources of input, in combination with appraisal of the context in which they occur, give rise to a feeling of what is happening to the body and self, often but not necessarily accompanied by specific thoughts. This felt meaning derives largely from the experience of the body and constitutes the immediate unpleasantness of pain. For Damasio, "the essence of feeling an emotion is the experience of such changes in juxtaposition to the mental images that initiated the cycle" (Damasio, A., 1994, p. 145). In the case of pain, the mental image is that of a physically intrusive and qualitatively unique somatic perception.

Psychophysical studies demonstrate that pain sensation and pain unpleasantness represent two distinct dimensions of pain that demonstrate reliably different relationships to nociceptive stimulus intensity and are separately influenced by various psychological factors. Pain unpleasantness can be selectively influenced by emotions, changes in meaning of the pain, and factors related to the predictability, controllability, and duration of pain (Buytendyck, F. J. J., 1961; Melzack, R. and Casey, K. L., 1968). Pain unpleasantness also often leads to and sustains pain-related emotions that are based on cognitive appraisals that are more reflective than is pain unpleasantness. We term these latter pain-related emotional feelings as secondary pain affect. Unlike pain unpleasantness, secondary pain affect is based on more elaborate reflection related to that which one remembers or imagines. This involves meanings such as perceived interference with one's life, difficulties of enduring pain over time, and the implications for the future (Buytendyck F. J. J., 1961; Price, D. D., 1999). Pain is often experienced not only as a threat to the present state of one's body, comfort, or activity, but also to one's future well being and life in general. The perceived implications that present pain-related distress or annoyance holds for future well being and functioning support the link between pain unpleasantness and secondary pain affect, as illustrated in Figure 1. Studies of pain patients show the distinction between immediate pain unpleasantness and secondary pain affect and their sequential interactions.

5.64.1.2 Overview of Neurophysiological Processing of Pain

The stages of pain processing just described are also related to our present understanding of the neurophysiology of pain. Underlying neural mechanisms of sensory as well as primary and secondary affective dimensions of pain include multiple ascending spinal pathways to the brain and both parallel and serial processing in the brain. The neural representation associated with the experience of pain is likely to be related to a distributed network of brain structures that participate in the different dimensions of pain, such as identification of unique sensory qualities and their intensity, response selection, arousal, emotional feelings, and finally emotional expression and motivation. This network of brain circuitry is itself controlled by inhibitory and facilitatory interactions within the brain, as well as descending inhibitory and facilitatory control within brain-to-spinal cord pathways (Basbaum, A. I. and Fields, H. L., 1984; Price, D. D., 2000; Rainville, P. *et al.*, 1997). Thus, pain can be enhanced or reduced by interactions that take place at any one of several points in the schematics in Figures 1 and 2. A major pathway for pain modulation, known since the 1970s, is that of a brainstem-to-spinal cord pathway that utilizes endogenous opioids (Figure 3).

5.64.1.2.1 Ascending nervous system pathways for pain

The principle ascending pathways for pain (Figure 2) originate in specialized receptors in body tissues, called nociceptors. These receptors are specialized to respond to stimuli to tissues that either cause damage or would cause damage if they were maintained for a sufficient length of time. Nociceptors are connected to primary afferent neuron axons that synapse onto dorsal horn neurons (Figure 2). The dorsal horn of the spinal cord receives somatosensory information from most of the body, and the dorsal horn of the medulla oblongata receives input from the orofacial area via the trigeminal nerve. There are different classes of primary nociceptive afferent neurons that innervate different types of tissues, such as skin, muscle, joints, and viscera. Dorsal horn neurons that receive primary nociceptive neuron input are at the origin of ascending pathways to the brain that have different functional roles in pain processing. Two types of dorsal horn sensory projection neurons include nociceptive-specific neurons (NS) that respond predominantly to nociceptive stimuli and wide-dynamic-range (WDR) neurons that respond differentially to gentle and nociceptive stimulation. Both WDR and NS neurons project in the spinothalamic tract, the main somatosensory pathway for pain. The spinothalamic tract projects to the ventro-posterior-lateral thalamic nucleus (VPL), some medial thalamic nuclei, and nuclei just posterior and inferior to VPL. VPL (and VPM in the case of the trigeminal system) projects to the somatosensory cortices (S1 and S2), whereas medial and posterior thalamic nuclei mainly project to limbic cortical areas (Figure 2). The pathway to VPL/VPM is critical for sensory qualities of pain and appreciation of its perceived sensory intensity. In addition to this major pathway, there are pathways that proceed from the dorsal horn directly to reticular formation nuclei of the medulla and midbrain and to the hypothalamus. There also is a pathway that ascends to the amygdala by way of a synapse in the pons (Bernard, J. F. *et al.*, 1996). These various target structures are involved in pain because they participate in such functions as arousal and diffuse cortical activation (reticular formation nuclei), body regulation (hypothalamus), and affective states such as fear (amygdala). The central nucleus of the amygdala has been strongly implicated in fear, emotional memory, and behavior, and autonomic and somatomotor responses to threatening stimuli (Bernard, J. F. *et al.*, 1996). Various hypothalamic nuclei have also been implicated in these functions. Based largely on their central targets, all ascending pathways described above are likely to participate in the affective dimension of pain. Thus, some pathways directly activate cortical and subcortical limbic structures and the pathway to VPL/VPM and somatosensory cortex

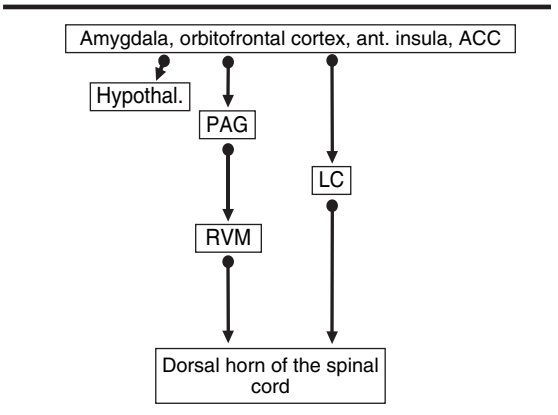

Figure 3 Schematic used to illustrate pathways and mechanisms that modulate pain. From Price, D. D. and Bushnell, M. C. (*eds.*) 2004. Pschological Methods of Pain Control: Basic Science and Clinical Perspectives, pp. 322. IASP Press.

activates these same limbic structures through a ventrally directed route, as shown in Figure 2. This latter pathway reflects the serial interaction between pain sensory qualities and intensity and pain unpleasantness. Thus, direct and indirect activation of emotion-related limbic structures is consistent with the pathways shown in the schematic of Figure 1. Emotions related to pain are a consequence of sensations related to pain (i.e., serial interrelationships) as well as other psychophysiological and contextual factors (i.e., parallel interrelationships). Some aspects of pain-related emotions may occur automatically as a result of direct input to subcortical limbic areas such as the amygdala, a structure implicated in fear.

5.64.1.2.2 Brain pathways and regions interrelating sensory and affective dimensions of pain

Once impulses in ascending pathways from the dorsal horn reach different targets within the brain, both serial and parallel circuitry is activated. The serial interconnections are established by the pathway to VPL and to somatosensory cortices that is anatomically interconnected with a ventrally directed corticolimbic pathway that integrates somatosensory input with other sensory modalities such as vision and audition and with learning and memory (Friedman, D. P. *et al.*, 1986). This pathway proceeds from primary and secondary somatosensory cortices to posterior parietal cortical areas and to insular cortex (IC) and from the latter to subcortical limbic structures (e.g., amygdala, perirhinal cortex, and hippocampus). This corticolimbic pathway may be critical for pain affect (Friedman, D. P. *et al.*, 1986). This serial corticolimbic somatosensory pathway ultimately converges on the same limbic and subcortical structures that may be more directly accessed by other ascending spinal pathways. The latter reflect parallel processing. This dual convergence may be related to a mechanism whereby multiple neural sources, including somatosensory cortices S1 and S2, contribute to pain affect and reflects both parallel and serial processing. This corticolimbic serial pathway directly implies that somatosensory cortices contribute to pain affect. This implication is consistent with psychophysical studies in which pain unpleasantness was shown to be the result of pain sensation intensity and with studies showing deficits in both pain sensation and pain unpleasantness as a result of somatosensory cortical lesions (see references in Price, D. D., 1999; 2000).

5.64.1.2.3 The pivotal role of the anterior cingulate cortex (ACC) in pain affect

As shown in Figure 2, ACC receives inputs from multiple sources, including thalamus, insular cortex, posterior cingulate cortex (PCC), and prefrontal cortex. Convergence of these inputs at the level of ACC would be consistent with a mechanism in which somatic perceptual and cognitive features of pain would be integrated with attentional and rudimentary emotion mechanisms. Based on neurological evidence, the ACC may have a complex pivotal role in interrelating attentional and evaluative functions with that of establishing emotional valence and response priorities (Devinsky, O. *et al.*, 1995). Response priorities would be closely related to premotor functions that are integrally related to motivation and emotions and may be associated with immediate efforts to cope with, escape, or avoid the pain and pain-evoking situation. For example, the projection of ACC to the supplementary premotor area may reflect the motor side of an overall affective-motivational dimension of pain. In this view, cortical areas controlling sensory, attentional, pre-motor, and affective functions of pain are part of a distributed network that has serial and parallel connections. This network has implications for psychological modulation of pain because each of these connections represents a stage of pain processing that can, in principle, be modified by psychological factors.

Response priorities change over an extended period of time. Pain unpleasantness endured over time engages prefrontal cortical areas involved in reflection and rumination over the future implications of a persistent pain condition. The ACC may serve this function by coordinating somatosensory features of pain with prefrontal cerebral mechanisms involved in attaching significance and long term implications to pain, a function associated with secondary pain affect (Apkarian, A. V. *et al.* 2001; Devinsky, O. *et al.*, 1995; Price, D. D., 1999; Verne, G. N. *et al.*, 2003). Thus, ACC may be a region that coordinates inputs from parietal areas involved in perception of bodily threat with frontal cortical areas involved in plans and response priorities for pain-related behavior. Both functions would help explain observations on patients with prefrontal lobotomy and patients with pain asymbolia as a result of insular cortical lesions (Price, D. D., 1999). The former have deficits in spontaneous concern or rumination about their pain but can experience the immediate threat of pain once it is brought to their attention. In contrast, asymbolia patients appear incapable of perceiving the threat of

nociceptive stimuli under any circumstances. The role of medial prefrontal cortical areas in secondary pain affect is also supported by recent brain imaging studies. These studies show increased prefrontal neural activity in clinical pain patients likely to have high levels of secondary pain affect (Apkarian, A. V. *et al.* 2001; Verne, G. N. *et al.*, 2003).

5.64.2 Modulation of Pain Sensation and Pain Affect by Attention and Distraction

There are neural circuits that provide top-down modulation of the pain experience. Central neural mechanisms associated with such phenomena as placebo/nocebo, hypnotic suggestion, attention, distraction, and even ongoing emotions are now thought to modulate pain by decreasing or increasing neural activity within many central neural structures, including the dorsal horn (Figure 3). This modulation includes endogenous pain-inhibitory and pain-facilitatory pathways that descend to spinal dorsal horn, the origin of ascending spinal pathways for pain (Basbaum, A. I. and Fields, H. L., 1978). Recent brain imaging studies have begun to reveal the cortical areas involved in pain modulation (Hofbauer, R. K. *et al.*, 2001; Koeppe, R. A. and Stohler, C. S., 2001; Petrovic, P. *et al.*, 2001, Rainville, P. *et al.*, 1997).

The modulation of pain by endogenous cortical and subcortical networks is consistent with other types of brain imaging experiments that show that anticipation of pain activates cortical nociceptive regions to some extent, though to a lesser degree than pain itself. Thus, the cortical networks shown in Figure 2 may be directly influenced by cognitive factors. These are likely to include not only anticipation of the presence of pain, but also anticipation of its reduction, as in the case of placebo or hypnotic analgesia. The modulatory mechanisms are likely to be diverse, extending from those which are confined only to neural interactions within the brain to those involving activation of brain-to-spinal cord circuits long known to potently reduce or enhance pain, as represented in Figure 3 (Basbaum, A. I. and Fields, H. L., 1978).

5.64.2.1 Psychophysical Studies of Effects of Attention and Distraction on Pain

Attentional manipulation can be achieved in numerous ways; however, distraction is the most general attentional manipulation for pain modification. An interesting stimulus can be presented to an individual, or the individual can engage in an attention-demanding task. Unfortunately, in addition to attention, other variables are often affected by these techniques. For example, mood and/or arousal may change in response to an interesting stimulus (e.g., music), and alteration of these states may contribute to changes in pain experience. Furthermore, simple distraction tasks often lack a measure of attentional state. This is problematic, as some individuals may attend to music during presentation of noxious stimuli, whereas others may focus only on the pain. In the case of attention-demanding tasks, some individuals who are particularly adept at performing the task (e.g., mental arithmetic) may devote much less attention to it than those who are less skilled.

A psychophysical paradigm with two balanced conditions provides a more controlled alteration of attentional state. An example is that of the cross-modality attention paradigm in which stimuli from two sensory modalities are presented simultaneously, and the participant must perform tasks that require attention to one modality. Attentional status is measured via task performance. These paradigms permit the control of level of arousal and vigilance, because the same stimuli are presented on all trials, task difficulty is equivalent between the two modalities, and only direction of attention is altered.

One variant of the balanced-condition psychophysical approach is the intra-modal spatial attention paradigm. In this paradigm, concurrent identical stimuli are presented to different receptive fields – or different body regions for somatosensory stimuli – and tasks are performed that require attention to one or the other location. Although used extensively with visual and auditory systems (Corbetta, M. and Shulman, G. L., 2002; Hikosaka, O. *et al.*, 1996), when applied to the pain system, this paradigm may engage diffuse noxious inhibitory controls (DNIC), a pain modulatory system evoked by simultaneous presentation of two noxious stimuli, that could alter pain perception (Le Bars, D. *et al.*, 1979a; 1979b; Price, D. D. and McHaffie, J. G., 1988). Consequently, this paradigm makes it difficult to distinguish changes in pain perception due to shifts of spatial attention from those due to other pain modulatory networks.

Finally, a balanced-condition psychophysical paradigm can require shifts of attention to different dimensions of the same stimulus within a single stimulus modality. For example, one can attend to the shape, color, texture, or motion of a visual stimulus.

Similarly, the quality of a painful stimulus – the burning, stinging, or aching sensations – can be the focus of attention. The unpleasantness of the sensation can also be attended to. Such manipulations can alter both the pain experience and pain-evoked neural activity.

5.64.2.1.1 Studies of basic distraction effects on pain

Many studies have compared experimental pain ratings in the presence and absence of a distracter (Bentsen, B. *et al.*, 1999; Hodes, R. L. *et al.*, 1990; Janssen, S. A. and Arntz, A., 1996; Johnson, M. H. and Petrie, S. M., 1997). Although not perfectly consistent, the vast majority of results indicate lower pain ratings during distraction. However, as noted above, caution is in order when attributing this pain modulation to directed attention, since uncontrolled other factors such as vigilance, mood, and anxiety, could contribute to the overall modulatory effect.

5.64.2.1.2 Studies of cross-modal attention effect on pain

Other studies have employed cross-modality psychophysical paradigms to specifically examine the modulatory effects of directed attention. For example, Miron (Miron, D. *et al.*, 1989) had participants detect changes in intensity of heat pain and visual stimuli. As expected, the speed and accuracy of detection of changes in stimuli were decreased when attention was directed to another stimulus modality. Their results further confirmed that pain stimuli were more effective in commanding attention than other stimuli. Subsequent results from the same investigators suggest that cross-modality attention may exert greater effects on the sensory dimension of pain than the unpleasantness dimension (Bushnell, M. C. *et al.*, 1999; Villemure, C. *et al.*, 2003). A limitation of all these studies is their focus on the sensory features of the stimulus. Requiring a study participant to attend to the emotional aspects of a stimulus might alter the affective more than the sensory component of pain.

5.64.2.1.3 Studies of spatial attention effects on pain

In a spatial attention paradigm, Bushnell M. C. *et al.* (1985) found that detection of changes to a heat stimulus applied to each side of the face was more rapid when these changes occurred on the side to which attention was directed. These results also demonstrated the modulatory effects of spatial attention on perceived intensity of noxious stimuli, as stimuli changes occurring outside a subject's attentional focus were less accurately detected. Furthermore, this study suggests that mechanisms of directed spatial attention involve areas of the nervous system that display a fine somatotopic organization of nociceptive information. The perceptual effects of spatial attention to pain are consistent with those of other sensory modalities and are critical for an organism's orientation to important features of the environment (Posner, M. E., 1980).

5.64.2.1.4 Studies of intra-modal attention effects on pain

In addition to focussing attention on different stimulus modalities and spatial locations, attention can also be directed to different features or dimensions of a stimulus. Several clinical and experimental studies have demonstrated decreased pain intensity and unpleasantness by directing subject attention to the sensory characteristics of pain (e.g., the burning, pricking, or aching sensation). A study of burn patients undergoing dressing changes found that those who focus on the sensory aspects of their pain report less pain than those distracted by music (Haythornthwaite, J. A. *et al.*, 2001). Another study of health-anxious chronic pain patients observed less anxiety and discomfort when attentional focus was directed only to the physical sensations of their pain (Hadjistavropoulos, H. D. *et al.*, 2000).

5.64.2.1.5 Other accounts of pain modulation by attentional and cognitive processes

An alternative account of attentional processing has been provided by Wegner D. M. (1994). He proposed the provocative theory of ironic processing, which has been applied to a number of cognitive processes (e.g., mood control, thought suppression) and has received some attention in the pain literature. This theory posits two cognitive mechanisms (the consciously controlled operating system and the automatic monitoring system) for achieving a desired mental state. The operating system searches for mental contents consistent with this state, whereas the monitoring system searches for mental contents inconsistent with this state. When the monitoring system locates such material, this material is brought into consciousness and thus activates the operating system. According to ironic processing theory, the operating system is compromised when mental capacity is reduced (e.g., because of pain, fatigue, stress), thereby permitting the undesired thoughts to enter

consciousness. A rebound effect then occurs where the undesired thoughts are more frequent than if they had not been initially suppressed (see Wenzlaff, R. M. and Wegner, D. M., 2000 for a review). As applied to pain, this theory holds that directed attention to pain would result in less pain compared to intentional distraction. Furthermore, pain suppression is suggested to have less antinociceptive effects than pain distraction. There is some evidence in the literature supporting both these hypotheses (e.g., Cioffi, D. and Holloway, J., 1993; Haythronthwaite, J. A. *et al.*, 2001).

What is to be made of the seemingly competing hypotheses of attentional modulation of pain and the divergent evidence that provides support for both these hypotheses? It may be that the antinociceptive effects of directed attention toward or away from pain is dependent upon the intensity of the pain and the cognitive and emotional state of the individual. For example, in situations of moderate pain intensity, where a patient is likely to be able to achieve/experience pain reduction, focused attention towards the pain may prove beneficial, à la ironic processing theory. How may this occur? Suppose a particular patient holds a moderate expectation for reduction in pain (due to some pharmacological agent, behavioral strategy, etc.) and a high desire for pain relief. Upon experiencing a small amount of pain relief – which the patient is able to perceive due to his/her focused attention on pain – some period of time following the treatment, the patient begins to notice that the treatment is working and, thus, expects further pain reduction. As a result of the experienced pain relief, the patient is also likely to be less fearful or anxious, and consequently reduces his/her desire for pain relief. As discussed more thoroughly below in the section on placebo, these changes in expectation (increase) and desire (decrease) can have powerful effects on the emotional state of the individual and, consequently, on the pain experience itself. In this manner, Wegner's contention that directed attention toward pain results in decreased pain is supported, although due to different mechanisms than outlined in his theory of ironic processing. Conversely, it may be the case that during episodes of extreme pain, directed attention away from the pain is the favored approach. During extreme pain, it is often the case that the patient has an intense desire for pain relief and a concomitant low expectation of achieving this relief. As this cognitive state is likely to produce intense negative emotions, which will be further reinforced by directed attention toward the pain and the experience of little pain reduction, it is likely that distraction techniques will prove most beneficial. Even in cases of moderate pain, if the patient has low expectations and high desire for pain relief (thus resulting in negative emotions), that individual may respond more favorably to a distraction technique than a pain-focused one. These are interesting and testable predictions, and they highlight the interaction between pain, cognition, and emotions. Other variables may also play an important role in these processes, as described below in the discussion of sex differences and pain-related attention.

In a laboratory cold-pressor paradigm, Keogh E. *et al.* (2000) found that for males, but not females, directed attention toward the pain sensation resulted in reports of less pain compared to a pain avoidance attentional condition. As a possible explanation for the seemingly paradoxical finding that men experience less pain by attending to it, the instructions required participants to concentrate on the sensations experienced during the task, and this sensory focussing may have reduced the painfulness of the situation. Thus, it appears that the use of attention-based strategies for pain reduction may be more effective for men than women.

5.64.2.2 Separating the Influence of Attention and Emotions

The attitude and emotional state of an individual can influence his/her perception of experimental and clinical pain (De Wied, M. and Verbaten, M. N., 2001; Marchand, S. and Arsenault, P., 2002; Meagher, *et al.*, 2001a; Schanberg, L.E. *et al.*, 2000; Weisenberg, M. *et al.*, 1998; Zelman, D. C. *et al.*, 1991). Unfortunately, pleasant stimuli used in laboratory studies to improve mood and reduce pain perception typically alter both attentional state and mood, thus confounding their effects. However, a recent study by Villemure C. *et al.* (2003) demonstrated that the effects of emotion and attention can be separated, and that these variables differentially alter pain intensity and pain-related unpleasantness. Using a cross-modality attention task, they showed that attending to the odor rather than heat pain reduced pain sensation intensity but did not alter pain-related unpleasantness, mood, or anxiety. In contrast, mood, anxiety level, and pain unpleasantness, but not pain intensity, were altered by odor valence. As compared to pleasant odor, unpleasant odor increased pain unpleasantness, negative mood, and anxiety. Their

results further suggest that the selective modulation of pain affect is a function of emotional changes, which were elicited by differences in odor valence.

5.64.2.3 Neurophysiological Studies of Effects of Attention on Pain Processing, Including Brain Imaging and Electrophysiological Studies

5.64.2.3.1 Effect of attention on pain-related activity in the dorsal horn

The attentional modulatory effects described above relate to studies of neural modulation of nociceptive transmission. Thus, dorsal horn sensory projection neurons, including WDR and NS neurons, undergo inhibition and facilitation from pathways that descend from the brain to the spinal cord (Figure 3). The stimulus-evoked impulse responses and the receptive field areas of these neurons can increase or decrease as a result of activity in various descending pathways under different behavioral conditions.

Descending modulatory influences and the behavioral conditions with which they are associated have been shown in experiments in awake trained monkeys (Hayes, R. L. *et al.*, 1981; Hoffman, D. S. *et al.*, 1981). These studies showed that responses of trigeminothalamic WDR and NS neurons of the medullary dorsal horn could be modified by different attentional sets and conditions of stimulus relevance. Nociceptive stimulus temperatures (45–49°) applied to the monkeys' face evoked impulse discharges in these neurons that were an increasing function of stimulus temperature. However, these neuronal impulse responses increased during a task in which the monkey discriminated a small temperature shift in the nociceptive range (a relevant attentional set) and decreased when they performed a similarly demanding visual discrimination task (an irrelevant attentional set). These opposing effects predict that the perceived intensity of pain should increase during thermal as compared to visual discrimination. A psychophysical study by Miron D. *et al.* (1989) confirmed this prediction.

The impulse frequencies elicited in WDR and NS trigeminothalamic neurons by the same range of nociceptive temperatures (45–49°) also can be modified by attentional factors related to anticipation. Impulse frequencies of these neurons were higher when a warning light preceded nociceptive stimuli as opposed to when these stimuli occurred unexpectedly. Thus, the magnitudes of the stimulus–response relationships are under dynamic modulatory control and may play as direct a role in determining pain perception as do the peripheral stimulus events themselves. The dorsal horn is part of a network involved in shaping pain perception, a network that includes the first synapse in ascending pathways for pain. This type of modulation had been anticipated by existing theories of pain (e.g., the gate control theory), but these studies were the first to demonstrate this principle in a behavioral context.

5.64.2.3.2 Effect of attention and distraction on pain-evoked activity in the brain

This type of study was extended by a similarly designed study of effects of attentional state on isolated nociceptive neurons in the thalamus (Bushnell, M. C. *et al.*, 1984; Bushnell, M. C. and Duncan, G. H., 1989). Similar to studies of trigeminothalamic neurons just described, tasks that directed a monkey's attention to a painful stimulus enhanced responses of medial thalamic neurons to nociceptive temperature stimuli applied to the monkeys' face, shown in Figure 4.

Imaging studies of the effects of attention and distraction in humans likewise show modulation of pain-evoked activity in the thalamus and several cortical regions, such as the primary somatosensory cortex (S1), anterior cingulate cortex (ACC), and insular cortex (IC) (Bantick, S. J. *et al.*, 2002; Brooks, J. C. *et al.*, 2002; Bushnell, M. C. *et al.*, 1999; Hoffman, H. G. *et al.*, 2004; Seminowicz, D. A. *et al.*, 2004; Valet, M. *et al.*, 2004). In one study, several pain-related brain regions were more activated during a pain-attention condition compared to a distraction condition (Peyron, R. *et al.*, 1999). In a similar study, Bushnell M. C. *et al.* (1999) showed the greatest attentional modulation of pain-evoked activity in S1 cortex, perhaps because subject attention was directed toward a sensory feature of the stimulus. Reciprocally, the primary auditory cortex was more activated when attention was directed to the auditory stimulus and not the painful stimulus, demonstrating the generality of attentional modulation across sensory modalities. Other regions, including the periaqueductal gray matter (PAG), ACC, and orbitofrontal cortex, may also be involved in the modulatory circuitry related to attention, as they have been shown to be activated during pain-distraction tasks (Petrovic, P. *et al.*, 2000; Tracey, I. *et al.*, 2002).

Results of EEG and MEG studies suggest that attentional modulation of pain likely involves both early sensory processing in S2-IC (Legrain, V. *et al.*,

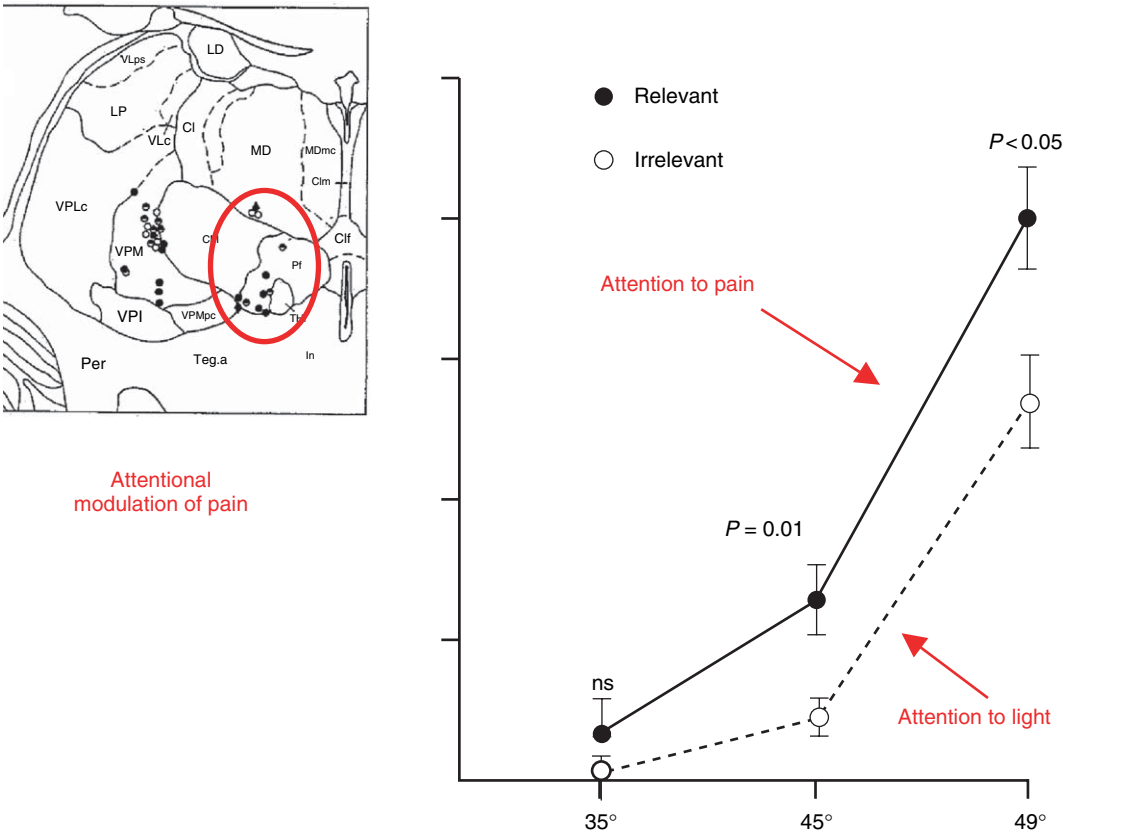

Figure 4 Stimulus–response functions showing single neuron responses in the medial thalamus (location shown in inset) during thermal stimuli of 35, 45, and 47 °C presented by a 1 cm^2 thermode on the maxillary facial area of a monkey. The solid line shows the responses when the monkey was required to attend to the thermal stimuli, and the dashed line shows responses to the same temperatures when the monkey was required to attend to a visual stimulus. Adapted from Bushnell, M. C and Duncan, G. H. 1989. Sensory and affective aspects of pain perception: Is medial thalamus restricted to emotional issues? Exp. Brain Res. 78, 415–418.

2002; Nakamura, Y. *et al.*, 2002) and later processing in ACC (Dowman, R., 2004; Garcia-Larrea, L. *et al.*, 1997; Siedenberg, R. and Treede, R. D., 1996). Changes in pain perception associated with attentional state appear to be due in part to changes in cortical processing and in part to a decrease in ascending afferent input from the spinal cord through activation of descending noxious inhibitory controls (DNIC).

5.64.3 Nonplacebo Effects of Expectation and Meaning

5.64.3.1 Effects on Pain Intensity

Studies attempting to modify either experimental or clinical pain intensity by manipulations designed to change expectancy show either weak or negligible effects, as indicated in a meta-analysis by Fernandez and Turk (Fernandez, E and Turk, D. C., 1989). Interestingly, 10 of 12 studies in their analysis showed that expectancy manipulations were least effective in reducing pain compared to other psychological strategies. A limitation of nearly all these studies, however, is that the independent variable is a manipulation or instruction designed to persuade participants to develop a positive expectation rather than a measure of expectation itself. Therefore, whereas the weight of all of these studies indicates weak or negligible effects of expectancy *manipulations* on pain intensity, it is not at all clear that direct effects of actual expectations have such weak effects. In fact, data published after Fernandez and Turk's (Fernandez, E and Turk, D. C., 1989) meta-analysis indicate that experiential manipulations of expectancy

have stronger effects than verbal manipulations of expectancy (Montgomery, G. H. and Kirsch, I., 1997; Voudouris, N. J. *et al.*, 1990).

5.64.3.2 Effects on the Affective Dimension of Experimental Pain

Studies of experimental pain wherein expectations can be directly manipulated provide the strongest evidence that desires and expectations are integral components of pain experience. Price D. D. *et al.* (1980) conducted a psychophysical analysis of experiential factors that influence the affective but not sensory discriminative dimension of heat pain. Trained participants made cross-modality matching judgments of both pain sensation intensity and unpleasantness. Non-noxious and noxious skin temperature stimuli were randomly interspersed during each experimental session. Changes in expectation of receiving painful stimulation were induced by preceding one-half of all the noxious stimuli by a warning signal. Results indicated that noxious temperatures were experienced as less unpleasant when preceded by a warning signal. In contrast, pain sensation magnitudes were unaffected by the warning signal. Moreover, the selective lowering of pain unpleasantness by the warning signal was greatest at the lowest end of the noxious temperature range (i.e. 45 °C) and was minimal at the highest end of the stimulus range (i.e., 51 °C). These data suggest that subjects prefer knowing that the next stimulus will be painful as compared to being surprised. Not knowing if the next stimulus will be painful is likely to produce anxiety; however, advanced warning has little effect if the intensity of stimulation is sufficiently high.

This interpretation of the anti-anxiety effects of a warning signal is supported by other experiments that reduce anxiety associated with experimental pain. Gracely *et al.* (1976) demonstrated that 5 mg diazepam significantly reduced affective descriptor responses to painful shock without altering sensory descriptor responses. Consistent with the Price D. D. *et al.* (1980) study, the reductions were greatest for low-intensity noxious stimuli. Another study by Gracely R. H. (1979) found a similar pattern for saline placebo administration. The results of all of these studies can be parsimoniously explained as a selective lowering of pain unpleasantness by reduction in anxiety. Part of pain unpleasantness is the anxiety associated with anticipating and receiving a noxious stimulus. Anxiety represents a state of wanting to avoid negative consequences combined with an experienced uncertainty of avoiding them (Barrell, J. J. *et al.*, 1985; Price, D. D. *et al.*, 1985). Regardless of how anxiety reduction is achieved, the result is that of selectively reducing pain unpleasantness, with the largest effects occurring for mildly painful intensities.

Expectations about the qualitative nature of pain sensations have also been shown to selectively influence pain affect. Johnson J. E. (1973) found that subjects who received a description of the painful sensations produced by forearm ischemia had lower levels of distress compared to subjects who only received a description of the procedure. Similar to Price D. D. *et al.* (1980), pain sensation intensities were unaffected by this difference in description. Thus, it appears that different kinds of expectations, either about the time of occurrence of pain or the types of sensations that will occur, can alter experienced unpleasantness without changing the intensity of experimentally induced painful sensation.

In summary, based on studies of experimental pain, it is apparent that expectations about different aspects of pain and about the contextual conditions in which pain is present influence pain differently. Expectations about when the pain will occur and what it means once it does occur may have relatively selective effects on the unpleasantness or immediate emotional disturbance associated with pain. Expectations about pain sensation intensity itself appear to have a modest influence on perceived pain intensity. Finally, manipulations designed to produce a positive expectation appear to have the weakest effect on pain intensity, although it is difficult to reach a definitive conclusion about this possibility because of the questionable pain measures used among most available studies.

5.64.3.3 The Influence of Expectancy on the Immediate Unpleasantness of Clinical Pain

The factors of desire for relief and expectation would intuitively have a greater influence on pain-related affect in the case of clinical pain, because the implications of having clinical pain are likely to be perceived as more open-ended and threatening than experimental pain. Unfortunately, few attempts have been made to directly assess the role of expectancy in clinical pain. Nevertheless, such a role is strongly supported by at least indirect evidence largely consistent with the idea that anxiety is a significant component of clinical pain affect. One study compared affective ratings of clinical pain in patients

whose pain is associated with a serious threat to health (cancer pain) to those of patients whose pain is of a less threatening nature (labor pain) (Price, D. D. *et al*., 1987). Comparisons were also made between women in labor whose focus was primarily on the birth of their child versus those who focused mainly on pain or on avoiding pain. In cancer pain patients, unpleasantness ratings were higher than sensory ratings, whereas the reverse was true for labor pain patients. Furthermore, patients who focused primarily on having the baby rated the unpleasantness of their pain as approximately one-half that of patients who focused primarily on pain or avoiding pain (Figure 5(a)); this difference occurred for each stage of labor. In contrast, no significant differences in pain sensation intensity ratings occurred between patients with these two orientations at any stage of labor (Figure 5(b)).

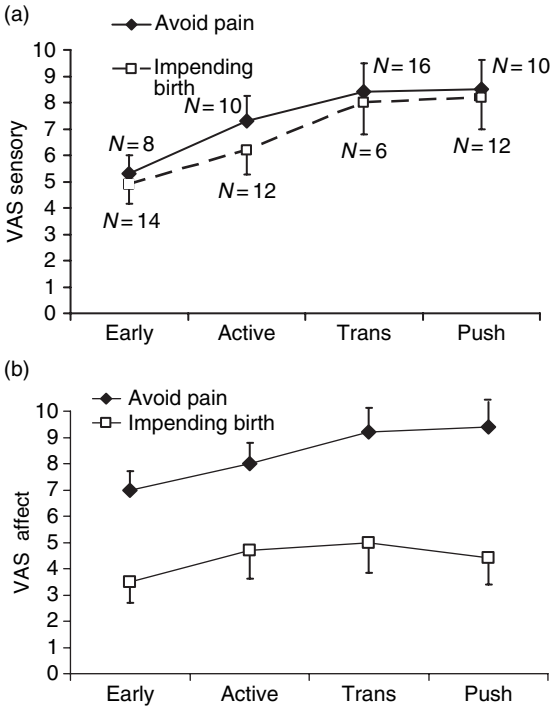

Figure 5 Mean sensory and affective VAS ratings of two groups of labor patients at various stages of labor. (a) Mean sensory ratings of the women who focused mainly on pain or avoiding pain (black diamonds) were very similar to women who focused mainly on the impending birth of the child. (b) Mean unpleasantness ratings of women focused on the impending birth were approximately half that of women who focused on pain or avoiding pain. Adapted from Price, D. D., Harkins, S. W., and Baker, C. 1987. Sensory-affective relationships among different types of clinical and experimental pain. Pain 28(3), 291–299.

The combination of all these results indirectly indicates that a person's goals, desires, and expectations about outcomes strongly influence emotional feelings associated with clinical pain. The influence of these factors is most apparent when divergent psychological orientations exist within a clinical pain condition. Thus, the unpleasantness generated by the immediate implications of cancer pain, including the reminder that pain sensation is a signal for the presence of disease, appears to add to that which is directly related to the pain sensations. One of the implications of having labor pain, on the other hand, is that birth of a baby is imminent. The positive emotional consequence of this implication appears to offset to some degree the unpleasantness of labor pain. This interpretation is further supported by the much greater degree of labor pain unpleasantness among women who focus on avoiding pain compared to those who focus on the birth of the baby. Part of what constitutes pain unpleasantness is the immediate implication of the pain condition. The implication, in turn, is related to a goal, desire, and an expectation associated with that goal.

Results from the studies of experimental pain described above indicate the existence of pharmacological and psychological manipulations that can selectively, and sometimes powerfully, reduce the immediate unpleasantness of pain. Some of these manipulations can be quite simple, such as stimulus duration or the presence or absence of a warning signal. Others are more complex and relate to restructuring the meanings associated with pain (e.g., some hypnotic suggestions). Manipulations that enhance pain unpleasantness also exist. The identification of experimental manipulations that selectively modify affective components of pain is critical for developing experimental strategies for identifying neurons, central pathways, and brain regions that are uniquely involved in the immediate affective dimension of pain.

5.64.4 Factors That Contribute to the Magnitude of Placebo Analgesia

For decades, placebo responses were mainly conceptualized as resulting from inert physical agents. Within the last few years, explanations of placebo responses have shifted from emphasis on environmental factors to human meanings and perceptions. We explore the roles of both external and experienced factors in producing placebo analgesia as well

as the relationships between them (see Chapter The Placebo Effect for placebo vignette).

5.64.4.1 The Magnitudes of Placebo Analgesia and the General Contexts That Influence Them

Although this study raised considerable controversy, the effect of placebo treatment was compared to a natural history condition in a recent meta-analysis of 29 studies (Hrobjartsson, A. and Gøtzsche, P. C., 2001). The effect size of placebo analgesia, measured as Cohen's d (pooled standardized mean difference), was 0.27, reflecting a small effect that is possibly clinically significant. Hrobjartsson and Gøtzsche suggested that the small placebo analgesia effect could be the result of confounding variables such as response bias, since pain reflects a subjective state. Interestingly, the large majority of the studies (24 of 29) included in the meta-analysis used a clinical trial design in which placebo administration served as the control condition. Verbal suggestions for analgesia are typically avoided in such studies and the only reference to placebo is made in the consent form in which patients are informed of the possibility of receiving an inert and/or ineffective agent. In most nonresearch clinical settings or in experimental studies of placebo analgesia mechanisms, however, positive suggestions or conditioning with effective agents are likely to enhance placebo analgesia, as will be discussed below. Therefore, patients are more likely to expect to receive a pain relieving medication in studies containing positive verbal suggestions in comparison to most clinical studies.

To determine whether placebo effect size is systematically influenced by the two contexts just described, two contrasting meta-analyses were conducted (Vase, L. *et al.*, 2002). In the first, twenty-three studies in which placebo treatments were used as a control condition were included, the majority of which were also included in the meta-analysis by Hrobjartsson and Gøtzsche. Most of these were clinical studies that tested an active drug or treatment. In the second, fourteen studies that were about placebo analgesic mechanisms were included. The mean effect size was 0.15 in the first meta-analysis of twenty-three studies, even smaller than Hrobjartsson and Gøtzsche's finding of 0.27. However, the mean effect size was 0.95 in the fourteen studies of placebo mechanisms, where strong suggestions for pain relief were typically given. Overall, these meta-analyses indicate that although the magnitude of placebo analgesia effects is highly variable, one of the potent factors influencing the placebo effect may be whether overt verbal suggestions are given for pain relief. The effect size of placebo analgesia in the studies where placebo analgesia was induced via either conditioning alone or suggestion alone was 0.83 and 0.85, respectively. However, the magnitude of placebo analgesia was 1.45 (almost twice as high as either factor alone) in the studies where the placebo analgesia effect was induced via a combination of conditioning and suggestion. Thus, it appears that the effect of external manipulations such as conditioning and suggestion are additive, implying that the placebo analgesia effect may be related to how the placebo agent is perceived, regardless of the exact external factors that lead to that perception.

5.64.4.2 Analyses of Factors That Contribute to the Magnitude of Placebo Analgesia

Given the variability in placebo analgesic effects and the systematic influence of the presence or absence of factors such as previous experience with effective treatments and verbal suggestions, an emerging goal of placebo analgesia research is to identify factors that contribute to the perceived efficacy of a therapeutic intervention. The contribution of placebo analgesia to the effectiveness of analgesic drugs was tested in a clinical study using hidden and open injections of traditional painkillers such as buprenorphine (Colloca, L. *et al.*, 2004). The patients needed less medication for analgesia when a doctor administrated open injections of painkilling agents with verbal suggestions for pain relief, than when a hidden machine administrated the painkilling agents. Presumably, the difference in analgesic response between open and hidden injections directly reflects the placebo analgesia effect. The difference between open and hidden injections could be eliminated by hidden injections of naloxone in a subsequent experimental study, demonstrating that part of the response variability to analgesic drugs can be attributed to opioid-mediated placebo analgesic effects. It may be particularly useful to explore exactly how subjects experience open injections versus hidden injections in order to clarify the mediating and moderating factors in placebo analgesia. As discussed below, such an approach is beginning to be applied to placebo analgesic research in general.

5.64.4.2.1 External factors that contribute to placebo analgesia

5.64.4.2.1.(i) Conditioning Previous experiences with pain, the analgesic remedy, and the setting are likely to influence perception of pain treatments. Some investigators propose the idea that placebo effects are based on Pavlovian conditioning. When a patient receives an agent (unconditioned stimulus) that leads to analgesia (unconditioned response), contextual cues such as the medical setting, the white coat, or the pill/syringe (conditioned stimuli) may be associated with pain relief (Wickramasekera, I. A., 1985). These contextual factors, which represent the conditioned stimuli, elicit pain relief in the absence of active agents. Cross-over studies have supported this hypothesis; the magnitude of placebo analgesia follows the graded doses of the active drug when placebo is given as the second drug (Laska, E. and Sunshine, A., 1973). Voudouris N. J. *et al.* (1985; 1989; 1990) conducted the first studies to investigate the contribution of conditioning with a design that included a repeated baseline control condition. Subjects were tested in three sessions: (1) pretest, where a noxious electrical stimulus was applied to determine the subjects' threshold, (2) manipulation, where an inert cream was applied to the skin and the stimulus was surreptitiously reduced to provide an experience of the cream's analgesic effect, and (3) posttest, where the analgesic cream was applied and the original intensity stimulus was delivered to the same area of the skin. Compared to a group given the cream with no conditioning, the conditioning group showed significant pain reduction by the placebo cream. This suggests that a previous pairing of reduced stimulus intensity with an inert cream can result in large analgesic effects.

With subjects undergoing ischemic arm pain, the contribution of conditioning also has been tested (Amanzio, M. and Benedetti, F., 1999). On the first day, subjects were tested during a no-treatment session. On the second and third day, a group of 14 subjects was conditioned with the opioid agent morphine and another group (14 subjects) was conditioned with the nonopioid agent ketorolac. On the fourth day, both groups received open injections of saline and were told that the agent was an antibiotic to test effects of conditioning alone without any effect of overt placebo suggestion. Conditioning in both the morphine and ketorolac groups produced moderate and statistically reliable placebo effects. When the open injection secretly contained naloxone in a subsequent morphine-conditioned group, the placebo effect could be completely prevented. In contrast, the placebo effect was not antagonized by naloxone if ketorolac was used as the conditioning stimulus. Thus, the placebo analgesia effect induced by opioid conditioning (morphine) was mediated by endogenous opioids, whereas the placebo analgesia effect induced by nonopioid conditioning (ketorolac) was not mediated by endogenous opioids.

5.64.4.2.1.(ii) Suggestion Expectation and belief in future pain relief can be induced by nonverbal and verbal suggestions, and expectations of caregivers can be transferred to patients. For example, the influence of nonverbal suggestions was indirectly tested in a study where the clinician knew that one group of patients would receive placebo whereas the other group would receive placebo as well as the active analgesic agent fentanyl (Gracely, R. H. *et al.*, 1985). The placebo analgesia effect was significantly higher in the second group, indicating that even without intentional or verbal communication, simply the clinician's belief that a patient may receive a powerful painkiller influences the magnitude of placebo analgesia. Several studies have investigated the influence of verbal suggestions for pain relief.

The same paradigm of ischemic tourniquet pain tolerance was used to test whether suggestion in itself was enough to produce placebo analgesia (Amanzio, M. and Benedetti, F., 1999). After the first day's no-treatment session, on the second day, patients were given an open injection of saline and told that the agent was a powerful painkiller. A small but statistically reliable placebo effect was produced by this placebo treatment. When the experiment was repeated with an open injection of naloxone instead of an open injection of saline on the second day, the placebo analgesia effect was entirely eliminated, indicating that suggestion induces a placebo analgesia effect that is mediated by endogenous opioids. Recent studies have shown that both direct and indirect suggestions for pain relief lead to placebo analgesia of large magnitudes (Pollo, A. *et al.*, 2001; Price, D. D. *et al.*, 1999; Vase, L. *et al.*, 2002). Additionally, several studies have shown that verbal suggestions can lead to reduction of pain in highly specific areas of the body and that these specific placebo effects may be mediated by endogenous opioids (Benedetti, F. *et al.*, 1999; De Pascalis, V. *et al.*, 2002; Montgomery, G. H. and Kirsch, I., 1996; Price, D. D. *et al.*, 1999).

The majority of the studies presented so far have shown that conditioning in itself or suggestion in itself may lead to placebo analgesia. However, in

most studies and especially in most clinical settings, previous exposure to analgesic agents and verbal suggestions for pain relief combine to produce placebo analgesia. The combination of morphine conditioning and verbal suggestions for inducing placebo analgesia was also examined in the study by Amanzio M. and Benedetti F. (1999). The magnitude of this placebo analgesia effect was approximately twice the size of the placebo effect induced via either conditioning or suggestion alone. Interestingly, this large placebo effect could be completely prevented by naloxone. Thus, even though conditioning and suggestion may make separate contributions to placebo analgesia effects, they are likely to both activate a common opioid analgesia network. A recent study suggests that conditioning and suggestion both influence conscious phenomena (e.g., pain) through expectations, whereas conditioning without conscious expectations can influence unconscious physiological processes such as cardiovascular responses and hormonal secretions (Benedetti, F. *et al.*, 2003).

5.64.4.2.2 Experienced factors that contribute to placebo analgesia

Patients are likely to perceive external factors such as conditioning and suggestion in different ways. Therefore, it is important to examine how these environmental factors and factors within the human experience relate to each other during placebo analgesia.

5.64.4.2.2.(i) Expectancy In pain studies, expectancy (the experienced likelihood of an outcome or an expected effect) can be measured by asking people about the level of pain they expect to experience. One of the first studies to directly measure and manipulate expected pain levels used a design in which subjects were conditioned with reduced stimulus intensity (cutaneous electrophoresis) in the presence of an inert cream (Montgomery, G. and Kirsch, I., 1997), similar to studies by Voudouris N. J. and co-workers (Voudouris, N. J. *et al.*, 1985; 1989; 1990). Subjects rated expected pain levels immediately after the conditioning trials. Pain ratings were noticeably reduced by the conditioning procedure in a group of subjects that did not know about the stimulus manipulation (i.e., the placebo analgesic effect). However, regression analyses showed that expected pain levels mainly accounted for this effect. Thus, expectancy accounted for 49% of the variance in post manipulation pain ratings. Furthermore, when another group of subjects was informed about the experimental design and learned that the cream was inert, their expected pain levels did not differ from expected pain levels during the baseline condition and the placebo analgesia effect disappeared. Thus, although conditioning can lead to placebo analgesia, it appears to be mediated by conscious expectations.

Using a similar paradigm, the extent to which expectations of pain relief can be graded and related to specific areas of the body was further tested (Price, D. D. *et al.*, 1999). In this study three 'strengths' of placebo cream were applied to the subjects forearm and external manipulations were performed to perpetuate the belief that cream A was a strong analgesic, cream B a weak analgesic, and cream C a control agent on three adjacent areas of the arm. Conditioning was accomplished by surreptitiously lowering the heat stimuli in areas A (large reduction) and B (small reduction) but not C (no reduction), after the creams were applied. Following these manipulation trials, subjects were asked to rate their expected pain levels for the next series of trials. The conditioning trials led to graded levels of expectancy for the three creams C, B, and A (of successively less intense pain). When identical stimulus intensities were applied during the postmanipulation trials, subjects rated pains in areas C, B, and A as progressively less intense, demonstrating a graded placebo effect. In this study, expected pain levels accounted for between 25% and 36% of the variance in postmanipulation pain ratings. These results provide further evidence for the somatotopic specificity of the placebo analgesic effect, given that these placebo effects were induced on three immediately adjacent areas of the arm.

5.64.4.2.2.(ii) Desire for pain reduction While expectancy appears to be an important psychological mediator of placebo analgesia, it is unlikely to work alone. Since motivation is known to influence perception, desire (the experiential dimension of wanting something to happen or wanting to avoid something happening) is also likely to be involved in placebo analgesia. In the study just described, the subjects' level of desire for pain reduction also was manipulated (Price, D. D. *et al.*, 1999). In one group, presenting them the prospect of receiving a large number of painful stimuli successfully increased their desire for pain relief. In a second group, informing them that only a few stimuli would be presented decreased desire. Interestingly, ratings of desire for

pain relief were not significantly associated with the magnitudes of placebo analgesia. One possible reason for this lack of association may be because pain was induced via brief heat stimuli in this experimental setting. Desire for pain relief may be more of a factor in clinical pain where the pain is threatening or has an uncertain duration, therefore likely inducing fear or anxiety. Consequently, it is important to investigate the contribution of expectations and desire for pain relief in more clinically relevant settings.

5.64.4.2.2.(iii) Memory of pain This same study also showed that distorted memory of recent pain also contributes to the placebo effect (Price, D. D. *et al.*, 1999). The placebo analgesia effect was assessed in two ways, on concurrent ratings of pain obtained immediately after the stimuli were applied and on retrospective ratings of pain obtained approximately two minutes after the stimuli were applied. Based on retrospective ratings, the magnitude of placebo analgesic effects was three to four times greater than the effect based on concurrent ratings. The main reason for this difference was that subjects remembered their baseline pain intensity as being much larger than it actually was. Similar to placebo analgesia effects based on concurrent ratings, the placebo effects based on remembered ratings were strongly correlated with expected pain intensities ($R = 0.5$–0.6). In fact, there was a stronger correlation between expected pain and remembered pain than between expected pain and actual pain. Consequently, it is important to measure placebo analgesia effects with concurrent ratings since it may be distorted by remembered pain. Moreover, since remembered pain and expected pain are closely related, these factors appear to interact. These effects of distorted memory on placebo analgesia have been replicated (De Pascalis, V. *et al.*, 2002).

5.64.4.2.3 Predicting placebo analgesia

Two similarly designed studies further explain how factors within and external to human experience may relate in placebo analgesia (Vase, L. *et al.*, 2003; Verne, G. N. *et al.*, 2003). In both studies, patients diagnosed with Irritable Bowl Syndrome (IBS) were exposed to rectal distention via a balloon barostat (a type of visceral stimulation that simulates their clinical pain) and tested under natural history, rectal placebo and rectal lidocaine conditions. Both pain intensity and unpleasantness were rated immediately after each stimulus. In the first study, a standard clinical trial was conducted where the patients were given an informed consent form stating that they "may receive an active pain reducing medication or an inert placebo agent" (Verne, G. N. *et al.*, 2003). The rectal lidocaine had a significant pain relieving effect compared to rectal placebo ($p < 0.001$), and the rectal placebo had a significant pain relieving effect compared to the natural history condition (Figure 6, left panel). Based on meta-analyses discussed earlier, the second study added a suggestion to the placebo condition and lidocaine condition (Vase, L. *et al.*, 2003). Patients of the second study were told at the beginning of each treatment condition that "the agent you have just been given is known to significantly reduce pain in some patients" (rectal placebo, rectal lidocaine). A much larger placebo analgesic effect was found in the second study. In fact, the magnitude of placebo analgesia was so high that there was no longer a significant difference between the magnitude of rectal lidocaine and rectal placebo (Figure 6, right panel). Therefore, these two studies indicate that it is possible to increase the magnitude of placebo analgesia to a level that matches an active agent by adding an overt suggestion for pain relief.

Patients were asked to rate their expected pain level and desire for pain relief immediately after the agent was administered (before the onset of its effects) in both studies. In the second study, the combination of expected pain levels and desire for pain relief accounted for 77% of the variance in post placebo pain ratings (see Table 1); however, expected pain levels have accounted for between 25% to 49% of the variance in post placebo pain ratings in previous studies. Therefore, it is possible that the combination of expected pain level and desire for pain relief accounts for a greater amount of the variance in post placebo pain ratings than either factor alone. Nevertheless, although the interaction between expected pain level and desire for pain relief seems to have contributed, the majority of the contribution came from the expected pain level (Table 1). Interestingly, the combination of expected pain level and desire for pain relief accounted for 81% of the variance in pain ratings during the rectal lidocaine condition. These findings further support the conclusion that placebo factors make strong contributions to the efficacy of active treatments.

5.64.4.3 Placebo Analgesia As an Emotional Response

More recently, the role of emotion in placebo analgesia has been examined in a number of studies.

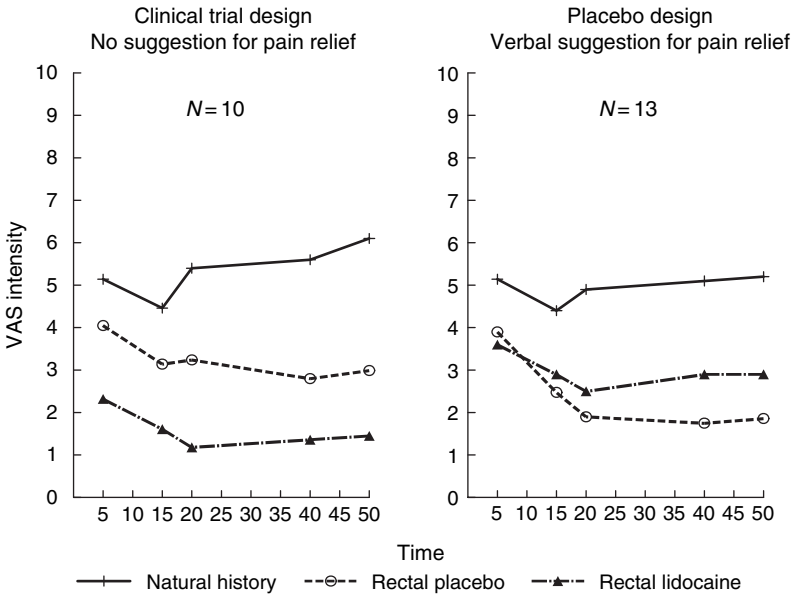

Figure 6 Comparisons of natural history, rectal placebo and rectal lidocaine scores on visceral pain intensity ratings (VAS) during a 50 min session within a clinical trial design, where no suggestions for pain relief are given (left) and within a placebo design with verbal suggestions for pain relief (right). From Vase, L., Robinson, M. E, Verne, G. N, and Price, D. D. 2003. The contribution of suggestion, expectancy and desire to placebo effect in irritable bowl syndrome patients. Pain 105, 17–25.

Interactions between desire and expectation account for magnitudes of positive and negative feelings during hypothetical emotional situations and emotional feelings during actual events (Price, D. D. and Barrell, J. J., 2000). These same interactions also can account for direction and strength of choices during instances of decision making (Price, D. D. *et al.*, 2001). Placebo analgesia may be added to the list of phenomena that are associated with the desire-expectation model in showing that interactions between desire for relief and expected pain levels account for large and significant amounts of the variance in the placebo response.

5.64.4.3.1 Do placebo effects result from changes in emotional states?

Placebo effects also may change over time as a consequence of changes in emotional states. Similar to the studies on IBS patients described above, 26 IBS patients were exposed to rectal distension under natural history, rectal placebo, and rectal lidocaine conditions and ratings were obtained of expected pain, desire for pain relief, anxiety, and actual pain during each experimental condition (Vase, L. *et al.*, 2005). In this study, however, ratings of expected pain levels, desire for pain relief, and anxiety were obtained at two time points, at the onset of placebo administration (early) and midway through the 40 min observation period (late). Ratings of these three factors decreased from early to late time points as did pain ratings within the placebo condition. Decreases in these three factors across natural history versus placebo conditions accounted for 11% (not significant) of the variance in placebo responses (pain in natural history minus pain in placebo condition) at the onset of placebo administration and for 58% (significant at $P < 0.001$) of the variance in placebo responses in the late period of observation. These results suggest that the placebo effect can increase over time as a function of decreases in expected pain levels, desire for relief, and negative

emotions such as anxiety. These findings support the view that placebo effects may be at least partly mediated by changes in emotional states. Equally interesting is that similar results occurred for the lidocaine condition, providing further evidence that placebo effects and the factors that evoke them are embedded in active treatments.

Placebo treatments can initiate a more positive or less negative emotional state for a patient. It is possible that the placebo analgesia effect can at least partly result from decreases in negative emotions or increases in positive emotions. This possibility is supported in part by the studies just described and also by a study, which shows that pain, unpleasantness, and pain intensity may be reduced by evoking positive emotions or increased by evoking negative emotions (Chretien, P. and Rainville, P., 2004). Since this study was not about placebo effects, it provides an independent line of evidence that emotional feelings modulate pain. If placebo manipulations alter pain, they may do so by altering emotional states. Alternatively, it is possible that desire and expectation are merely factors that are common to both placebo mechanisms and emotions. In a recent study, it was found that low desire for pain relief decreased pain intensity and unpleasantness, whereas a high desire for pain relief increased pain unpleasantness but not pain intensity, suggesting that a decrease in desire may actually lower pain intensity (Chretien, P. and Rainville, P., 2004). These results are consistent with placebo studies described above (Vase, L. *et al.*, 2003; Verne, G. N. *et al.*, 2003).

5.64.4.3.2 Future directions

Whereas past explanations of placebo analgesia focused mainly on environmental factors and classical conditioning models, modern explanations focus more on human meanings, conscious expectations, and emotions as mediators or moderators of this phenomenon. This shift in emphasis is exciting because it suggests that the placebo analgesic response can be understood as a mind-body interaction and as a phenomenon of human consciousness, which has parallels within pain-regulating areas of the brain. Thus, future studies that combine brain imaging with analyses of dimensions of human experience should provide important neuroscientific and psychological insights into the mechanisms of placebo effects, with both significant scientific benefits and consequent improvements in the care of patients with pain.

5.64.5 Modulation of Pain Intensity and Pain Unpleasantness by Emotions

Emotions are closely related to pain in several ways. The notion of pain-related suffering corresponds to the experience of strong negative emotion associated with pain. Emotions also share a number of features with pain, including output viscero-motor responses and several experiential dimensions. In addition to co-occurring with pain, increasing evidence suggests that emotions play an important role in pain modulation. This may reflect the overlap between pain and emotion-related neurophysiological processes. This section begins with a brief discussion of emotions and follows with a consideration of the effects of emotion on experimental and clinical pain.

5.64.5.1 Negative Emotions As a Constituent of Pain

5.64.5.1.1 Pain definitions

The International Association for the Study of Pain (IASP) defines pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage" (Merskey, H. and Spear, F. G., 1967). A slightly different definition is offered by Price D. D. (1999) in which pain is "a somatic perception containing (1) a bodily sensation with qualities like those reported during tissue damaging stimulation, (2) an experienced threat associated with this sensation, and (3) a feeling of unpleasantness or other negative emotions based on this experienced threat" (p. 1–2). In both definitions, negative emotions are a component of the pain experience. Price's (1999) stages of pain processing described earlier also highlight the relationship between pain and emotions.

5.64.5.1.2 Is pain an emotion?

The components of emotion theories also relate to pain processes. Perhaps the primary difference between pain and emotion is that pain requires the presence of "a bodily sensation with qualities like those reported during tissue damaging stimulation" (Price, D. D., 1999; p. 1). Pain sensations then can be regarded as a specific inducer of a primitive emotional response, which is consistent with theoretical accounts of emotion systems as closely related to evolutionary processes (e.g., Izard, C. E., 1993; Plutchik, R., 1980). The prototypical "pain face" has been documented and can be differentiated from

facial expressions of the basic emotions of fear, anger, and sadness (reviewed in Williams, A. C., 2002). Patterns of autonomic responses to nociceptive stimuli well documented in animals (Sato, A. *et al.*, 1997) may contribute to pain-related emotional responses as well as subjective feelings of unpleasantness (e.g. Fillingim, R. B. *et al.*, 1998; Rainville, P. *et al.*, 1999). The stages of pain processing described earlier include primary and secondary affective stages (Price, D. D., 1999), where the first corresponds to the basic experience of a threat, or the fear of tissue damage, and may include self-perception of autonomic and motor responses triggered automatically. The second stage reflects secondary evaluative processes consistent with modern views on the role of cognitive evaluative processes in emotions. This is also consistent with the experiential model in which emotional experiences are related to goals, desires, and expectations. A study by Price D. D. *et al.* (1980) indicated that this experiential model of emotions is predictive of variations in pain unpleasantness, but not pain intensity, which is consistent with the view that pain-related affective processes are emotional responses to pain sensations.

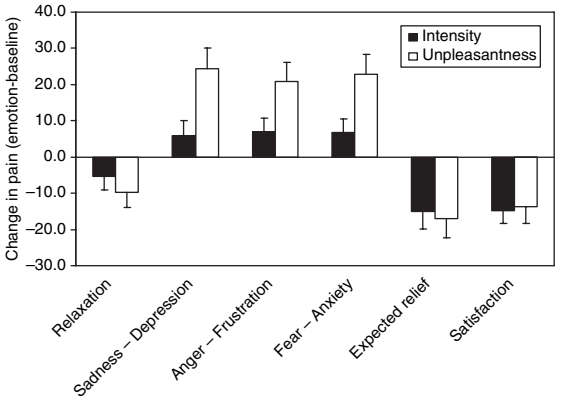

Figure 7 Changes in pain intensity and pain unpleasantness produced by 1 min immersions of the hand in hot water, from a baseline control condition and following the hypnotic induction of emotions. Significant increases in pain ($p < 0.05$) are found in response to negative emotions relative to the baseline ($y = 0$) and relaxation condition, with larger effects observed in pain unpleasantness than pain intensity. Decreases in pain were less pronounced and ns. in response to positive emotion induction. Adapted from Rainville, P. 2004. Pain and Emotions. In: Psychological Methods of Pain Control: Basic Science and Clinical Perspectives (*eds.* D. D. Price and M. C. Bushnell), pp. 117–141. IASP Press.

5.64.5.2 Effects of Emotion on Pain: Experimental Studies

In order to determine the effects of emotion on pain, one must first distinguish between emotions related to pain from emotions that co-occur with pain but are otherwise unrelated to pain. Emotions that are related to pain constitute secondary affective responses to pain. Emotions that are not related to pain may be considered distracters and/or they may produce brain-body responses that increase or decrease pain.

5.64.5.2.1 The experience of pain-related emotions

Hypnosis is one experimental paradigm that has been used to test the effect of pain-related emotions on pain. In a series of studies conducted by Rainville (reviewed in Rainville, P., 2004), positive and negative emotions were hypnotically induced in subjects undergoing an experimental pain task. Compared to baseline and hypnotic relaxation conditions, ratings of pain intensity and unpleasantness decreased in positive emotions conditions and increased in negative emotions conditions (Figure 7) (Huynh Bao, Q. V. and Rainville, P., 2002). Although affecting both pain intensity and unpleasantness, pain-related negative emotions primarily increased pain unpleasantness (Figure 7).

In a subsequent study examining the effects of anger and sadness, hypnotic suggestions for these emotions were associated with significant increases in desire to avoid and/or escape pain during the experimental task and reductions in expectations of avoiding and/or escaping pain (Figure 8(a)). Ratings of negative valence and arousal increased significantly in both negative emotion conditions, and subject ratings of their feeling of being in control (dominance) decreased significantly only in the sadness condition. In both negative emotion conditions, pain intensity and unpleasantness increased significantly, with pain unpleasantness showing a larger change (Figure 8(b)). Importantly, changes in pain unpleasantness, and pain intensity to a lesser degree, were predicted by changes in emotions (Table 2). The associations with pain unpleasantness remained significant after controlling for changes in pain intensity. However, after accounting for changes in pain unpleasantness, the associations with pain intensity were reduced to almost zero, save expectation that contributed some unique variance to changes in pain intensity. In a recent study, however, Chretien and Rainville (Chretien, P. and Rainville, P., 2004) found

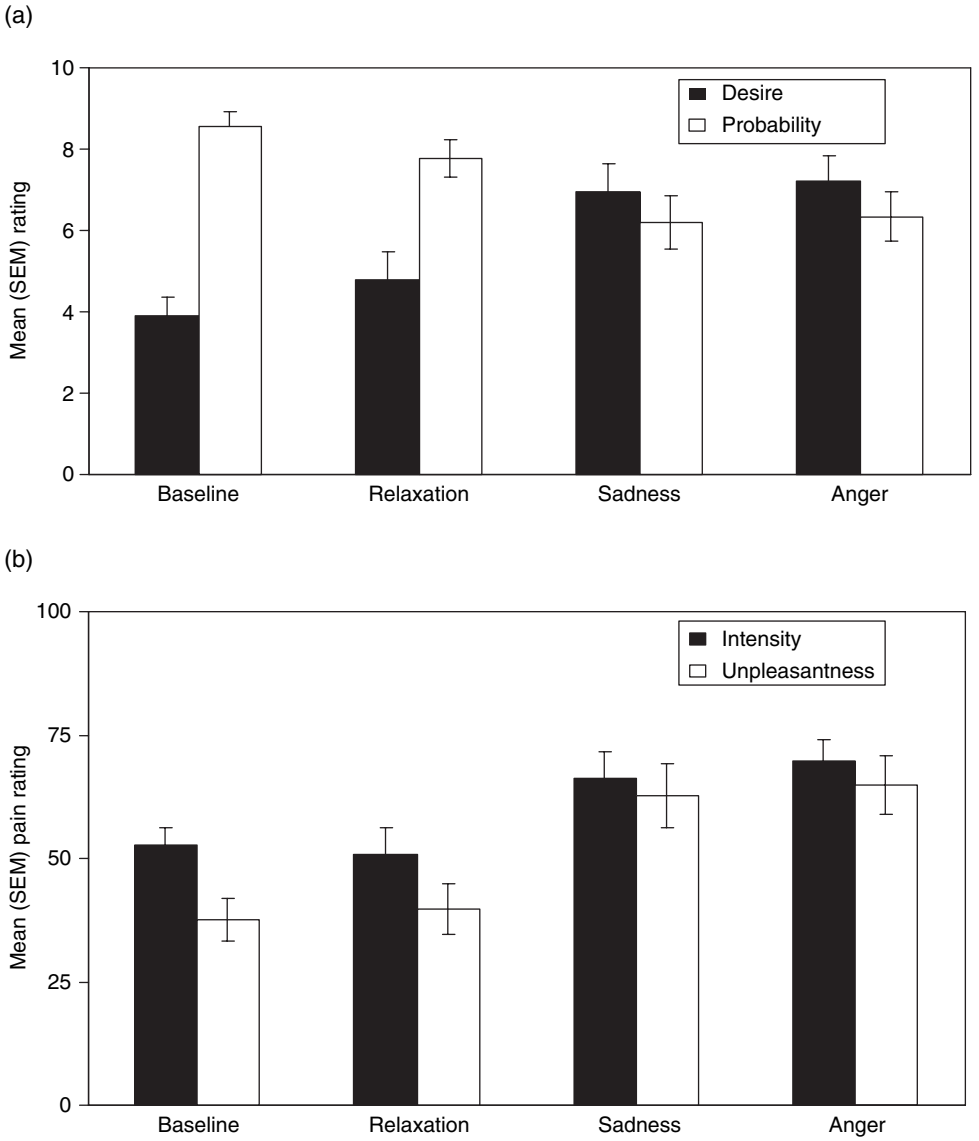

Figure 8 Effects of hypnotic relaxation and hypnotic induction of anger and sadness on subjective desires and expectations to avoid/escape pain (a) and on the pain intensity and unpleasantness produced by 1-min immersion of the hand in hot water (b). Desire increased and expectation decreased in the negative emotion conditions ($p < 0.05$). As a result, pain unpleasantness, and to a lesser extent, pain intensity increased in both conditions ($p < 0.05$). Figure adapted from Rainville, P. 2004. Pain and Emotions. In: Psychological Methods of Pain Control: Basic Science and Clinical Perspectives (*eds.* D. D. Price and M. C. Bushnell), pp. 117–141. IASP Press.

that the specific, hypnotic manipulation of desire to avoid/escape pain does produce a significant change in pain unpleasantness, independent of changes in pain intensity and expectation.

The previous study also included autonomic measures and found changes in heart rate to the experimental heat pain stimuli. Significant increases in heart rate were observed during negative emotions compared to baseline and control conditions, and this increase was positively associated with changes in pain and emotional experience (Table 3). After controlling for changes in pain intensity and felt arousal, changes in pain unpleasantness remained positively correlated with changes in cardiac responses. Conversely, cardiac responses were not significantly correlated with pain intensity after controlling for pain unpleasantness, and were only slightly correlated with pain intensity after controlling for

arousal. As would be expected, changes in felt arousal were positively associated with cardiac responses; however, this association was attenuated when changes in pain unpleasantness were controlled. This suggests that feelings of arousal and pain unpleasantness are closely related.

Figure 9 summarizes the findings of these studies examining the effect of pain-related emotions on pain. In this model, the nociceptive stimulus contributes to pain intensity, which then contributes to pain unpleasantness (Price, D. D., 1999; 2000; Rainville, P. *et al.*, 1999). The nociceptive stimulus also elicits autonomic responses and somatic feedback, and these factors influence felt arousal and pain unpleasantness. Pain-related desire and expectation contribute to modulate pain. Desire to avoid or escape pain primarily affects pain unpleasantness, independent of pain intensity (Table 2). Alternatively, expectation appears to have a modulatory affect on both pain intensity and unpleasantness, which is consistent with the placebo literature discussed previously. Furthermore, pain-related autonomic activity may be enhanced or diminished by descending neurophysiological mechanisms that are responsive to modulation of pain unpleasantness. When considered in their entirety, these results indicate that pain-related negative emotions have the primary effect of increasing pain unpleasantness and to a lesser degree pain intensity.

5.64.5.2.2 Pain anticipation and pain-related fear/anxiety

Other experimental studies have taken different approaches to examine the effects of emotions on pain perception. One phenomenon that has received particular attention is pain anticipation and the associated negative emotions. In addition to producing increased vigilance and attention towards future painful stimulation, anticipation of pain may also produce fearful responses and anxiety associated with the expectation of potential harm.

The effects of pain-related anxiety, fear, and fear-avoidance have been examined in clinical contexts as well as in animal studies. Meagher and Grau have

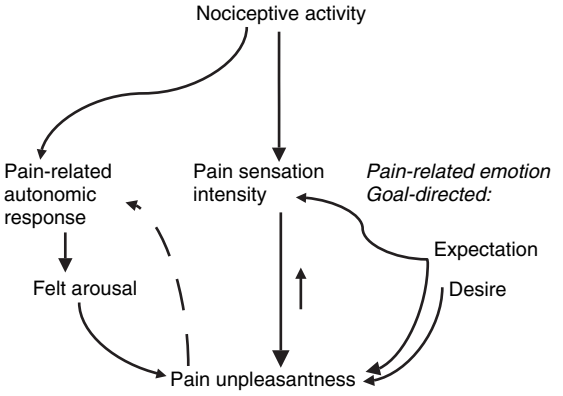

Figure 9 Pain-related emotions are suggested as affecting pain experience in several ways. Goal-directed desires appear to mainly influence pain unpleasantness, whereas goal-directed expectations affect both sensation intensity and pain unpleasantness. Physiological activity associated with autonomic activity that contributes to felt arousal. Adapted from Rainville, P. 2004. Pain and Emotions. In: Psychological Methods of Pain Control: Basic Science and Clinical Perspectives (*eds.* D. D. Price and M. C. Bushnell), pp. 117–141. IASP Press.

attempted to bridge the gap between these paradigms in a series of studies. Mild electric shocks in rats have been shown to produce hyperalgesia, whereas higher intensity stimuli typically results in stress-induced analgesia (e.g. Meagher, M. W. *et al.*, 2001b). In two human studies by Rhudy and Meagher (2000; 2001), pain threshold was increased in an anxiety condition and decreased in a fear condition, which they argued was consistent with the animal literature demonstrating anxiety-related hyperalgesia and fear-related analgesia. A subsequent study, however, found pain reductions in all conditions (Rhudy, J. L. and Meagher, M. W., 2003). Further complicating matters, the specific emotion experienced and its physiological features played important roles in pain modulation and these effects were influenced by gender. The mixed results of these and another study (Rhudy, J. L. and Meagher, M. W., 2003) highlight the importance of individual differences in the effect of the experimental manipulation and the effect of the emotion experienced on pain. A further complication arises when one considers attentional effects. The emotion-induction stimuli used in these studies, being distinct from the pain stimulus used to assess pain perception, might have competed with the less intense target pain stimulus for the subject's attentional resources. This possibility cannot be excluded based on the design of these studies.

Anticipation of pain is also suggested to be an important factor in pain modulation. Consistent with the previous discussion of the differential effects of pain-related and pain-unrelated emotions, Dougher M. J. *et al.* (1987) observed increased pain sensitivity in response to pain-specific, compared to non-specific, anxiety. Pain expectancies may also serve as a mediator of the effects of pain catastrophizing and depression on experimental pain in normals, as suggested recently by Sullivan M. J. *et al.* (2001a; 2001b). Interestingly, in this study expected mood was a stronger predictor of pain rating than expected pain, suggesting that the anticipation of an emotional response may contribute significantly to pain modulation.

5.64.5.2.3 Emotions unrelated to pain

Several experimental methods have been employed to induce emotions unrelated to pain in order to further examine the effect of emotional modulation on pain perception. Meagher M. W. *et al.* (2001b) found that presenting subjects with pictures that display fear and disgust before they underwent a cold-pressor test reduced threshold of pain intensity and unpleasantness; the fear stimuli also reduced pain tolerance. Conversely, erotic pictures increased pain intensity and unpleasantness threshold in men, but not women. A positive, graded increase in pain tolerance was observed with increases in the pleasantness of pictures presented during a cold-pressor test, whereas negative pictures that displayed pain-related images decreased pain tolerance (De Wied, M. and Verbaten, M. N., 2001). This is consistent with the distinction between pain-related and pain-unrelated emotions, pain-related emotions being generally associated with increased pain.

Reading positive and negative affectively valenced statements (Velten, E., 1968) has also been observed to increase and decrease experimental pain tolerance, respectively (Zelman, D. C. *et al.*, 1991). Willoughby S. G. *et al.* (2002), using this method, found decreases in pain tolerance related to pain catastrophizing in a depressed mood induction condition. Induction of positive affect via films has also been shown to reduce ratings of experimental pain (Weisenberg, M. *et al.*, 1998; Zillmann, D. *et al.*, 1996). Likewise, emotionally valenced music can exert pain modulatory effects (Roy, M. *et al.*, 2003; Whipple, B. and Glynn, N. J. 1992). Results of the studies by Roy and co-workers suggest that that the effects of emotions/moods are specific to pain processing and not merely due to non-specific distracting effects.

Sweet taste (Lewkowski, M. D. *et al.*, 2003) and pleasant odors (Marchand, S. and Arsenault, P., 2002) have also been shown to reduce experimental pain; however, the effect was only present in those with low arterial blood pressure in the study on taste and in women in the study on odors. Although providing further confirmation for the effects of positive and negative mood on pain perception, these findings highlight the importance of individual differences in these effects.

Studies using a cognitive-stress paradigm also demonstrate the effects of emotional modulation on pain perception and further highlight the importance of sex of the subject in this context. The cognitive stress of the stroop color-word task increased pain associated with capsaicin injection in women compared to men in one study (Logan, H. *et al.*, 2001). In this study, men showed a stronger correlation between pain increases and *physiological* indices of arousal, whereas women showed a stronger correlation between pain increases and *subjective* measures of arousal. This suggests that the effects of emotion-related physiological and subjective arousal on pain modulation may vary by sex. This study did not assess the specific emotion elicited during the cognitive task; however, a similar study found induced anger to be associated with increases in pain tolerance (Janssen, S. A. *et al.*, 2001).

5.64.5.2.4 Emotion or attention?

Emotion-induction stimuli naturally attract attention and consequently may compete with pain for attentional resources. This potential confound has long been recognized in the literature (e.g., Gardner, W. L. and Licklider, J. C., 1959; Gardner, W. L. *et al.*, 1960). As discussed earlier in section II.B. on attention, Villemure C. *et al.* (2003) demonstrated the pain modulatory effects of mood independent of attention. Although perhaps explaining the pain reduction induced by positive emotions in some instances, distraction does not account for increased pain ratings associated with negative emotions (e.g., Meagher, M. W. *et al.*, 2001b). Furthermore, attention usually exerts its effects on pain intensity and unpleasantness (e.g., Miron, D. *et al.*, 1989), whereas emotions – both pain-related and pain-unrelated – have a larger impact on pain unpleasantness (e.g., Huynh Bao, Q. V. and Rainville, P., 2002; 2003; Roy, M. *et al.*, 2003; Villemure, C. *et al.*, 2003). Specifically, negative emotions may increase pain unpleasantness by heightening an individual's awareness of his/her viscero-somatic responses independent of pain intensity. This would be consistent with studies showing negative emotions to be associated with increased self-focus and attention to somatic signals (Mor, N. and Winquist, J., 2002; also see Salovey, P., 1992).

5.64.5.3 Effects of Emotions on Pain: Clinical Studies

Clinical studies of the effects of emotions on pain have largely focused on specific emotions or emotion disorders. These studies have not extensively investigated the effects of arousal, valence, or specific experiential dimensions of emotions. Depression and anxiety have received the most attention in this literature (see the reviews by Robinson, M. E. and Riley, J. L., 1998; Keefe, F. J. *et al.*, 2001; Huyser, B. A. and Parker, J. C., 1999; Fernandez, E. and Milburn, T. W., 1994; Fernandez, E. and Turk, D. C., 1995), and a large-scale study by the World Health Organization found that patients with chronic pain have higher rates of depressive and anxious disorders (Gureje, O. *et al.*, 1998). Comorbid negative mood in patients with pain has been observed to be a significant negative predictor of treatment outcome in several domains, including spine surgery (Junge, A. *et al.*, 1995; Riley, J. L. *et al.*, 1995), multidisciplinary treatment programs (Swimmer, G. *et al.*, 1992) and conservative therapies (Gerke, D. C. *et al.*, 1989). Negative emotions may also serve as a mediator in the pain, impairment, and disability nexus, as suggested by Banks S. M. and Kerns R. D. (1996) and demonstrated by Holzberg and colleagues (1996). A number of investigations have demonstrated that the chronicity of injury and related pain is predicted by measures of negative mood. In particular, a strong association has been observed in chronic pain patients between pain unpleasantness and feelings of depression, anxiety, frustration, fear, and anger (Wade, J. B. *et al.*, 1990; 1996). Patient care cost and health care utilization have also been associated with negative mood in chronic pain patients (Engel, C. C. *et al.*, 1996). As a whole, this literature suggests that negative emotions are extremely prevalent in patients with pain and are predictive of a number of key variables, including treatment efficacy and health care costs.

One theory on the nature of the relationship between pain and negative emotions is that the experience of negative emotion increases or maintains

the report of chronic pain through some sensory process such as enhanced sensitivity to pain. By this account, the physiological perception of pain is modulated by one's emotions and cognitions, with depression and pain modulated by a similar process in the periaqueductal gray area of the dorsal horn. There is some evidence in the clinical literature for this contention, such as the study by Salovey P. and Birnbaum D. (1989) that found induction of negative mood to be associated with increased reports of aches and pains; however, this literature is thin and inconclusive.

Cognitive evaluations of the meaning of pain are an important component of the pain-emotion nexus. This is demonstrated in a study in which cancer patients who believed their pain to be due to the cancer reported more pain than patients who did not possess these beliefs. Pain-related emotions may mediate this effect. Other cognitive processes, such as attributional style (Love, A. W., 1988) and negative self-image (Holzberg, A. D. *et al.*, 1993), have been implicated in the relationship between pain and emotions. The constructs of pain catastrophizing and fear of pain have received considerable recent empirical attention and have been demonstrated to contribute to pain severity and distress in various patients (Crombez, G. *et al.*, 1999; Eccleston, C. *et al.*, 2001; Sullivan, M. J. *et al.*, 2001; Vlaeyen, J. W. and Linton, S. J., 2000); these effects may be mediated by increased attention to pain and/or changes in emotions. In fact, pain catastrophizing, fear, and other pain-related negative emotions, are consistently strong predictors of pain-related disability.

The effects of anger on pain also appear to depend on several factors, particularly the object of anger. Okifuji A. *et al.* (1999) found a positive relationship between pain severity and both anger directed at oneself and overall anger experienced. Depression and anger shared a similar relationship. In a recent review of this literature, Greenwood K. A. *et al.* (2003) found that gender, hostility, and anger management style, contribute to the effect of anger on pain. Interactions between these factors are complex (e.g., Burns, J. W. *et al.*, 1996) and beyond the scope of this discussion; however, anger remains of topic of increased interest in the pain literature.

In summary, negative emotions generally increase clinical pain, particularly pain unpleasantness, and are consistent predictors of pain behaviors and disability. Although the mechanisms by which emotions modulate clinical pain have not yet been entirely elucidated, the object of emotions appears to play a critical role. Emotions that are pain-related or directed toward the self appear to have the most deleterious effect.

5.64.6 Summary and Conclusions

This chapter has illustrated the potent modulating effects of psychological factors on pain. The evidence of these influences includes experimental studies that manipulate psychological factors such as mood, expectation, and desire for pain relief. Further evidence is provided by clinical studies that show strong predictive relationships between mood and pain, mood and disability, and placebo/expectancy manipulations and pain. Clearly, there is much overlap between different psychological mechanisms of pain modulation. For example, desires for relief and expectations are integral factors in placebo analgesia, yet they also play important roles in emotional influences on pain (Figure 9). Placebo analgesic mechanisms may well reflect modulation of pain by changes in emotions. On the other hand, attention and emotions have at least partly separate influences on pain. The neurophysiological basis of these psychological factors are partially understood, but much more work needs to be done to fully understand the basic mechanisms. Furthermore, the relationships and interactions of psychological factors to more traditional physiological and drug effects are also poorly understood and ripe for further study.

Glossary

immunosuppressive Adjective that indicates an inhibitory action on the immune system.

μ-opioid receptor Subtype of opioid receptors that bind μ-agonist drugs, such as morphine.

naloxone Antagonist drug of opioids.

natural history Spontaneous time course of a symptom, e.g., pain.

nocebo It has the opposite meaning of placebo, which indicates that a symptom may also increase after suggestions of increase.

Parkinson's disease Motor disorder characterized by three typical symptoms: rest tremor, muscle rigidity, and bradykinesia (reduction of movement velocity).

Pavlovian conditioning Conditioning according to Pavlov, in which the temporal contiguity between a neutral (conditioned) and an unconditioned stimulus leads to a conditioned response.

proglumide Antagonist drug of cholecystokinin.

subthalamic nucleus Nucleus located under the thalamus, which represents a major target of the surgical treatment of Parkinson's disease.

sumatriptan Agonist drug of serotonin 5-HT1 receptors that is used in the treatment of migraine.

5.65.1 Top-Down Modulation of Pain

The input coming from a damaged tissue and traveling along the pain pathways up to the brain is not always experienced in the same way. A complex modulation occurs at the supraspinal level and may either increase or decrease the global experience of pain (see chapter 5.65). Many psychological factors, for example, attention, emotions, mood, stress, expectation, anticipation, distraction, anxiety, depression, and fear, all modulate the global experience of pain, although the underlying mechanisms are poorly understood. In recent times, the placebo effect, particularly placebo analgesia, has emerged as an interesting model to understand the psychological and physiological mechanisms through which this intricate top-down modulation occurs. Of course, the understanding of the placebo effect can only explain some of these factors, such as expectation and anticipation. Nonetheless, its investigation has yielded new insights into the biological mechanisms that link a complex mental activity to different body functions. This chapter is a brief overview of what we know today about the neural mechanisms underlying the placebo effect. It will appear clear that this complex phenomenon can give us important information on the intricate mechanisms that link mind, brain, and body.

5.65.2 Methodological Aspects

The investigation of the placebo effect is full of pitfalls and drawbacks since, in order to identify a real psychobiological placebo response, several other phenomena have to be ruled out. In fact, the placebo itself is not always the cause of the effect that is observed (Colloca, L. and Benedetti, F., 2005). For

example, most painful conditions show a spontaneous temporal variation that is known as natural history. If subjects take a placebo just before their discomfort starts decreasing, they may believe that the placebo is effective, although that decrease would have occurred anyway. Clearly, this is not a placebo effect but a spontaneous remission that leads to a misinterpretation of the cause–effect relationship. Another example is regression to the mean, a statistical phenomenon assuming that individuals tend to receive their initial clinical assessment when their pain is near its greatest intensity, and that their pain level is likely to be lower when they return for a second pain assessment. In this case also, the improvement cannot be attributed to any intervention they might have undergone. A further source of confusion is represented by the fact that a particular type of error made by the patient, a false positive error, may explain the placebo effect in some circumstances. This phenomenon is based on signal detection theory, and is due to the occurrence of errors in the detection of ambiguous signals. It also happens that a co-intervention actually is responsible for the reduction of a symptom, such as the analgesic effect following the mechanical insertion of a needle to inject an inert solution. All these examples show that, although an improvement may occur after the administration of a placebo, the placebo is not necessarily the cause of the effect that is observed. Since all these phenomena are sometimes difficult to identify, the mechanisms of the placebo response must be investigated under strictly controlled experimental conditions (Vase, L. *et al.*, 2002; Colloca, L. and Benedetti, F., 2005). For example, in order to rule out spontaneous remission, a group taking the placebo is compared to a group receiving no treatment, the latter giving information on the natural course of the symptom. The difference between the placebo group and the no-treatment group represents the real psychobiological placebo response.

5.65.3 Psychological Explanations

The placebo effect involves both cognitive factors and conditioning mechanisms. The deceptive administration of a placebo treatment can lead the subjects to believe that the treatment is effective, so that anticipation and expectation of analgesia lead to a placebo analgesic response. Some studies show that different verbal instructions lead to different expectations and thus to different responses, and this plays a fundamental role in the placebo effect (Amanzio, M., and Benedetti, F., 1999; Benedetti, F. *et al.*, 1999b; Price, D. D. *et al.*, 1999). The context around a therapy may act not only through expectation and conscious anticipatory processes. In fact, there are some lines of evidence indicating that the placebo response is sometimes a conditioned response due to repeated associations between a conditioned stimulus (e.g., shape and color of aspirin pills) and an unconditioned stimulus (the active substance of aspirin) (Amanzio, M., and Benedetti, F., F., 1999; Siegel, S., 2002; Benedetti, F. *et al.*, 2003). In this case, it is the context itself that is the conditioned stimulus. However, even by considering a typical conditioning procedure, it has been shown that a conditioned placebo analgesic response can result from conditioning but is actually mediated by expectation. In other words, conditioning would lead to the expectation that a given event will follow another event, and this occurs on the basis of the information that the conditioned stimulus provides about the unconditioned stimulus (Benedetti, F. *et al.*, 2003).

There is experimental evidence that some physiological functions are affected by placebos through anticipatory conscious processes whereas some other functions undergo an unconscious mechanism of conditioning (Benedetti, F. *et al.*, 2003). For example, verbally induced expectations of either analgesia or hyperalgesia antagonize completely the effects of a conditioning procedure in experimentally induced pain. By contrast, verbally induced expectations of either increase or decrease of growth hormone and cortisol do not have any effect on the secretion of these hormones. However, if a preconditioning is performed with sumatriptan, a 5-$HT_{1B/1D}$ agonist that stimulates growth hormone and inhibits cortisol secretion, a significant increase of growth hormone and decrease of cortisol plasma concentrations can be found after placebo administration, even though opposite verbal suggestions are given. These findings suggest that placebo responses are mediated by conditioning when unconscious physiological functions, like hormonal secretion, are involved, whereas they are mediated by expectation when conscious physiological processes, like pain, come into play. Thus the placebo effect seems to be a phenomenon which can be learned either consciously or unconsciously, depending on the system that is involved (e.g., pain or hormone secretion).

5.65.4 Physiological Mechanisms

The complex cascade of events that may occur after placebo administration is shown in Figure 1. Several studies show that placebo-induced analgesia is antagonized by the opioid antagonist, naloxone, thus suggesting mediation by endogenous opioids (Levine, J. D. *et al.*, 1978; Amanzio, M., and Benedetti, F., 1999; Benedetti, F. *et al.*, 1999b). The cholecystokinin (CCK) antagonist, proglumide, has been found to enhance the placebo analgesic effect (Benedetti, F. *et al.*, 1995), which indicates that CCK has an inhibitory role in placebo-induced analgesia. The placebo analgesic responses are thus the result of the balance between endogenous opioids and endogenous CCK.

Placebo analgesia is not always mediated by endogenous opioids. In fact, if the placebo response is induced by means of strong expectation cues, it can be blocked by naloxone. Conversely, if the placebo response is induced by means of prior conditioning with a nonopioid drug, like ketorolac, it is naloxone-insensitive (Amanzio, M., and Benedetti, F., 1999). Today we know that specific placebo analgesic responses can be obtained in different parts of the body, and that these responses are naloxone-reversible (Benedetti, F. *et al.*, 1999b), which suggests that the placebo-activated endogenous opioid systems have a somatotopic organization.

The investigation of placebo analgesia by means of positron emission tomography found that similar

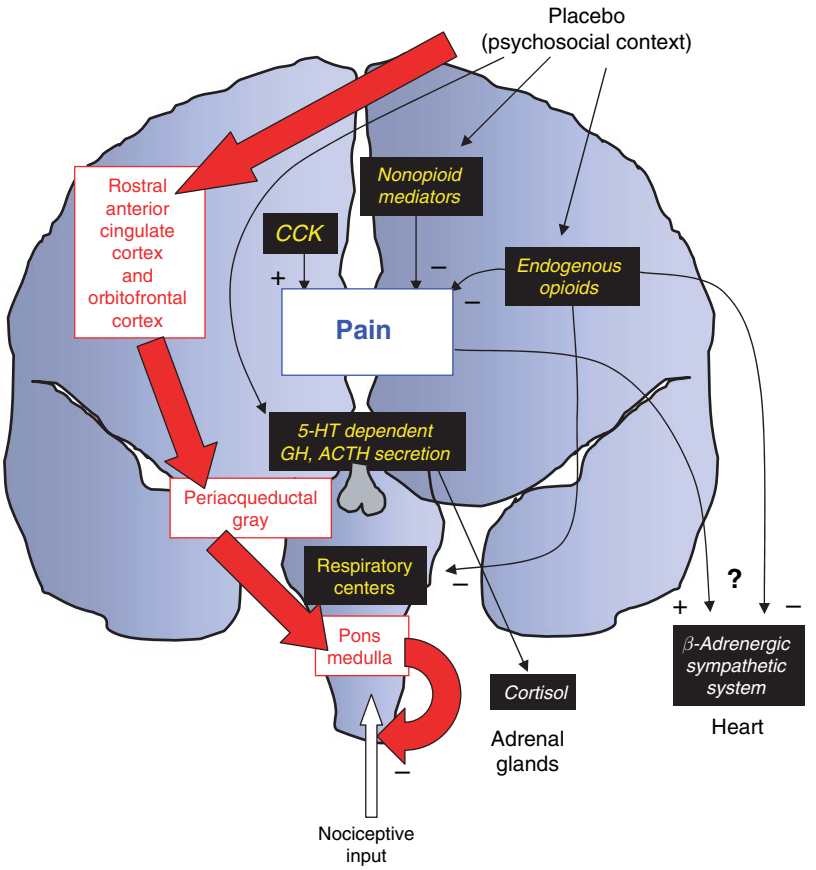

Figure 1 Events that might occur in placebo-induced analgesia. Nociceptive input may be inhibited by a descending network that involves the rostral anterior cingulate cortex, the orbitofrontal cortex, the periaqueductal gray, and the pons/medulla. Endogenous opioids might inhibit pain through this descending network and/or other mechanisms. The endogenous opioids also inhibit the respiratory centers. The β-adrenergic sympathetic system is also inhibited during placebo analgesia, although the mechanism is not known (either reduction of the pain itself or direct action of endogenous opioids). Nonopioid mechanisms are also involved. Cholecystokinin (CCK) counteracts the effects of the endogenous opioids thus reducing the placebo analgesic response. Placebo can also act on serotonin-dependent hormone secretion, mimicking the effect of the analgesic drug sumatriptan. 5-HT, serotonin; ACTH, adrenocorticotropic hormone; GH, growth hormone.

regions of the brain are affected by both a placebo and a narcotic drug, which indicates a related mechanism in placebo-induced and opioid-induced analgesia (Petrovic, P. *et al.*, 2002). In fact, the administration of a placebo induced the activation of the rostral anterior cingulate cortex (rACC) and the orbitofrontal cortex (OrbC). Moreover, there was a significant covariation in activity between the rACC and the lower pons/medulla corresponding to the rostral ventromedial medulla (RVM), and a subsignificant covariation between the rACC and the periaqueductal gray (PAG), thus suggesting that a descending rACC/PAG/RVM pain-modulating circuit is involved in placebo-induced analgesia. It is worth remembering that ACC and PAG are rich with opioid receptors, thus confirming the pharmacological studies with naloxone described above. By using functional magnetic resonance imaging to analyze the brain regions that are involved in placebo analgesia, another study showed that the activity of different regions involved in pain transmission, such as the thalamus, the anterior insula (aINS), and the caudal rACC, was decreased by a placebo treatment, which indicates a reduction of nociceptive transmission along the pain pathways (Wager, T. D. *et al.*, 2004). Furthermore, during the anticipatory phase of the placebo analgesic response, an activation of the dorsolateral prefrontal cortex (DLPFC), OrbC, superior parietal cortex (SPC), PAG, and other frontal regions occurs, suggesting the activation of a cognitive-evaluative network just before the placebo response. A recent attempt to identify the regions where endogenous opioids are released has been performed by using *in vivo* receptor binding techniques (Zubieta, J. K., 2005). A placebo-induced activation of μ-opioid receptors has also been found in different brain regions, such as the pregenual rostral anterior cingulate, DLPFC, INS, and the nucleus accumbens, which confirms once again the pharmacological blockade of placebo analgesia by opioid antagonists.

Placebo-activated endogenous opioids have also been shown to induce respiratory depression (Benedetti, F. *et al.*, 1999a), indicating that they act not only on pain mechanisms, but also on the respiratory centers. Also β-adrenergic sympathetic activity is reduced in placebo analgesia, and this might be due to either pain reduction itself or a direct action of placebo-activated endogenous opioids (Pollo, A. *et al.*, 2003). Some nonopioid mechanisms, such as the serotonin 5-$HT_{1B/1D}$ receptors, have also been investigated. For example, placebo-induced increase of growth hormone secretion and decrease of cortisol secretion have been described after pharmacological preconditioning with the serotonin agonist sumatriptan (Benedetti, F. *et al.*, 2003).

The placebo response is not limited to pain and analgesia, but it also occurs in many other conditions. The integration of the understanding of the placebo mechanisms in the field of pain and in other diseases is crucial and essential to identify similarities and differences that might help us appreciate the complexity of the placebo effect better. For example, as described above, placebo-induced hormonal responses can be obtained after repeated administrations of a hormone-stimulating drug (Benedetti, F. *et al.*, 2003), so can placebo-induced immunosuppressive responses after repeated administrations of an immunosuppressive drug (Goebel, M. U. *et al.*, 2002), which suggests a mechanism of Pavlovian conditioning in the endocrine and immune systems. Parkinson's disease has also been used as an interesting model to understand the neurobiological mechanisms of the placebo response, which might help understand placebo analgesia better. It has been shown that placebo administration in patients with Parkinson's disease activates endogenous dopamine in the striatum (de la Fuente-Fernandez, R. *et al.*, 2001) and modifies the pattern of activity of the neurons in the subthalamic nucleus (Benedetti, F. *et al.*, 2004). The placebo-induced release of dopamine might represent a mechanism of reward, whereby dopamine release by expectation of reward (in this case the expectation of clinical benefit) could represent a common biochemical substrate in many conditions, including pain.

5.65.5 The Nocebo Effect

The nocebo effect, or response, is a placebo effect in the opposite direction. In fact, expectation of pain increase may induce a hyperalgesic effect. In this case, anticipatory anxiety may play a fundamental role. In one study, negative expectations were induced by injecting an inert substance (saline solution) along with the instructions that pain was going to increase in a few minutes (Benedetti, F. *et al.*, 1997). As a consequence of this procedure, a pain increase was observed, and this increase was blocked by the CCK antagonist, proglumide. This indicates that expectation-induced hyperalgesia is mediated, at least in part, by CCK. These effects of proglumide

are not antagonized by naloxone, thus endogenous opioids are not involved. Since CCK plays a role in anxiety and negative expectations themselves are anxiogenic, proglumide is likely to act on a CCK-dependent increase of anxiety during the verbally induced negative expectations. Although, mainly due to ethical constraints, the nocebo effect has not been investigated in detail as has been done for the placebo effect, it shows the powerful effect of the top-down modulation of pain. In other words, cognitive and emotional factors can modulate pain perception in opposite directions.

5.65.6 Clinical Implications

One of the best evidences that suggest the important role of expectations and the top-down modulation of pain and analgesia is the decreased effectiveness of hidden therapies. In fact, it is possible to eliminate the placebo (psychosocial) component and to analyze the pharmacodynamic effects of an analgesic treatment, free of any psychological contamination. To eliminate the patient's expectations, the patient is made completely unaware that a medical therapy is being carried out. To do this, drugs are administered through hidden infusions by computer-controlled machines. The crucial point here is that the patients do not know that any analgesic is being injected, so that they do not expect anything. In postoperative pain, it was found that a hidden injection of different painkillers, in which the patients do not expect any outcome, is significantly less effective than an open one, in which the patients know that a pain reduction will occur (Colloca, L. *et al.*, 2004).

The difference between the open and hidden administration represents the placebo component, and underscores the importance of the placebo response in clinical practice. In fact, it basically shows that the specific effect of a treatment and the placebo response are additive. Since no placebo is given, the difference between an open and hidden injection cannot be called a placebo effect. Nevertheless it strongly indicates the important role of the psychosocial component of a therapy and the importance of the patient's perception that a therapy is being received. This new approach to the identification of the placebo effect might also have an important impact on the design of clinical trials (Colloca, L. and Benedetti, F., 2005; Finniss, D. G. and Benedetti, F., 2005).

Glossary

affective dimension of pain The feelings of unpleasantness and/or other negative emotions associated with the sensory experience of pain. This dimension of the pain experience encompasses both the basic emotional and the motivational responses produced by the actual or potential threat associated with pain.

Automaticity Behavioral responses and changes in perception and subjective experience produced without a feeling voluntary control (self-agency), that is, changes induced by hypnotic suggestions may be felt passively, as if they were induced by an external cause/agent.

hypnotic state The coordinated changes in activity within networks of brain regions involved in the regulation of consciousness (vigilance, attention, and self-monitoring), associated with self-experienced increases in mental relaxation, mental absorption, and feelings of automaticity, and typically (although not necessarily) induced by suggestions.

hypnotic suggestion Suggestion given during a context of hypnosis for an experience to occur or a behavior to be carried out.

nociceptive processes Biological responses induced by actual or potential tissue damage and normally (although not always) associated with the experience of pain in humans.

nociceptive withdrawal reflex (RIII reflex) The RIII reflex is a spinally mediated multisynaptic cutaneous reflex involving the flexion of the stimulated limb and the extension of the opposite limb. It can be induced experimentally by a transcutaneous electrical stimulation of the sural nerve at the level of the ankle and measured by the amplitude of the electromyographic response of the ipsilateral bicep femoris (flexor of the leg).

positron emission tomography (PET) A nuclear medical imaging technique where a radioactive tracer is injected into the blood circulation of a living organism. Applied to brain imaging, this technique allows for the measurement of the distribution of blood flow or the availability of various receptors in the brain. In functional brain imaging studies, this technique is used to test the changes in local brain activity in various experimental conditions.

self-monitoring Processes by which intentions, actions, and somatic activity are registered by the brain and mind. This process is central to the representation of self and is thought to be altered during hypnosis.

somatosensory-evoked potential Changes in regional electrical activity of the cerebral cortex in response to acute somatosensory stimuli and typically measured using surface electroencephalography.

5.66.1 Introduction

Scientific conceptions of hypnosis can be traced back to the end of the eighteenth century, when the pseudoscientific theory of Franz Anton Mesmer on *Animal Magnetism* (Bouleur, Jt., 1998) was formally examined by a Royal Commission ordered by King Louis XVI and chaired by Benjamin Franklin (Salas, C. and Salas, D., 1996; Laurence, J. R., 2002). Although the commissioners noted that the interventions (i.e., magnetization) used by Mesmer did produce dramatic responses in some patients (including analgesia), they concluded that the subjects' imagination was the main mediating mechanisms activated under the power of suggestion. This explanation based on the subject's imaginative resources is consistent with most contemporary theories of hypnosis.

Modern theories of hypnosis are based on complementary psychosocial, cognitive, and neurobiological interpretations (Fromm, E. and Nash, M. R., 1992). Experimental research has provided objective evidence that hypnotic interventions have robust, and in many cases specific, physiological effects. Furthermore, recent brain imaging methods have provided insight into the mechanisms underlying hypnotic states and into the specific responses to various types of hypnotic suggestions, including those aimed at reducing pain. Those advances are paralleled by well-controlled clinical studies, providing conclusive evidence on the efficacy of hypnosis in the control of pain.

5.66.2 Hypnosis Affects Consciousness-Related Brain Mechanisms

At the core of hypnosis is a social interaction where a hypnotist gives suggestions to another person, thus leading some authors to explain hypnosis-related effects primarily as suggestion-induced changes in expectancy (Kirsch, I. and Lynn, S. R., 1995). Hypnosis may also be defined as basic changes in subjective experience typically induced by standard hypnosis induction procedures and sometimes described as a hypnotic state or an altered state of consciousness. As those changes may be self-induced (e.g., in autohypnosis or some forms of meditation), an explanation strictly based on social interactions and suggestions may be limited. The analysis of experiential changes associated with the induction of hypnotic states has revealed increases in mental ease and absorption, followed by reductions in self-monitoring and orientation, which in turn lead to feelings of automaticity (Price, D. D., 1996; Rainville, P. and Price, D. D., 2004). Increases in absorption (e.g., concentration and fascination) are consistent with the central role of attention processes in hypnotic responsiveness (Tellegen, A. and Atkinson, G., 1974; Nadon, R. *et al.*, 1987; Radtke, H. L. and Stam, H. J., 1991; Balthazard, C. G., and Woody, E. Z., 1992; Crawford, H. J., 1994). However, the subjective increase in automaticity has been identified as the classical suggestion effect characterizing hypnosis (Weitzenhoffer, A. M., 1980). This sense of automaticity may also relate to dissociative processes posited to explain the dual streams of consciousness reported by some subjects during hypnosis (Hilgard, E. R., 1992).

In agreement with the involvement of basic consciousness-related processes, increases in mental ease and absorption are associated with the changes in activity within brain networks underlying the regulation of vigilance and attention, including brainstem and medial thalamic nuclei, the anterior cingulate cortex, and the prefrontal and posterior parietal cortices (Maquet, P. *et al.*, 1999; Rainville, P. *et al.*, 1999b; 2002). Those findings are consistent with increases in rhythmic electroencephalographic activity within the theta frequency band, associated with attention and mental imagery (Sabourin, M. E. *et al.*, 1991; Crawford, H. J., 1994; Ray, W. J., 1997). Neurophysiological effects have been suggested to reduce the reciprocal inhibition between competing mental representations and processes, thereby facilitating the consideration of alternative experiences and allowing for a reinterpretation of sensory inputs during hypnosis (Rainville, P. and Price, D. D., 2004). In addition, feelings of automaticity relative to movement produced in response to hypnotic suggestions have been suggested to reflect a disruption of the coordinated activity of brain systems underlying the production and monitoring of self-generated actions within the frontoparietal cortices, thus leading to an altered sense of self-agency (Blakemore, S. J. and Frith, C., 2003; Blakemore, S. J., *et al.*, 2003). Generalizing those findings to the generation and regulation of mental images and thoughts, this suggests that hypnosis-related changes in perceptual and cognitive processes are felt as automatic because of the alteration in self-monitoring processes or the disruption in the communication

between brain systems involved in the production of the perceptual–cognitive–behavioral changes and those involved in self-monitoring of those changes (also see Woody, E. and Szechtman, H., 2000; Rainville, P. and Price, D. D., 2004; Raz, A. *et al.*, 2005; Egner, T. *et al.*, 2005). These basic changes provide the background state upon which suggestions are given to further modulate specific perceptual processes such as those involved in pain.

5.66.3 Hypnotic Analgesia in the Brain

There are a number of psychophysiological studies providing convincing evidence that hypnotic suggestions to modulate pain perception affect nociceptive processes in the central nervous system (CNS) (Arendt-Nielsen, L. *et al.*, 1990; Zachariae, R. and Bjerring, P., 1994; Crawford, H. J. *et al.*, 1998; De Pascalis, V. *et al.*, 1999; 2001). New evidence based on modern functional brain imaging methods has further demonstrated that the hypnotic modulation of pain affects responses within pain-related brain network. In normal conditions, brain responses to acute experimental pain tests involve the activation of primary and secondary somatosensory cortical areas, the insular cortex, and the anterior cingulate cortex (Apkarian, A. V. *et al.*, 2005). In a positron emission tomography (PET) experiment (Hofbauer, R. K. *et al.*, 2001), hypnotic suggestions were given to modulate the sensory intensity of pain before subjects immersed their hand in painfully hot water. In those conditions, the subjects' ratings of pain intensity confirmed the expected effects on pain experiences (Figure 1). Brain activity measured by PET further demonstrated significant changes in the amplitude of the responses within the primary somatosensory cortex, consistent with a role of this area in the perception of pain sensory intensity. In an earlier PET study using the same experimental model (immersion of the hand in hot water) (Rainville, P. *et al.*, 1997), hypnotic suggestions were given to modulate specifically the affective dimension of pain experience. In those conditions, the subjects reported changes in pain unpleasantness, but not pain intensity, and brain responses were modulated within the anterior cingulate cortex, but not the somatosensory cortex (Rainville, P. *et al.*, 1997). Furthermore, activity within the anterior cingulate cortex was found to correlate significantly with subjective reports of pain

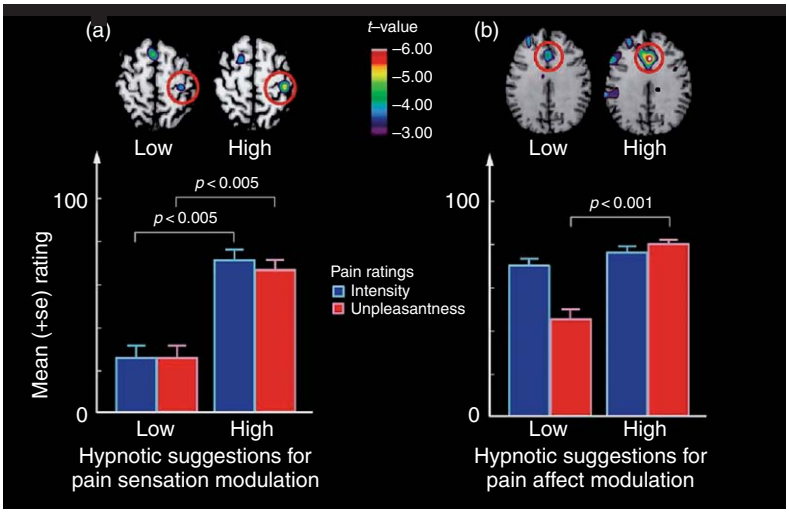

Figure 1 (a) Modulation of pain intensity and S1 activity. (b) Modulation of pain unpleasantness and anterior cingulate cortex activity. Horizontal slices of the brain are shown in conditions of decreased and increased pain intensity (a) and unpleasantness (b). Bar graph represent ratings of pain intensity and pain unpleasantness obtained in those conditions and demonstrate the significant modulation of both pain intensity and unpleasantness in the sensation-modulation experiment (a) and the significant modulation of pain unpleasantness only in the affect-modulation experiment (b). Reproduced from Rainville, P. 2002. Brain mechanisms of pain affect and pain modulation. Curr. Opin. Neurobiol. 12, 195–204.

unpleasantness, consistent with a contribution of this area to the affective dimension of pain. These studies

1. confirmed the efficacy of hypnosis to modulate pain-related brain responses,
2. demonstrated a functional segregation of brain activity associated more specifically with the sensory or affective dimensions of pain, and
3. provide further evidence supporting the specificity of hypnosis-related effects as a function of the precise content of the suggestions.

Importantly, such anatomofunctional specificity of the effects of hypnotic suggestions on perceptual processes has been observed in both the auditory modality (Szechtman, H. *et al.*, 1998) and in the visual modality (Kosslyn, S. M. *et al.*, 2000). This implies that the effect of hypnotic suggestions does not simply reflect a nonspecific response but involve the precise top-down modulation of targeted sensory–perceptual or affective–emotional processes. In the specific case of pain, this process may involve descending modulatory mechanisms affecting lower-level nociceptive activity in the CNS.

In addition to changes specifically found in pain-related areas, suggestions also produce widespread increases in lateral and medial prefrontal cortices including the dorsal aspect of the medial prefrontal cortex, as well as in parietal cortices (Rainville, P. *et al.*, 1999b; Faymonville, M. E. *et al.*, 2000). Interestingly, the activation found in the frontal and parietal cortices in response to hypnotic suggestions for pain modulation is consistent with the observations of the activation of the medial prefrontal cortex during hypnotic auditory hallucination (Szechtman, H. *et al.*, 1998), and of the lateral parietal cortex during hypnotically induced delusion of movement (Blakemore, S. J. *et al.*, 2003), as discussed above. In the case of pain modulation, those changes may also reflect the activation of modulatory circuits that affect pain-related areas directly through corticocortical connections or indirectly through descending projections affecting thalamic or brainstem nuclei. The medial prefrontal cortex, including the more dorsal and rostral parts of the anterior cingulate cortex may interact with other cortical and subcortical structures of the cerebral network involved in pain perception, including the insular cortices, the pain-related cingulate area, right prefrontal cortices, striatum, thalamus, and brainstem. Coactivation of the brainstem with the medial prefrontal cortex may further reflect the activation of descending mechanisms involved in the regulation of ascending spinothalamic nociceptive pathways (Faymonville, M. E. *et al.*, 2003). In addition to their contribution to the regulation of ascending pathways, descending modulatory processes are likely to influence the reflex nociceptive responses generally observed in the periphery.

5.66.4 Somatic Consequences of Hypnotic Analgesia

Descending mechanisms have played a central role in the conceptualization of pain modulation over the past 40 years (Melzack, R. and Wall, P. D., 1965; Melzack, R. and Casey, K. L., 1968). In relation to descending inhibitory mechanism, there are abundant research reports examining the effects of hypnotic analgesia on peripheral physiological responses to acute pain stimuli. One of the most interesting effects reported in that literature is the effect of hypnotic analgesia on the nociceptive withdrawal reflex (the RIII reflex). Various experimental conditions involving pain modulation by conditioning stimuli, contextual factors, and psychological variables have demonstrated a robust modulation of the RIII reflex (Willer, J. C. *et al.*, 1979; 1981; Sandrini, G. *et al.*, 2005). The modulation of pain by hypnotic suggestion has been shown to affect the amplitude of the RIII reflex, consistent with the involvement of descending modulatory processes during hypnotic analgesia (Kiernan, B. D. *et al.*, 1995; Sandrini, G. *et al.*, 2005). However, a subsequent study also showed that some subjects demonstrated an increase in the RIII response during effective hypnotic analgesia as reflected in increased pain threshold and reduced cortical response (somatosensory-evoked potential), suggesting that the activation of descending modulatory processes during hypnotic analgesia may present considerable interindividual variability (Danziger, N. *et al.*, 1998).

In addition to studies examining the RIII response, several reports have demonstrated that hypnotic analgesia affects autonomic response. Those include studies showing reduced cardiovascular response and pain ratings evoked by experimental ischemia (Lenox, J. R., 1970) and the cold pressor test (Hilgard, E. R.*et al.*, 1974; Hilgard, E. R. and Hilgard, J. R., 1994), and reduced cutaneous and cardiac sympathetic responses evoked by painful electric shocks (De Pascalis, V. *et al.*, 2001). In addition, a study

examining the effect of hypnotic suggestions focusing on the affective dimension of pain has found changes in heart rate responses correlated with changes in ratings of pain unpleasantness (Rainville, P. *et al.*, 1999a). Importantly, those effects were independent from changes in ratings of pain intensity, further supporting the distinction between pain sensation and pain affect and the stronger functional relation between autonomic responses and affective responses.

Taken together, studies on the modulation of motor and autonomic responses to noxious stimuli imply that the central neurophysiological mechanisms engaged during hypnotic analgesia modulate low-level brainstem and spinal systems responsible for the regulation of acute somatic responses to nociceptive stimuli. Combined with the studies demonstrating changes in pain-related brain activity, this strongly supports the specificity of hypnosis-related effects for the control of pain, providing a convincing demonstration that hypnotic analgesia can modulate both central and peripheral pain-related responses. This experimental demonstration of the neurophysiological mechanisms underlying hypnotic analgesia argues strongly in favor of the application of hypnosis for the control pain.

5.66.5 Clinical Applications of Hypnotic Analgesia

The increasing number of sophisticated neurophysiologic studies on hypnosis and pain has largely contributed to the renewed interest in hypnosis within healthcare settings. Consistent with the validation of hypnotic analgesia in experimental studies, nonpharmacological approaches including hypnosis have been strongly recommended in the management of pain. Among psychological strategies, there is accumulating evidence suggesting that hypnotic interventions are helpful for the management of acute procedural pain and anxiety. Chronic pain may also benefit from hypnosis interventions that must be integrated to the psychological, social, and environmental context.

Since the meta-analysis of Montgomery G. H. *et al.* (2000), which has focused on hypnotic analgesia in both clinical and experimental settings, some new randomized clinical trials have further documented the effectiveness of hypnosis in reducing pain and anxiety in various conditions. A more recent review of the literature has focused on randomized clinical trials to assess the efficacy of hypnotic interventions (Patterson, D. R. and Jensen, M. P., 2003). Authors have concluded that hypnosis has a reliable and significant impact on acute procedural as well as chronic pain conditions in adults. Evidence is also presented supporting the successful application of hypnosis in children to decrease pain and distress during needle-related procedures. Nevertheless, authors recommend that more high quality studies have to be conducted to specify the scope and limits of hypnotic interventions. Furthermore, they underline that reviews on hypnosis effectiveness are limited by the heterogeneity of the type of hypnotic interventions, emphasizing the importance of a more detailed description of the specific suggestions used (Patterson, D. R., 2004; Jensen, M. P. and Patterson, D. R., 2005). This also appears to be critical in view of the specificity of the effects of different types of hypnotic suggestions as described above for suggestions focusing on sensory or affective dimensions of the pain experience.

To illustrate the potential benefit of hypnotic analgesia, some clinical studies provide particularly convincing evidence. (Note: the readers should refer to Medline or Cochrane Review sites for an extensive search of clinical trials on hypnosis; here we describe a few original reports to illustrate the potential efficacy of hypnosis in a clinical setting.) The potential benefits of hypnosis in patients receiving conscious sedation for plastic surgery have been demonstrated in a randomized clinical trial ($n = 60$) (Faymonville, M. E. *et al.*, 1997). In this study, hypnosis did not only provide better perioperative pain and anxiety relief, but also decreased medication used and improved patient's satisfaction and surgical conditions as compared with conventional stress-reducing strategies support. In another randomized clinical trial ($n = 241$), the effects of structured attention and self-hypnotic relaxation on pain and anxiety during percutaneous vascular and renal procedures in radiology were compared to standard care (Lang, E. V. *et al.*, 2000). The hypnotic intervention was performed during the surgery with suggestions for relaxation, eye closing, deep breathing, sensation of floating, and finally suggestion to self-generate imagery and focus on a safe and pleasant experience. As pain increased with the procedure time in the standard care and attention groups, it remained stable or decreased slightly in the hypnosis group even if the patients in the hypnosis group had requested less intravenous analgesia during the procedure. Mean anxiety scores also decreased during the procedure

in the hypnosis group, while it remained stable in the structured attention group and increased in the standard care group. Finally, hypnosis improved hemodynamic stability significantly during the procedure consistent with the notion that the improvement in subjective reports of pain and negative emotions are accompanied by beneficial impact on peripheral responses to the noxious stimuli (here the surgical procedure). These results are highly consistent with the experimental studies reported above showing that the improvements in pain reports reflect a reduction in pain-related brain responses and are paralleled by an attenuation of peripheral responses as a consequence of active inhibitory processes acting on low-level nociceptive processes in the brain and spinal cord.

The benefits of hypnotic intervention on procedural pain and distress have also been demonstrated in children (Woodgate, R. L. and Degner, L. F., 2003; Wild, M. R. and Espie, C. A., 2004; Richardson, J. *et al.*, 2006). In a recently published randomized clinical study in children with cancer ($n = 45$), Liossi and co-workers have illustrated the benefit of teaching self-hypnosis to children undergoing repeated lumbar punctures by comparing the effects of a local anesthetic plus self-hypnosis, to the effects of a local anesthetic or a local anesthetic plus attention. In addition to showing hypnosis-related pain relief, this study also demonstrated a decrease in the child's anticipatory anxiety before the procedure (Liossi, C. *et al.*, 2006). Repeated invasive procedures such as cystourethrography are also painful and frightening for young children. Forty-four children (age range: 4–15 years) who were scheduled for at least the second VCUG were randomized to receive hypnosis ($n = 21$) or routine care with support ($n = 23$) while undergoing the procedure (Butler, L. D. *et al.*, 2005). Hypnosis was found to be beneficial for children, because it may decrease distress, improve the collaboration of patients, and facilitate the procedure. However, as children are often receiving light sedation and analgesia in addition to local anesthetic, more studies have to be conducted to determine the specific contribution of hypnosis in pain and anxiety management strategies and, more critically, the potential interaction between multiple interventions.

Another clinical application for hypnosis is labor pain. A recent Cochrane review on complementary and alternative therapies for pain management in labor concluded that women who were taught self-hypnosis (five clinical trials for a total of 749 women) had decreased requirements for pharmacological analgesia including epidural analgesia and were more satisfied with their pain management in labor compared with controls (Smith, C. A. *et al.*, 2006). In a preliminary study, Marc I. *et al.* (2007) also suggested that hypnosis significantly reduces the need for analgesic/sedative medication without increasing pain or distress in patients undergoing a first-trimerter surgical abortion. These effects further validate the use of hypnosis as an effective means to complement or replace the standard pharmacological approaches without reducing the quality of care, and sometimes by improving it.

There are several other conditions in which hypnosis may provide an advantageous approach to treat pain. In recent years, considerable work has been done by several teams on the use of hypnotic intervention in the treatment of mind–body dysfunction especially when stress and anxiety are involved. For example, irritable bowel syndrome is a functional gastrointestinal disorder characterized by chronic abdominal pain and altered bowel habits in the absence of any organic cause. Hypnosis as part of a structured intervention has been found to improve the status of all major symptoms in this condition (Gonsalkorale, W. M. and Whorwell, P. J., 2005). However, as is the case of many uncontrolled clinical studies, the use of hypnosis is associated with significant improvement but the specific contribution of hypnosis-related phenomena remains unclear. Of course, from a practical clinical perspective, the available evidence may be sufficient for the integration of hypnosis to clinical interventions, especially given the fact that adverse effects are unlikely to occur when hypnosis is proposed as an adjunct to standard care. Nevertheless, additional randomized controlled trials must be performed to extend the available evidence on the efficacy of hypnotic analgesia for the relief of acute pain and chronic pain condition (Stewart, J. H., 2005).

5.66.6 Conclusion

The effects of hypnosis and analgesic suggestions on brain activity are highly consistent with a modification of sensory and affective processes underlying the experience of pain. The available evidence clearly demonstrates the specificity of the effects on pain-related physiological processes both in the CNS and in the periphery. Hypnosis may also be used to improve relief during painful procedures and may

be integrated to the arsenal of strategies to relieve chronic pain conditions, especially if stress and anxiety are involved. Although many questions on the neurobiological mechanisms underlying hypnosis-related effects remain to be answered, the available evidence strongly supports the instrumental use of hypnosis to study conscious perceptual processes and the clinical use of hypnosis to reduce pain and suffering.

Glossary

Aβ fiber Typically the largest-caliber, myelinated axons of sensory neurons that supply innervation to the skin and other tissues. They are typically low-threshold mechanoreceptors. Note: A different nomenclature using a Roman numeral system is often used in referring to axons of sensory neurons that supply skeletal muscle.

Aδ fiber Typically the smaller-caliber, myelinated axons of sensory neurons that supply innervation to the skin and other tissues. Although typically regarded as nociceptors, different types may have high- or low-threshold responses to different types of stimuli (mechanical, chemical, or thermal). Note: A different nomenclature using a Roman numeral system is often used in referring to axons of sensory neurons that supply skeletal muscle.

C fiber An unmyelinated axon of a sensory neuron that supplies the skin and other tissues. They are also very thin caliber, less than 1.5 μm in diameter. Although typically regarded as high-threshold nociceptors, different types may have high- or low-threshold responses to different types of stimuli (mechanical, chemical, or thermal). Note: A different nomenclature using a Roman numeral system is often used in referring to axons of sensory neurons that supply skeletal muscle.

chemoreceptor A sensory ending that responds optimally to chemical stimulation. The term may also refer to the entire sensory neurons whose ending have this property.

cranial root ganglion A swelling in cranial nerves which is located close to the brain stem cord and contains the cell bodies of primary sensory neurons whose axons are contained within cranial nerves. These nerves supply the skin and skeletal muscles of the entire body except for that of the face and oral and nasal cavities.

cutaneous innervation The nerve supply to the skin including the blood vessels and sweat glands of the skin. This consists of sensory components that detect various types of environmental stimuli, and autonomic motor components that cause changes in the diameter of arteries and arterioles and the secretion of sweat from sweat glands.

dermal papillae Cone-like dermal extensions that protrude in the epidermis or base of hair follicles.

Dorsal root ganglion A swelling in spinal nerves which is located close to the spinal cord and contains the cell bodies of primary sensory neurons whose axons are contained within spinal nerves. These nerves supply the skin and skeletal muscles of the entire body except for that of the face and oral and nasal cavities.

epidermis The outer layer of the skin that is composed primarily of several layers of compact keratinocytes. The deepest layer, stratum basalis, contains melanocytes and, in glabrous skin, may contain Merkel cells. Cells of the immune system – Langerhans/dendritic cells – are scattered among the keratinocytes.

free nerve ending The endings of axons in a target organ that typically resemble thin threads. They lack a unique morphology and accompanying structures composed of terminal glia or other accessory cells.

glabrous skin A special type of smooth skin that has a thick epidermis, often penetrated by dermal papillae, and lacks hair follicles. It is typically located on the ventral surfaces of the hands and feet.

high threshold Requiring strong stimulation to generate an action potential.

low threshold Able to generate action potentials in response to very faint stimulation.

mechanoreceptor A sensory ending that responds optimally to mechanical stimulation. The term may also refer to the entire sensory neurons whose ending has this property.

Meissner corpuscles Compact stacks of alternating layers of terminal glial cells and endings of Aβ and C fibers. Located in many dermal papillae of glabrous skin. Implicated as low-threshold mechanoreceptors that respond optimally to low-frequency (flutter) vibrations.

Merkel cell A specialized cell located in the deepest layer of the epidermis or the outermost layer of hair follicles that is in contact with sensory endings of Aβ fibers that are implicated in responding to gentle sustained compression of the skin or deflection of hairs.

Merkel endings or disks Flattened terminals of some types of low-threshold Aβ fiber mechnoreceptors that are juxtaposed to Merkel cells. Implicated as low-threshold, slowly adapting mechanoreceptors that have a prolonged response to sustained compression of the skin or deflection of hairs.

modality A particular physical property of a stimulus that can generate activity in sensory neurons.
myelin Layers of membrane that is formed by some Schwann cells wrapping around some types of axons (myelinated axons). In nerves, a Schwann cell will make a myelin sheath only around a segment of one axon.
nerve fiber An old anatomical term for an axon in a nerve. The term was originally used in reference to filamentous components within nerves before it was known that they were the axons of nerve cells.
neurons Nerve cells.
nociceptor A sensory ending that responds optimally to stimuli (mechanical, chemical, thermal, or mixed, i.e., polymodal) that elicit a perception of pain or pain-related behavioral response. The term may also refer to the entire sensory neurons whose ending has this property.
Pacinian Corpuscles Large-caliber unbranched sensory endings that are embedded in a large bulbous laminated structure composed of flattened terminal glia. The ending is supplied by a large-caliber Aβ fiber that is a low-threshold rapidly adapting mechanoreceptor that responds optimally to high-frequency vibrations.
pilo-neural complex A combination of several types of sensory endings that form an ensemble around hair follicles at about the mid-level of the hair shaft. Typically the ensemble consists of a palisade of blade-like lanceolate endings supplied by Aβ fibers, and a mix of circumferentially oriented endings supplied by Aβ and C fibers.
primary sensory neurons Special types of nerve cells that lack dendrites and that are activated by environmental stimulation instead of by synaptic input from other nerve cells. They have a single process that bifurcates into an axon. One end of the axon extends through spinal or cranial nerves to terminate as a specialized structures in the skin that respond to environmental stimuli. The other end extends through connectors to the spinal cord or brain stem (dorsal roots or cranial roots) to synapse on nerve cells in the central nervous system.
rapidly adapting neurons Nerve cells that briefly produce action potentials in response to sustained stimulation, typically at the onset and/or cessation of the stimulus.
Schwann cells A type of cell that encases axons within nerves. Each Schwann cell encases a short segment of the axon. The entire lengths of all axons in a nerve are encased by many consecutive Schwann cells.
slowly adapting neurons Nerve cells that have a prolonged production of action potentials in response to a sustained stimulation, although this activity may eventually cease after several milliseconds.
terminal glial cell A type of Schwann cell that forms an association with the endings of Aβ fibers that terminate in the dermis, skeletal muscle, tendons, joint capsules, and the wall of organs.
thermoreceptor A sensory ending that responds optimally to heat exchange. The term may also refer to the entire sensory neurons whose ending has this property.
unmyelinated axons Axons that are encased in Schwann cells that do not form myelin sheaths. Typically, segments of several unmyelinated axons are embedded in the surface of a single, non-myelinating Schwann cell.

6.01.1 Overview of Tactile Perception

A hungry seal glides beneath the ice searching for food in the darkened water. Despite the vigorous stimulation of his whiskers (vibrissae) caused by the rushing water and the presence of natural water currents, the seal detects a miniscule turbulence and in a split second recognizes that it is the wake of a fish and tracks it to his prey. This is a task that the seal can accomplish several minutes after the wake was generated by using only tactile input through its facial vibrissae (Dehnhardt, G. *et al.*, 2001; Schulte-Pelkum, N. *et al.*, 2007). A concert pianist performs a Beethoven concerto at lightening speed. Independently, all 10 of her fingers deftly detect the right keys and exert the appropriate pressure to convey the nuance of the composition to perfection. The complexity of the task has become so second nature that she is only conscious of the musical experience,

not the minute details that her fingertips are extracting from their contact with the piano keys. The joy that she brings to others is both fulfilling and is her means of earning a living.

This chapter will consider how the skin and its innervation in mammals are structurally and chemically organized to extract an extraordinary variety and range of physical features from the environment in order to provide a basis for the brain to formulate tactile perception. First, we will consider some basic principles of sensory perception and traditional functional classifications of cutaneous sensory innervation. Second, we will consider how several varieties of cutaneous innervation are integrated with microanatomical specializations to form highly sensitive and complex tactile organs, particularly vibrissa follicle–sinus complexes and glabrous fingertip skin. Third, we will briefly consider some of the known molecular mechanisms related to the detection of tactile stimulation. Finally, we will consider how the molecular complexity of individual sensory endings, local interactions between multiple sensory endings, and local interactions with non-neuronal components may result not only in sensory detection, but importantly also sensory integration beginning directly in the skin before sensory input reaches the central nervous system (CNS).

6.01.1.1 Tactile Perception Depends upon Stimulus Detection and Predictability

The fundamental principle underlying sensory systems is that every animal needs to establish a metabolic equilibrium that enables it to survive and procreate. In order to establish a survival equilibrium, an animal must be able to detect changes in its environment (stimuli) and generate appropriate reactions (responses) to those changes. In order for this to succeed, these processes must be consistent and predictable. This inherent stimulus–response capacity is present in all living animals, from single-celled animals such as amoebas to relatively simple multicellular animals like jellyfish to complex multicellular animals like mammals. In complex multicellular animals, the collective survival of individual cells requires differentiation into specialized superceding and collaborating systems (e.g., digestive, respiratory, cardiovascular). The nervous system is designed to coordinate the collective survival strategy but the fundamental principle remains the same: the need to consistently and predictably detect stimuli and generate survival responses. An important part of this strategy is to monitor not only the external environment, but also the internal environment. Both must be coordinated and interpreted in the context of each other, that is., the homeostasis of the animal in relation to its external environment.

6.01.1.2 The Skin is a Sense Organ as Well as a Protective Barrier

As a protective barrier, skin forms the largest interface with the external environment. As such, it is also the largest sense organ of the body. Importantly, any natural environmental interaction with the skin or its hairs, either by direct physical contact with an object or even minute air currents, typically involves more than one type of stimulus. These tactile stimuli can be a combination of mechanical force, heat exchange, or chemical interactions (Gardner, E. and Martin, J., 2000). Each type of stimulus can have a wide range of intensities and features such as sustained or fluctuating contact with the skin surface, deflection of a hair in a particular direction, loss or gain of heat, and irritating or soothing tissue reactions.

6.01.1.2.1 Primary sensory neurons

Cutaneous innervation is supplied by a structurally unique types of neurons – primary sensory neurons – that lack dendrites and synaptic contacts typical of all other types of neurons in the nervous system (Gardner, E. *et al.*, 2000). Primary sensory neurons bridge the gap between the peripheral skin, which is impacted by the external environment, and the CNS (brain, brainstem, and spinal cord) where these impacts are ultimately interpreted as tactile perception. The ability to perceive and integrate all types of cutaneous tactile stimuli (mechanical, thermal, and chemical) in parallel is the basis of normal tactile perception, attributable to the fact that no natural environmental interaction with the skin involves only a single type of cutaneous stimulation. Moreover, the sensory neuron innervation to the skin also assesses the intrinsic status of the organ, including internal mechanical activity such as vibration and tension caused by blood flow, and distortion of the skin caused by contractions of the musculature and movements of joints.

In keeping track of the location where a stimulus impinges on the body surface, the skin is organized into bilaterally symmetrical paired strips (referred to as dermatomes) that consecutively cover the entire body surface (Gardner, E. *et al.*, 2000). Each pair of

dermatomes has their stimulation detected by thousands of primary sensory neurons whose cell bodies are contained within consecutive pairs of dorsal root ganglia (DRG) and cranial nerve ganglia. These ganglia are located immediately lateral to each side of the spinal cord and the brainstem. As is discussed below, many functional types of primary sensory neurons have been categorized based on their capacity to respond to different physical properties of cutaneous stimuli. Since the primary sensory neurons are the first of many neurons involved in somatosensory processing, they are also referred to as first-order neurons responding to cutaneous stimuli. In bridging the gap between the skin and the CNS, each primary sensory neuron has a single process – an axon – that bifurcates, with one branch extending the length of a nerve to terminate in the skin, and the other branch extending through a dorsal or cranial root to enter, respectively, the spinal cord or brainstem and synapse on second-order neurons. Each second-order neuron receives converging inputs from several first-order neurons, thereby beginning the process of integrating the entire range of activity generated by cutaneous stimulation.

6.01.1.2.2 Sensory endings

Within the skin, the tip of the axon forms a sensory ending that is restricted to and responds to stimulation of a skin location referred to as a receptive field (Gardner, E. *et al.*, 2000). The receptive field may be a patch of skin or one or more hair follicles. In turn, each location in the skin is supplied by numerous neurons having different functional types of sensory endings (Figures 1 and 2). The size of the receptive field for a particular primary sensory neuron varies depending on the type of sensory ending and the location on the body surface. Performance of tactile tasks that require a high degree of spatial resolution, such as detecting the serrated edge of a coin, is accomplished by a high innervation density in which the skin territory is supplied by a large number of sensory neurons whose individual endings have small receptive fields. Each territory within the dermatome receives endings from a specific set of primary sensory neurons, and the neurons that supply adjacent sites within the dermatome terminate in adjacent second-order neurons. Thus, the body surface is mapped into the circuitry of the CNS to predictably keep track of each site of stimulation on the skin.

6.01.1.3 Functional Classifications of Cutaneous Sensory Neurons

6.01.1.3.1 Basic categories

The ability to discern different types and features of cutaneous stimuli at specific locations within the skin is due to the fact that each site is innervated by several functional types of sensory neurons. Different functional types have been traditionally classified according to three basic electrophysiological criteria: the rate at which the axon conducts action potentials, the type of stimulus (modality) that optimally generates an action potential, and the rate that the neuron adapts and no longer responds to a sustained stimulus (Brown, A. G. and Iggo, A., 1967; Gardner, E. *et al.*, 2000).

6.01.1.3.1.(i) Conduction rate Cutaneous sensory neurons are generally classified by having axons designated as Aβ, Aδ, or C fibers. Aβ fibers have the fastest conductance ($\sim$35–75 m s^{-1}) due to the fact that they have the largest caliber and the thickest myelin sheath. Aδ fibers are significantly slower ($\sim$5–30 m s^{-1}), having a much thinner caliber and thinner myelin sheath. C fibers are by far the slowest ($\sim$0.5–2 m s^{-1}), having the thinnest caliber and being unmyelinated.

6.01.1.3.1.(ii) Stimulus modality Modality generally refers to the type of physical energy that is converted to electrochemical activity in sensory neurons. However, the term is also used in the context of the related stimulus perception. Cutaneous sensory neurons are fundamentally restricted to responding to mechanical force, heat exchange, and chemical reactions. Low- and high-threshold mechanoreceptors are sensory neurons that are optimally activated by relatively mild or strong mechanical stimuli, respectively (Brown, A. G. and Iggo, A., 1967; Burgess, P. R. and Perl, E. R., 1967; Koerber, H. R. and Mandell, L. M., 1992). Mechanoreceptors have been further classified based upon whether the optimal activity is dependent upon the rate of application, duration, and direction of the stimulus with respect to the skin surface or hair. Warm or cold thermoreceptors respond to particular temperatures or changes in temperatures as a function of heat exchange to or from the skin (Iggo, A., 1964; Brown, A. G. and Iggo, A., 1967; Dhaka, A. *et al.*, 2006; Caterina, M. J., 2007). The heat exchange will depend upon the relative temperature and mass of the stimulus to the relative

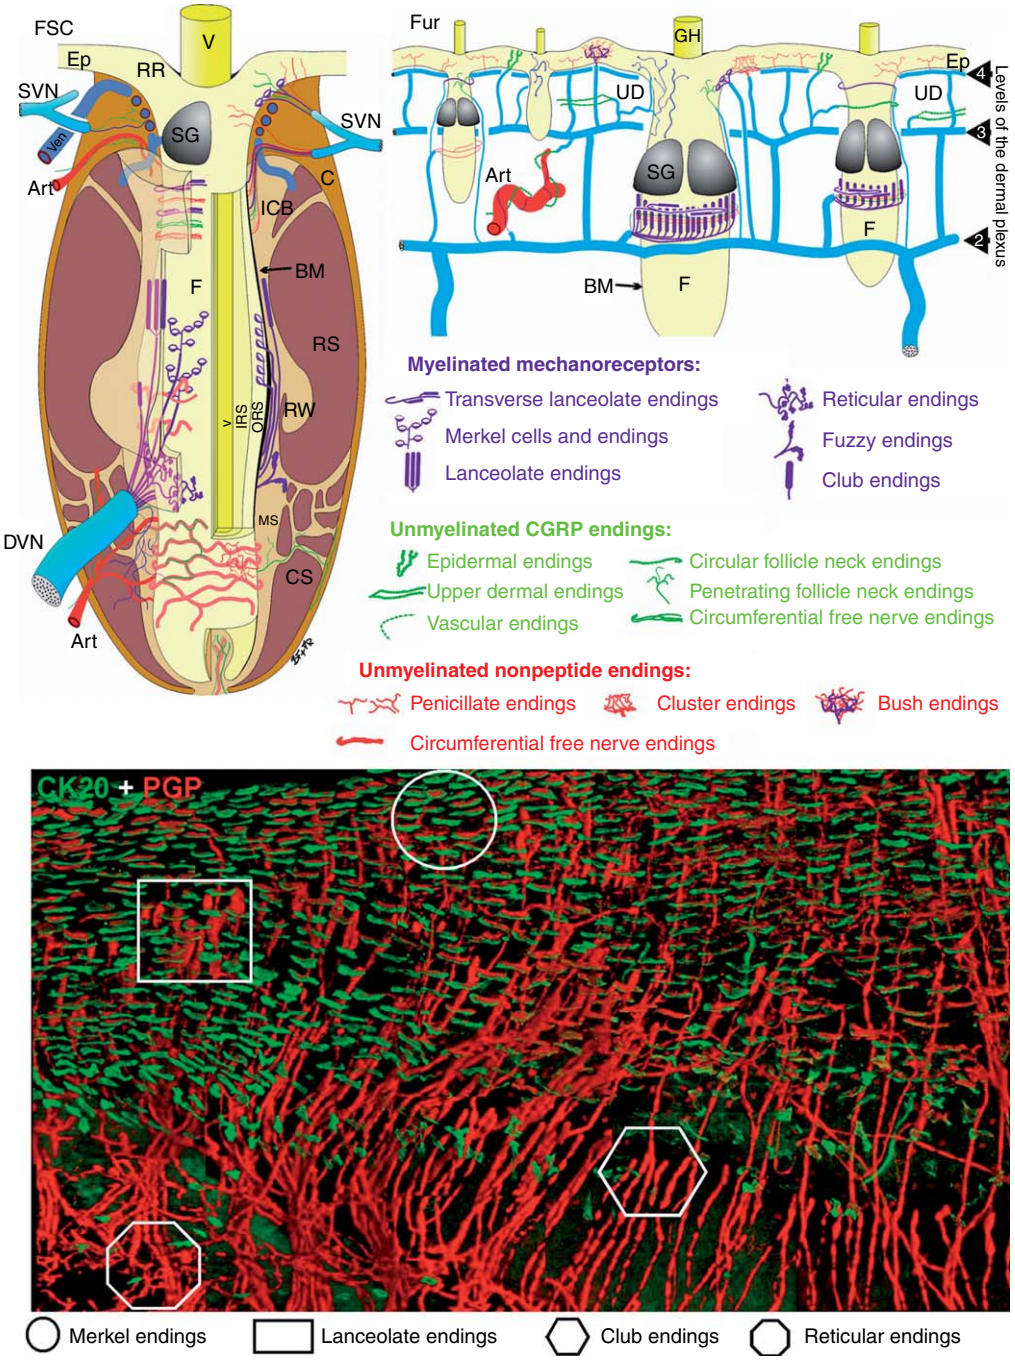

Figure 1 Top: Schematics of the structure and innervation of vibrissa follicle–sinus complexes (FSCs) and intervibrissa fur in mice and rats. Adapted from Funfschilling, U., Ng, Y. G., Zang, K., Miyazaki, J., Reichardt, L. F., and Rice, F. L. 2004. TrkC kinase expression in distinct subsets of cutaneous trigeminal innervation and nonneuronal cells. J. Comp. Neurol. 480, 392–414. Types of innervation are indicated by the color-coded symbols. Bottom: Confocal montage of double-labeled immunofluorescence images compiled from around the perimeter of whole-mount rat vibrissa follicle as seen from the interior where the vibrissa was located. Reproduced with permission from Dr. Satomi Ebara. All of the innervation is labeled by anti-PGP9.5 (red). Merkel cells are labeled by anticytokeratin 20 (green). Examples of different types of endings are shown in white contours. For additional details, see Fundin, B. T. *et al.* (1997b); Rice, F. L. *et al.* (1997); Ebara, S. *et al.* (2002); and Fünfschilling, U. *et al.* (2004). Art, arteriole; BM, basement membrane; C, collagen capsule; CS, cavernous sinus; DVN, deep vibrissa nerve; EP, epidermis; F, Follicle; GH, Guard hair; ICB; inner conical body; IRS, inner root sheath; MS, mesenchymal sheath; ORS, outer root sheath; RR, rete ridge; RS, ringsinus; RW, ring wulst; SG, sebaceous gland; SVN, superficial-vibrissa nerve; Tr, trabeculae; UP, upper dermis, V, vibrissa; VF, vibrissa follicle.

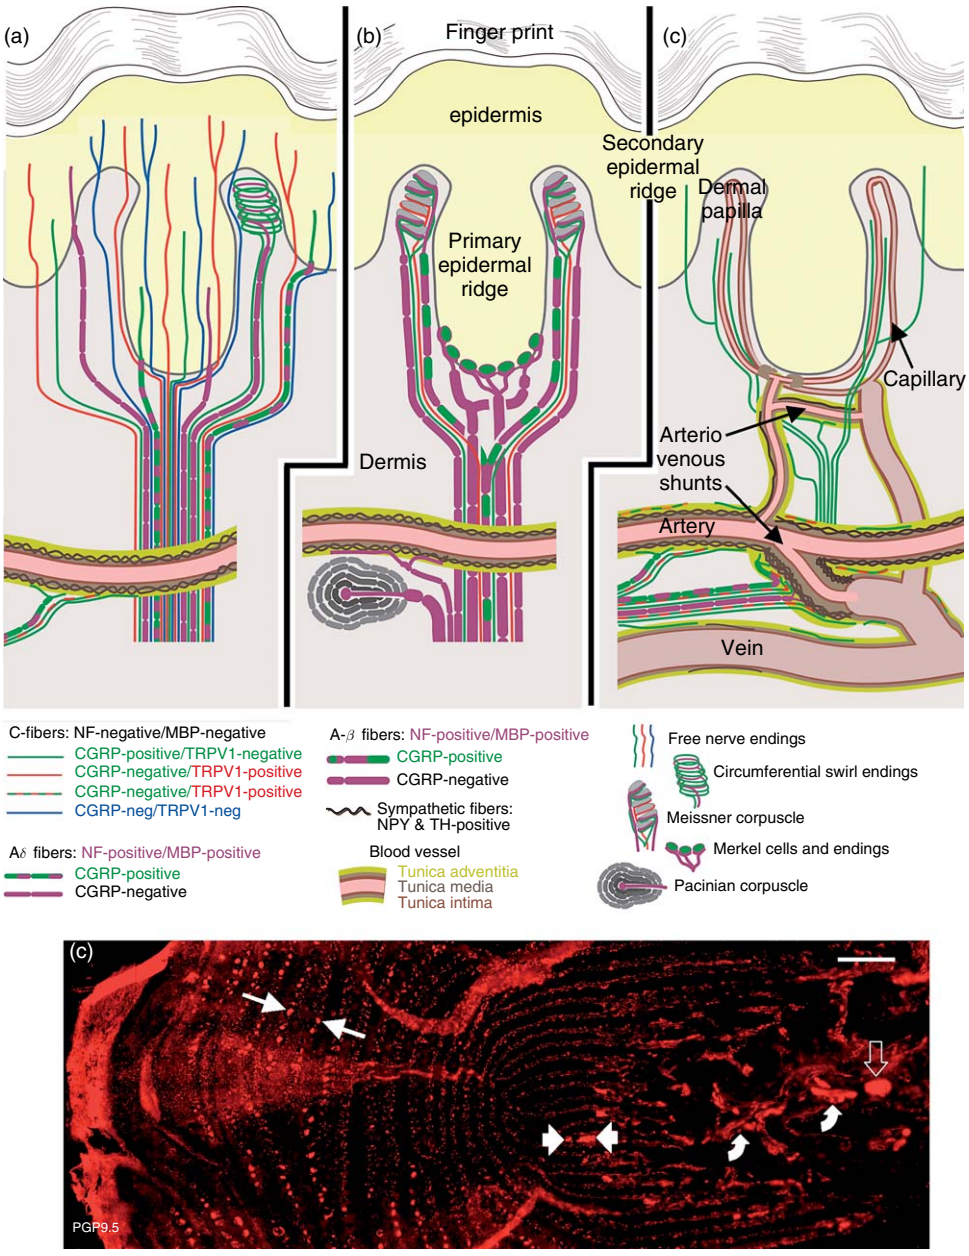

Figure 2 Schematics (a–c) and digital image montage (d) of the structure and innervation of the glabrous fingertip skin from Old World monkeys. Panels (a–c): Schematics representing the skin as seen in a cross section through a fingerprint ridge. Panel (a) represents only the Aδ- and the C-fiber innervation to the epidermis, the dermal papillae, and to a branch of a digital artery. Panel (b) represents only the Aβ fiber innervation and a nonpeptidergic Aδ-fiber innervation to a branch of the digital artery. Panel (c) represents the organization of the vasculature and its affiliated innervation. The superimposition of panels (a)–(c) would represent the total innervation and vasculature to such a site in glabrous digital skin. Types of innervation are indicated in the schematics below (a) and (b). (c) Anti-protein–gene product (PGP) immunofluorescence labeling and mapping of innervation in a 14 μm-thick section of the distal volar pad of the index finger. The section is cut parallel to the skin surface along the long axis of the finger and passes obliquely through the distal tip to the left. The central part of the section shows a transition to the dermal layer to the right. Rows of Meissner corpuscles (thin arrows) outline the pattern of the fingerprints. The pair of thin arrows shows two corpuscles that flank the same primary epidermal ridge. Broad arrows indicate Merkel endings sectioned parallel to the base of a primary epidermal ridge. The open arrow indicates a Pacinian corpuscle that is located among innervated arteries (curved arrows) deep in the dermis. Scale bar = 100 μm. Adapted from Paré M. *et al.* (2002; 2007).

temperature and mass of the skin. Chemoreceptors optimally respond to chemical substances and have been subdivided based upon relative responses to substances such as acids, plant extracts such as capsaicin or menthol, and/or other molecules endogenous to the skin such as glutamate and adenosine triphosphate (ATP) (Bessou, P. and Perl, E. R., 1969; Iggo, A., 1984; Owsianik, G. *et al.*, 2006). These responses will also be relative to the chemical status of the skin.

Another modality classification of primary sensory neurons is based on whether the stimulus evokes activity that is noxious to the point of being perceived as painful. These neurons are referred to as nociceptors and pain is regarded as a modality even though the activity is related to force, heat exchange, or chemical reactions that have the potential to, or actually do, cause tissue damage (Perl, E. R., 1980). As such, classifications of nociceptors are further subdivided into mechanical nociceptors, thermal nociceptors, chemonociceptors, or polymodal nociceptors (Burgess, P. R. and Perl, E. R., 1967; Perl, E. R., 1968; Bessou, P. and Perl, E. R., 1969; Cohen, R. H. and Perl, E. R., 1988; Koerber, H. R. and Mandell, L. M., 1992; Perl, E. R., 1996; Tominaga, M. and Caterina, M. J., 2004).

The existence of a perception that tissue is at risk or damaged presupposes that there must be an ongoing assessment of tissue conditions that fall within a range that are deemed viable. Although ongoing fluctuations of physical activity within the range of healthy tissue homeostasis need not be perceived consciously (and indeed would be distracting), nonetheless there are obviously sensory neurons that are perceiving these fluctuations and regulating responses to maintain this homeostasis. Such neurons detecting this unperceived modality have been referred to as metaboreceptors (Light, A. R. and Perl, E. R., 2003; Molliver, D. C. *et al.*, 2005). Although primarily regarded in relation to sensing muscle metabolism, metaboreceptors presumably would innervate and monitor all tissues including the skin. Indeed, it is quite likely that such metaboreceptors are constantly detecting stressful activity, which elicits subconscious corrective responses before conditions surpass a threshold perceived as painful. As is discussed below, a large population of neurons have chemical properties and experimentally assessed electrophysiological properties that are characterized as nociceptive, despite the fact that acute pain normally occurs on relatively rare occasions. Thus, it might be argued that all of these nociceptive neurons are metaboreceptors and that pain is the consciously perceived activity at the extreme of a continuum that is mostly involved in the unperceived regulation of homeostasis (Craig, A. D., 2003a; 2003b; Light, A. R. and Perl, E. R., 2003).

6.01.1.3.1.(iii) Adaptation Sensory neurons are classified as slowly adapting (SA) if they have a prolonged generation of action potentials in response to a sustained optimal stimulus, or as rapidly adapting (RA) if the generation of action potentials quickly ceases (Gardner, E. *et al.*, 2000). In the latter case, there is typically a brief response both when the stimulus begins and when it is removed. SA neurons are regarded as optimal for discriminating sustained events such as compression of the skin, and RA are optimal for transient events such as vibrations in the skin. Neurons may also be further classified based upon regular or irregular patterns of action potentials (e.g., SA type I, SA type II).

6.01.1.3.2 Cross category correlations

In general, primary sensory neurons that are low-threshold mechanoreceptors have Aβ fibers (Brown, A. G. and Iggo, A., 1967). Neurons that are high-threshold mechanoreceptors, thermoreceptors, chemoreceptors, nociceptors and metaboreceptors generally have either Aδ or C fibers (Burgess, P. R. and Perl, E. R., 1967; Bessou, P. and Perl, E. R., 1969; Kumazawa, T. and Perl, E. R., 1977). However, there are numerous exceptions to these generalities. At least some Aδ and C fibers were classified as low-threshold mechanoreceptors even among the earliest electrophysiological studies (Iggo, A., 1960; Bessou, P. *et al.*, 1971; Light, A. R. and Perl, E. R., 2003; Cole, J. *et al.*, 2006), but their existence has typically been overlooked in the emphasis on the relationship of most of these fibers to pain and thermal sensation. Moreover, some Aβ fiber, low-threshold mechanoreceptors have been shown to have biochemical properties implicated in thermal, chemical, and noxious stimulus transduction (Rice, F. L. *et al.*, 1997; Paré, M. *et al.*, 2001). The potential functional contributions of these properties have barely been investigated.

6.01.1.4 Multineuronal Activation and Tactile Perception

6.01.1.4.1 Adequate or preferred stimulus

Importantly, a long-known aspect of sensory ending physiology that is often unappreciated in

oversimplifying the classifications noted above is that the test parameters investigated are by necessity limited under experimental conditions. Thus, the experimentally determined electrophysiological assessments do not necessarily represent the complete, or perhaps even true, functional capability of a particular sensory neuron in response to natural environmental interactions (Bessou, P. and Perl, E. R., 1969). Therefore, the optimal stimulus that activates a sensory neuron under experimental conditions has rightly been referred to as the adequate or preferred stimulus in recognizing that other stimuli can also activate the neuron at least to a lesser degree (Gardner, E. and Martin, J., 2000). Consequently, electrophysiological studies have always shown a wide range of response properties that, for purposes of simplification, have been somewhat arbitrarily grouped into different classes (Gibson, J. M. and Welker, W. I., 1983a; 1983b). However, *in vivo*, any stimulus applied to the skin surface likely generates different levels of activity across several different types of sensory neurons (Connor, C. E. *et al.*, 1990; Khalsa, P. S. *et al.*, 1998; LaMotte, R. H. *et al.*, 1998; Friedman, R. M. *et al.*, 2002; Bensmaia, S. J. *et al.*, 2005; Leung, Y. Y. *et al.*, 2005; Leiser, S. C. and Moxon, K. A., 2007). Importantly, axons known to terminate in cutaneous locations have frequently been encountered that elicited no change in activity in relation to tested stimuli, indicating that their preferred stimulus may involve several combinations of different stimuli that may occur only under natural conditions (Brown, A. G. and Iggo, A., 1967; Burgess, P. R. and Perl, E. R., 1967).

6.01.1.4.2 Complex multineuronal integration

While making such classifications serves a useful purpose, it is important to recognize that the total pattern of all of the sensory neurons – not only that of the neurons optimally activated – contribute to the brain's formulation of a tactile perception. Regardless of the obvious complexity of this process, it is clear that the various physical properties of a natural cutaneous stimulation are differentially extracted across several types of neurons and then the input is reintegrated centrally to formulate a tactile perception. Indeed, the formulation of a tactile perception likely includes not only an assessment of those sensory neurons that are activated to varying degrees, but also the assessment of those neurons that have not been activated (Gardner, E. and Martin, J., 2000). In addition to the activity of cutaneous innervation during tactile tasks, activity in muscle- and joint-related sensory endings generated by exploratory movement also contributes to tactile perception.

6.01.1.5 Stimulus Transduction by Sensory Endings

Once sensory stimuli have sufficiently activated a sensory neuron, the outcome is an action potential that is electrochemically similar to that in any other neuron, although the shape of the axon potential may differ across fiber types (Dijouhri, L. *et al.*, 1998; Koerber, H. R., and Woodbury, C. J. 2002. As in any other neuron, the generation of an action potential depends upon sufficiently depolarizing the membrane to a threshold level at a site located at the beginning of the axon (Gardner, E. and Martin, J., 2000). In a typical neuron, the impulse-generating zone is located where the axon is attached to the cell body (the axon hillock). The threshold depolarization is achieved at this site through the spatiotemporal integration of excitatory and inhibitory graded responses generated by numerous synapses on the dendrites and the cell body. In general, the excitatory synaptic mechanisms open sodium channels to permit depolarization, whereas inhibitory synaptic mechanisms cause a countering hyperpolarization by activating potassium channels. In a primary sensory neuron, the impulse-generating zone is at the transition between the sensory ending and the beginning of the axon, and the threshold depolarization is achieved by activating ion channels in the sensory ending. Thus, the specific stimulus detection property of primary sensory neurons is dependent on the location (local tissue environment), structure, and chemistry of its sensory ending.

6.01.2 Organization of Innervation Among Structurally Complex Tactile Organs

Among large multicellular animals, especially mammals, the orofacial area and distal limbs are best positioned to interact with tactile environments. Thus, these areas have a particularly high innervation density and a wide variety of sensory endings. Moreover, important tactile sites also have intricate non-neuronal tissue specializations that likely enhance the impact of the various physical components of a stimulus. Two exceptional examples of these combined features are: (1) the presence of

patterned arrays of long tactile vibrissae and their associated follicle–sinus complexes (FSC) on the hairy-skin snouts of most mammalian quadrupeds (Figure 1) and (2) the presence of patterned epidermal ridges (fingerprints) on fingertip glabrous skin (Figure 2) especially in bipedal primates. In both examples, the different types of sensory endings are strategically located among specific microanatomical features (Cauna, N., 1954; Rice, F. L. *et al.*, 1997; Ebara, S. *et al.*, 2002; Paré, M. *et al.*, 2002).

6.01.2.1 Complex Tactile Organs with Multiple Types of Innervation

6.01.2.1.1 Vibrissa follicle sinus complexes

Each FSC consists of a large follicle core (an epidermal invagination), which is encased within dermal derivatives consisting of a thin mesenchymal sheath and an encapsulated blood sinus (Figures 1 and 3). The epidermis is thickened at the mouth of the follicle (rete ridge collar). The mesenchymal sheath expands at the upper end of the sinus (inner conical body, ICB), anchors a ring of tissue at the mid-level of the sinus (ringwulst), and exudes tissue strands (trabeculae) that fan out to the connective tissue capsule at the deep end of the sinus. The upper portion of the blood sinus – referred to as the ring sinus – has an open lumen in which the ringwulst is suspended, while the lower portion – referred to as the cavernous sinus – is laced with trabeculae. The base of each follicle is penetrated by a dermal papilla.

The FSC receives innervation via a deep vibrissal nerve (DVN) that penetrates the deep aspect of the sinus capsule and via several smaller superficial vibrissal nerves (SVN) that penetrate the superficial aspect. Each type of nerve supplies sensory endings to separate deep and superficial portions as though the FSC consisted of two distinct functional entities. Importantly, each type of nerve supplies more than one type of Aβ fiber whose particular morphologically distinct ending has a unique site of termination within the FSC microanatomy (Rice, F. L. *et al.*, 1997; Ebara, S. *et al.*, 2002). A unique morphological type of Aβ fiber ending is affiliated with each aspect of the FSC microanatomy. Furthermore, each nerve supplies several chemically distinct types of Aδ and C fibers, and many of these terminate at the same locations as the Aβ fiber endings.

Taken together, the specific distributions of sensory ending types among distinct microanatomical locations indicates that any perturbation of the vibrissa will generate a variety of mechanical forces at each location and would, therefore, differentially activate all the types of innervation terminating at these locations (Gibson, J. M. and Welker, W. I., 1983a; 1983b; Szwed, M. *et al.*, 2003; Leiser, S. C. and Moxon, K. A., 2007). Slight differences in the perturbations of the vibrissa would differentially alter the mechanical forces at each location, and thus the pattern of activity among all the sets of innervation. In general, the Aβ fibers supplied by the DVN have been implicated in detecting various movements of the vibrissa with respect to the interior structure of the FSC. The Aβ fibers supplied by SVN have been implicated in detecting movement of the vibrissa with respect to the mouth of the follicle and the movement of the entire FSC with respect to the skin surface caused by contraction of papillary muscles. Reflecting these potential different functions, SVN and DVN that supply the same FSC have been shown to have different patterns of terminations in the brainstem (Arvidsson, J. and Rice, F. L., 1991).

The vibrissae and their FSCs are also organized into predictable rows and numbers. Each row of follicles is paralleled by a dedicated fascicle of the trigeminal nerve. Based upon the organization of this macroanatomy and innervation, any encounter with a vibrissa-perturbing stimulus will generate differential patterns of activity among the innervation to all the follicles depending upon the size, shape, orientation, direction, velocity, texture, duration, and intensity of the stimulus (Mehta, S. B. and Kleinfeld, D., 2004; Kleinfeld, D. *et al.*, 2006; Mehta, S. B. *et al.*, 2007).

6.01.2.1.2 Guard hair follicles

Although less elaborate than FSCs, the much smaller hair follicles over the rest of the body also have associated with them different types of sensory endings that respond to various stimulations of hairs, consisting of sustained or transient displacements with or without preferential orientations (Brown, A. G. and Iggo, A., 1967). Although all follicles receive some innervation (Figure 1), the follicles of the larger body hairs – referred to as guard hairs – can have several varieties of endings in two locations (Figures 4(a)–4(c)): (1) at the mouth and the neck of the follicle, and (2) below the sebaceous gland. The latter site has an integrated array of endings referred to as the piloneural complex.

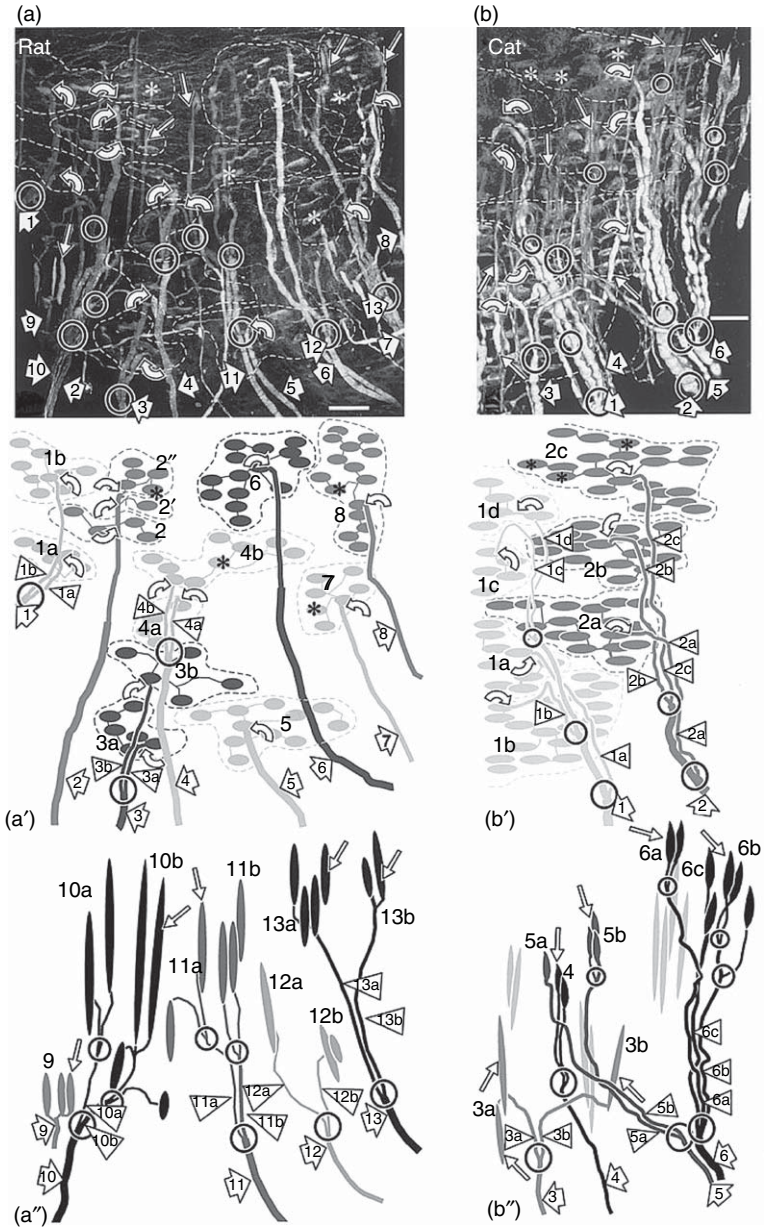

Figure 3 Comparison of the Merkel and lanceolate innervation at the level of the ring sinus in the rat (panels (a), (a′), and (a″)) and the cat (panels (b), (b′), and (b″)) as seen in confocal images of 100 μm-thick longitudinal sections that graze the surface of the vibrissa follicles. (a,b) Confocal images of anti-PGP9.5 labeling. Aβ fibers supplying Merkel endings (asterisks) and lanceolate endings (thin arrows) are indicated by the broad numbered arrows. Reconstructions of the Merkel arbors are shown in panels (a′) and (b′) and lanceolate arbors in panels (a″) and (b″). Curved arrows indicate where the distal ends of the Merkel Aβ fibers (broad numbered arrows) or their branches cross the basement membrane of the follicle to form terminal arbors enclosed by dashed lines. Larger circles indicate the first branch point. Successive branch points are indicated by successively smaller circles. Scale bars = 50 μm in (a) and 25 μm in (b). Reproduced from Ebara, S., Kumamoto, K., Matsuura, T., Mazurkiewicz, J. E., and Rice, F. L. 2002. Similarities and differences in the innervation of mystacial vibrissal follicle–sinus complexes in the rat and cat: a confocal microscopic study. J. Comp. Neurol. 449, 103–119.

6.01.2.1.3 Glabrous fingertip skin

In the glabrous fingertips of primates, the elevated fingerprints at the skin surface overlie especially thick primary epidermal ridges (Figures 2 and 5) (Cauna, N., 1954; Paré, M. *et al.*, 2002). The grooves between the fingerprints overlie relatively thinner

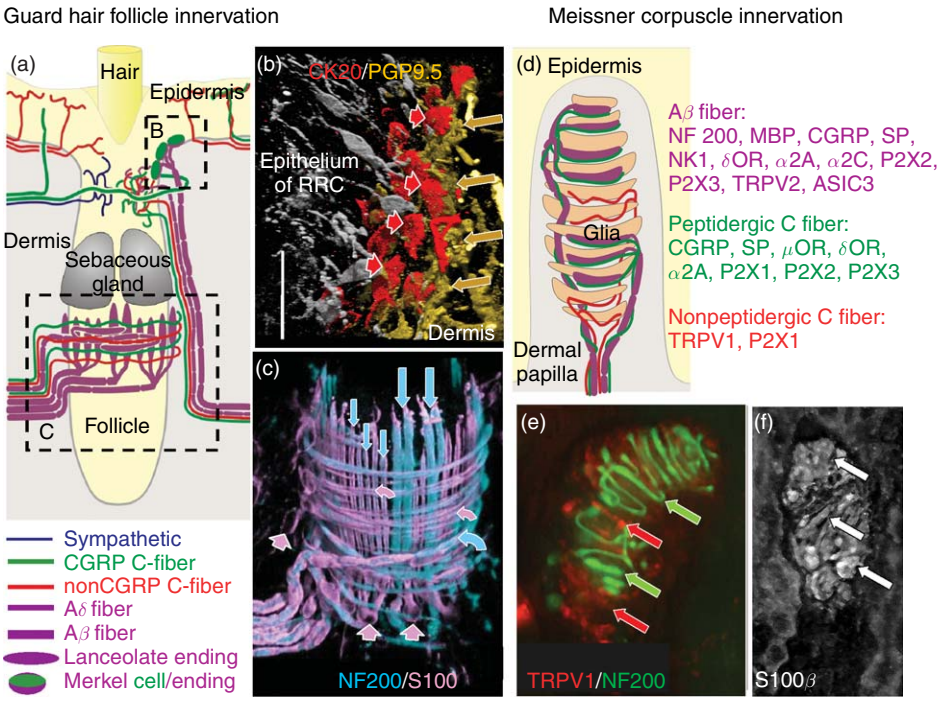

Figure 4 Schematic illustrations of mixed Aβ-fiber and C-fiber innervation to guard hair follicles (panels (a)–(c)) and Meissner corpuscles (panels (d)–(f)) accompanied by immunofluorescence images. (a) Enlargement from fur schematic in Figure 1 (see key in Figure 1). Broken line rectangles indicate sites of confocal images in panels (b) (Merkel rete ridge) and (c) (piloneural complex). (b) Confocal image of the epidermal rete ridge at the mouth of a cat hair follicle as seen in a 100 μm-thick section perpendicular to the skin surface. Reproduced with permission from Dr. Satomi Ebara. Merkel cells are labeled with anticytokeratin 20 (red) and Merkel endings with anti-PGP9.5 (gold). Each Merkel cell can be contacted by an ending from more than one Aβ fiber, and each Aβ fiber can form an ending on more than one Merkel cell. (c) Confocal image of a piloneural complex in a cat showing Aβ fiber endings (blue arrows) labeled with an antibody against 200 kDa neurofilament protein (blue) and terminal glial cells and their processes (pink arrows) labeled with anti-S100 (pink). Reproduced with permission from Dr. Satomi Ebara. Some Aβ fibers terminate as a palisade of longitudinally oriented lanceolate endings (narrow arrows). The fibers may terminate as one or two large endings (larger arrows) or multiple small endings (small arrows). Other Aβ fibers terminate as circumferentially oriented lanceolate endings (blue curved arrows). Terminal glial cells have multiple processes that line the lanceolate endings. Circumferentially oriented C-fiber terminals lack NF200 but are lined by terminal glial processes (pink curved arrows). Individual terminal glia can contact endings from more than one Aβ fiber. (d) Schematic of the innervation and immunolabeling characteristics of Meissner corpuscles in primate glabrous skin. Immunochemical properties of each type of innervation are shown to the right. Adapted from Paré, M., Elde, R., Mazurkiewicz, J. E., Smith, A. M., and Rice, F. L. 2001. The Meissner corpuscle revised: a multiafferented mechanoreceptor with nociceptor immunochemical properties. J. Neurosci. 21, 7236–7246. (e) Double immunolabeling reveals that Aβ fiber endings (green) terminate in strata alternating with TRPV1 expressing C fibers (red). (f) Terminal glia within the Meissner corpuscles express S100.

secondary epidermal ridges. Along the juncture between the parallel primary and secondary ridges, regularly and closely spaced dermal papillae protrude under epidermal invaginations and are slightly angled toward the elevated fingerprint (Bolanowski, S. J., Jr. and Pawson, L., 2003). Analogous to the nerve fascicles dedicated to each row of vibrissae, small nerves fascicles run in the dermis deep and parallel to the primary epidermal ridges. At regular intervals, smaller nerves ascend toward and branch to each side of the primary epidermal ridge (Figure 2). Thus, a functional unit analogous to a vibrissa follicle would be a skin sector parallel to the long axis of the primary ridge and spanning between the adjacent secondary ridges (Figure 2) (Cauna, N., 1956; Khalsa, P. S. *et al.*, 1998; LaMotte, R. H. *et al.*, 1998; Paré, M. *et al.*, 2002). However, unlike the spatial segregation of individual FSC, there is a gradually shifting overlap in the innervation along the primary ridge and to a lesser degree between adjacent primary ridges. As in the FSC, different types and combinations of Aβ, Aδ, and C fibers terminate at strategic locations in this microanatomical organization (Figure 2). Thus, the

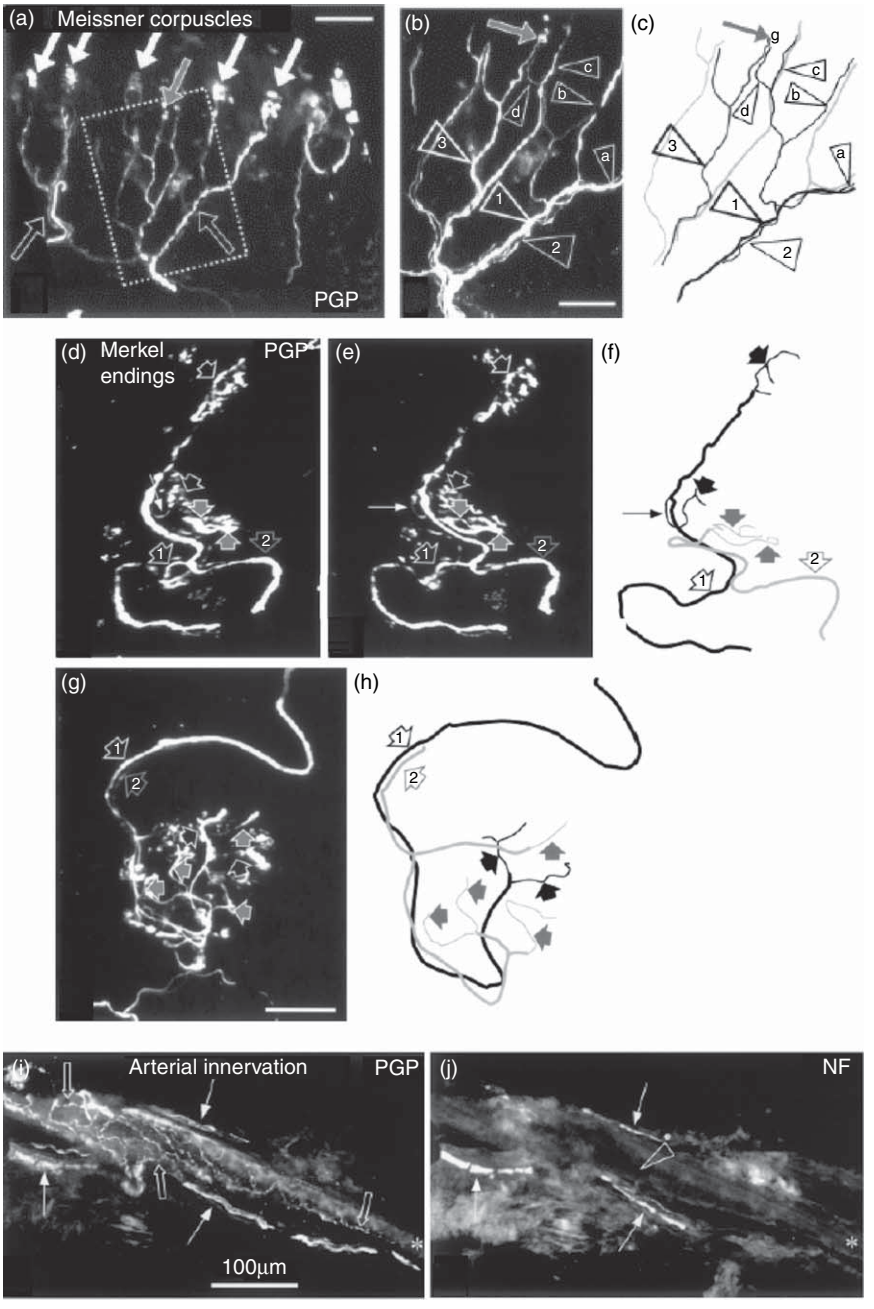

Figure 5 Immunofluorescence images and arbor reconstructions of Meissner, Merkel, and arterial innervation in monkey glabrous hand skin. (a–c) Confocal images and reconstructions of individual arbors in 100 μm-thick sections demonstrating that Meissner corpuscles can be innervated by more than one Aβ fiber, some of which innervate just one corpuscle, and others multiple corpuscles. (d–h) Confocal images and reconstructions of individual arbors in 100 μm-thick sections demonstrating that some Aβ fibers terminate on a discreet cluster of Merkel cells in one locale, whereas others give rise to *en passant* branches that terminate on Merkel cells in disparate locales. (I–j) Double-labeled immunofluorescence reveals that spindle-shaped structures typically interpreted as Ruffini corpuscles are arterial profiles that are innervated by a mix of neurofilament-negative C fibers and neurofilament-positive Aδ fibers. Reproduced from Paré, M., Smith, A. M., and Rice, F. L. 2002. Distribution and terminal arborizations of cutaneous mechanoreceptors in the glabrous finger pads of the monkey. J. Comp. Neurol. 445, 347–359.

fingertip anatomy and innervation are organized so that any contact with the fingerprints will generate differential patterns of activity across the entire ensemble of sensory endings enabling a detailed discrimination of the stimulus (Connor, C. E. and Johnson, K. O., 1992; Khalsa, P. S. *et al.*, 1998; LaMotte, R. H. *et al.*, 1998; Bensmaia, S. J. *et al.*, 2005; Leung, Y. Y. *et al.*, 2005).

6.01.2.1.4 Patterned vasculature

Importantly, the anatomical patterns of the vibrissa pads (Figure 1) and fingerprints (Figure 2) are paralleled by an equally elaborate vascular pattern (Fundin, B. T. *et al.*, 1997b; Paré, M. *et al.*, 2002). Although most vascular research has focused on the sympathetic innervation, vasculature also has an elaborate sensory innervation consisting of several different chemically distinct types of Aδ and C fibers. This sensory innervation preferentially terminates at strategic anatomical locations. Thus, the sensory innervation of the vasculature likely has a somatotopic organization that is as equally detailed as the rest of the skin. In the glabrous skin of primates and carnivores, one type of sensory ending – Pacinian corpuscles – supplied by Aβ fibers is commonly located in close affiliation with arteries in the dermis (Figures 2 and 7) (Rice, F. L. and Rasmusson, D. D., 2000; Paré, M. *et al.*, 2002). Pacinian corpuscles are typically regarded as tactile, low-threshold mechanoreceptors; however, both they and some of the Aδ and/or C fibers are likely assessing mechanically generated activity in the blood vessels, such as tension caused by blood pressure and vibrations caused by blood flow (Tuttle, R. S. and McCleary, M., 1975; Freeman, B. and Rowe, M., 1981). Conceivably, this innervation may function in a subconscious realm by monitoring the vasculature, as well as in the conscious realm when a vibratory stimulus is applied to the skin or the vasculature is distorted by mechanical displacement of the skin.

6.01.2.2 Morphological Variations Among Specific Types of Mechanoreceptive Endings

Both the FSC (as well as common hair follicles) and the glabrous skin contain the most common and widely distributed, morphologically distinct types of sensory endings (Iggo, A. and Andres, K. H., 1982). These endings had been detected by using reduced silver techniques in the late nineteenth century, long before physiological functional differences were detected. Variations of these types specific to other species and locations have been demonstrated. Although particular functions are commonly associated with particular types of endings, most of these associations are circumstantial despite numerous attempts to establish direct correlations.

6.01.2.2.1 Merkel endings

The tips of many Aβ fibers in both hairy and glabrous skin branch near the basement membrane of the epidermis. The branches penetrate the basement membrane to terminate as flattened disks juxtaposed to chemically distinct Merkel cells. Merkel cells are located next to the basement membrane among the deepest cells in the epidermis (lamina basalis) or the outermost cells of vibrissa follicles (outer root sheath) (Andres, K. H., 1966a; 1966b; Patrizi, G. and Munger, B. L., 1966; Iggo, A. and Muir, A. R., 1969). In the primate glabrous fingertips, Merkel cells and endings are located at the base of the primary epidermal ridges (Figures 2 and 5(d)–5(h)). In hairy skin, they are located at slightly thickened epidermal pads (Haarschibe), at the mouth of many hair follicles (Figure 4(a)), or at thickened epidermal spots (touch domes) between hairs. In the vibrissa FSC, SVN contain Aβ fibers that terminate on Merkel cells in the rete ridge collar (Figure 1), while DVN contain Aβ fibers that terminate on Merkel cells in the outer root sheath only at the level of the ring sinus (Figures 1 and 3(a′) and 3(b′)).

Physiologically, Merkel endings are purportedly SA, low-threshold mechanoreceptors that respond to skin compression or hair deflection for a fairly sustained duration (Iggo, A. and Muir, A. R., 1969; Gottschaldt, K. M. *et al.*, 1973). They are regarded as SA type I receptors that have a regularly spaced discharge rate, which increases in proportion to the intensity of the stimulus. Endings with this type of physiology typically have relatively small skin-surface receptive fields or are limited to a single vibrissa usually with a preferred direction of deflection. As such, Merkel endings have been implicated in high-resolution object discrimination (Connor, C. E. *et al.*, 1990; Friedman, R. M. *et al.*, 2002; Bensmaia, S. J. *et al.*, 2005).

Interestingly, detailed morphological assessments of individual Aβ fibers that terminate as Merkel endings have revealed a variety of terminal branch patterns (Rice, F. L. *et al.*, 1997; Ebara, S. *et al.*, 2002), which suggests that Merkel fibers might account for a variety of physiological response

properties (Gottschaldt, K. M. *et al.*, 1972; 1973; Gibson, J. M. and Welker, W. I., 1983a; 1983b). Both at the ring sinus level of the vibrissa follicles (Figure 3(a′)) and at the base of primary epidermal ridges in glabrous skin (Figures 5(d)–5(h)), some Aβ fibers terminate as several short branches, with each branch terminating directly on a single Merkel cell. The Merkel cells individually supplied by these short branches are located within a small, tightly circumscribed contiguous territory. This pattern of termination would be consistent with a regular discharge rate in response to a sustained stimulus. However, some Aβ fibers end with just a few relatively long branches that each contact several cells in succession over an extended territory. Moreover, in both types of terminal patterns, some Aβ fibers branch only at their tip whereas others can have several branches that arise *en passant* from different nodes along the length of the fiber (Figures 3(b′) and 5(g)–5(h)). In the latter case, the Merkel cells innervated by each *en passant* branch in FSC are located in adjacent territories along the length of the follicle. Both the terminations by branches on several Merkel cells in succession as well as the *en passant* branching patterns would indicate that such endings could generate complex patterns of activity that would be more consistent with irregular discharge rates classified as SA type II fibers.

Interesting differences also occur between Merkel endings that terminate along the length of the follicles in FSCs and those that terminate at the mouth of vibrissa and other hair follicles. Among the former, the Merkel disks contact the Merkel cells on the surface facing away from the basement membrane, whereas the latter contact the surface facing toward the basement membrane (Andres, K. H., 1966a; Patrizi, G. and Munger, B. L., 1966; Iggo, A. and Muir, A. R., 1969). The functional significance of these different arrangements is unknown. Among terminations along the length of the follicles, each Merkel cell is contacted by a single disk from a single Aβ fiber, albeit that fiber contacts several Merkel cells (Figures 3(a′) and 3(b′)) (Ebara, S. *et al.*, 2002). Moreover, a branch from one Aβ fiber never appears to cross over a branch from another fiber. Thus, each of these Aβ fibers innervates multiple Merkel cells located in segregated, nonoverlapping territories.

In contrast, single Merkel cells located in the epidermis at the mouth of follicles and epidermal touch domes have been shown to be innervated by more than one disk arising from more than one Aβ fiber (Figure 4(b)) (Ebara, S., personal communication). Additionally, branches from one fiber can cross over a branch from another fiber (Rice, F. L. *et al.*, 1997). Thus, the Merkel innervation at the mouth of hairs appears to be an overlapping system. Importantly, the activation of Merkel endings by mechanical stimuli was once thought to be limited to mechanisms intrinsic to the endings. However, recent data indicates that Merkel cells may be directly involved in initiating or mediating the transduction of mechanical sensory stimuli (Cahusac, P. M. *et al.*, 2005; Cahusac, P. M. and Senok, S. S., 2006; Lucarz, A. and Brand, G., 2007). Therefore, the anatomical arrangement of the Merkel innervation at the mouth of hairs may enable peripheral sensory stimuli integration at the level of the initial sensory transduction.

6.01.2.2.2 Lanceolate endings and Meissner corpuscles

Many Aβ fibers terminate as either lanceolate endings associated with vibrissae and guard hair follicles (Figures 1, 3, 4(a) and 4(c), and 6) (Fundin, B. T. *et al.*, 1997a; Rice, F. L. *et al.*, 1997) or Meissner corpuscles in the dermal papillae of glabrous skin (Figures 2, 4(d)–4(f), and 5(a)–5(c)) (Paré, M. *et al.*, 2001; 2002).

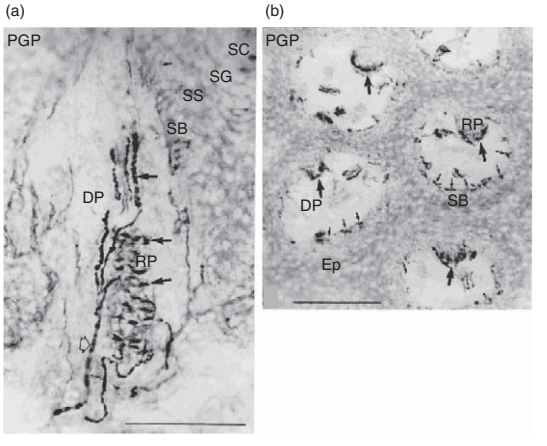

Figure 6 Merkel innervation in dermal papillae (DP) underlying epidermal domes in the glabrous digital skin of the raccoon. Panel (a) is cut perpendicular to the skin surface and panel (b) parallel to the surface. Merkel innervation (larger arrows) that is oriented and looks like a Meissner corpuscle as seen in panel (a) actually terminate in epidermal rete pegs. (RP) that protrude into the dermal papillae from the epidermis. Reproduced from Rice, F. L. and Rasmusson, D. D., 2000. Innervation of the digit on the forepaw of the raccoon. J.Comp. Neurol. 417, 467-490.

Lanceolate and Meissner Aβ fibers consistently have a slightly smaller caliber than those that terminate as Merkel endings and should have a slightly slower conduction velocity. Even though the endings are utterly different morphologically, they are being discussed together because they share many common properties (Figure 4). Conceivably, both are derivatives of the same type of sensory neurons whose endings only differ because of the locations that are available to innervate in the different types of skin. Both types of endings terminate in the dermis but are closely affiliated with the basement membrane of the epidermis or hair follicles, which are epidermal derivatives. Both types of endings are also affiliated with terminal glial cells, which are Schwann cell derivatives (Cauna, N. and Ross, L. L., 1960; Andres, K. H., 1966b; Patrizi, G. and Munger, B. L., 1966; Takahashi-Iwanaga, H. and Shimoda, H., 2003). Electrophysiological studies indicate that both types of endings are likely RA, low-threshold mechanoreceptors (Gottschaldt, K. M. *et al.*, 1973; Connor, C. E. and Johnson, K. O., 1992).

6.01.2.2.2.(i) Lanceolate endings Lanceolate endings are elongated flattened blade-like structures that are typically oriented parallel to the long axis of the vibrissa or hair follicles (Figures 1, 3(a″), and 3(b″), and 4(a)–4(c)). An Aβ fiber may terminate as a single ending or multiple endings arrayed like the tines of a fork. As seen in cross section by electron microscopy, the flat surface of each ending is lined by a terminal glial lamella, and the sharp edges have a fringe of cytoplasmic blebs lined with the basement membrane (Andres, K. H., 1966b; Patrizi, G. and Munger, B. L., 1966). The endings are slightly angled so that the blebs of one edge are embedded in densely packed collagen bundles in the basement membrane while the other edge is embedded in more loosely packed collagen bundles in the surrounding dermis. It has been assumed that these embedded edges would be subject to shear forces caused by hair deflection and are the likely sites of mechanically driven depolarization.

As seen in association with guard hair follicles, numerous lanceolate endings are arrayed side-by-side, forming a palisade around the perimeter of the follicle at a level just below the sebaceous gland (Figures 4(a) and 4(c)) (Biemesderfer, D. *et al.*, 1978; Rice, F. L. *et al.*, 1997). Smaller hair follicles can sometimes have just a few endings. In most cases, the palisade is formed by lanceolate endings supplied by multiple Aβ fibers that include a mix of those forming several relatively short endings and those with only one or two slightly longer endings. The endings from each fiber terminate adjacent to each other so that each fiber supplies a unique sector around the perimeter of the follicle. Serial reconstructions in thick sections indicate that some of the Aβ fibers may terminate exclusively on one follicle while others may branch fairly proximally and innervate multiple follicles (Mosconi, T. M. and Rice, F. L., 1991). Thus, a single follicle may activate some Aβ fibers exclusively, but activate other fibers in collaboration with other follicles. This arrangement may account for the fact that some Aβ fibers have been detected that respond transiently to single hair deflections with a preferred orientation, while others can be transiently activated by multiple hair deflections with little or no directional preference (Brown, A. G. and Iggo, A., 1967). Importantly, this arrangement indicates that hair follicles can be part of a punctate, single follicle system and a relatively diffuse, overlapping multifollicle system.

The palisades of lanceolate endings are actually part of a more extensive combination of endings referred to as the piloneural complex (Figures 5(a) and 5(c)). Slightly centrifugal to the palisades of lanceolate endings are usually circumferentially oriented free nerve endings (FNE) supplied by at least two different types of C fibers: a peptidergic type containing the neuropeptides, calcitonin gene-related peptide (CGRP) and substance P (SP), and a non-peptidergic type, which lacks these neuropeptides (Fundin, B. T. *et al.*, 1997a; Rice, F. L. *et al.*, 1997). In addition, some smaller-caliber Aβ fibers can each contribute multiple circumferentially oriented lanceolate-like endings that appear to arise *en passant* along the trajectory of the axon (Mosconi, T. M. *et al.*, 1993; Rice, F. L. *et al.*, 1997). The function of the C fiber innervation at this location is unknown, but the *en passant* lanceolate ending presumably would be a low-threshold mechanoreceptor that would lack any directional preference.

The longitudinally oriented lanceolate endings in the FSC are supplied by DVN and are much larger than those innervating guard hairs (Figures 3(a″) and 3(b″)). They are located in the mesenchymal sheath at the ring sinus level of FSC, at about the same level of the Merkel endings. Some of these Aβ fibers also terminate as a few longer branches, while others terminate as many shorter branches, but each fiber appears only to supply endings to one FSC (Arvidsson, J. and Rice, F. L., 1991). The circumferentially oriented components of piloneural complexes around guard hair follicles appear to be

displaced to the level of the ICB in FSC and are supplied by SVN.

6.01.2.2.2.(ii) Meissner corpuscles Like the piloneural complexes, Meissner corpuscles are supplied by multiple Aβ fibers, as well as at least two types of C fibers (Figures 4(d)–4(f)) (Cauna, N., 1956; Hilliges, M. *et al.*, 1996; Paré, M. *et al.*, 2001; 2002). The Aβ fibers terminate as stacks of multiple disks alternating with terminal Schwann cells. Within each corpuscle, zones of terminal disks from the Aβ fibers alternate with intervening zones supplied by nonpeptidergic C fibers. A second set of peptidergic C fibers (containing CGRP and SP) are intimately associated with the Aβ fiber terminals. The potential functional significance of this arrangement is discussed below. These endings have been implicated in optimally responding to low-frequency flutter vibration such as that caused by the mechanical friction stimulus generated when skin is rubbed against an object (Mountcastle, V. B. *et al.*, 1967; Connor, C. E. *et al.*, 1990; Friedman, R. M. *et al.*, 2002; Bensmaia, S. J. *et al.*, 2005). This is consistent with the fact that in fingertips they are located in closely spaced dermal papillae that protrude under the epidermis on each side of the primary epidermal ridges that underlie the raised fingerprint. This anatomical arrangement likely enhances the mechanical friction stimuli associated with contacting a surface. The corpuscles are purportedly anchored to the basement membrane of the enveloping epidermis by thin connective tissue strands, heightening their ability to detect even the slightest mechanical deformations of the skin surface (Cauna, N. and Ross, L. L., 1960; Takahashi-Iwanaga, H. and Shimoda, H., 2003).

Given their location on each side of the fingerprint, Meissners corpuscle are presumably impacted particularly by mechanical force transverse to the fingerprint, consistent with the fact that Meissner corpuscle activation often has a preferred directional component (Friedman, R. M. *et al.*, 2002). Because they are best activated by a moving stimulus (or movement of the skin over a static object) their individual resolving power is relatively poor compared to that of Merkel endings. As is the case with the lanceolate endings in the piloneural complexes, some Aβ fibers appear to innervate only one Meissner corpuscle, while the same corpuscle is also supplied by other fibers that innervate multiple corpuscles (Figures 5(a)–5(c)) (Paré, M. *et al.*, 2002). Thus, each corpuscle appears to participate in both punctate, nonoverlapping receptive systems and more diffuse, overlapping receptive systems.

6.01.2.2.3 Pacinian and Golgi–Mazzoni corpuscles

Particularly large-caliber Aβ fibers terminate within large, onion-like corpuscles composed of multiple, fairly loose concentric layers of Schwann cell lamellae enclosed within a dense outer capsule. They are located in the dermis well below the epidermis in both the hairy and the glabrous digital skin of primates and carnivores. In most cases, referred to as Pacinian corpuscles (Figures 7(b), 7(d), and 7(f)), the Aβ fiber terminates in the core as a single large-caliber blunt ending with a knob at the tip (Winkelmann, R. K. and Osment, L. S., 1956; Rice, F. L. and Rasmusson, D. D., 2000; Paré, M. *et al.*, 2002). In other cases, referred

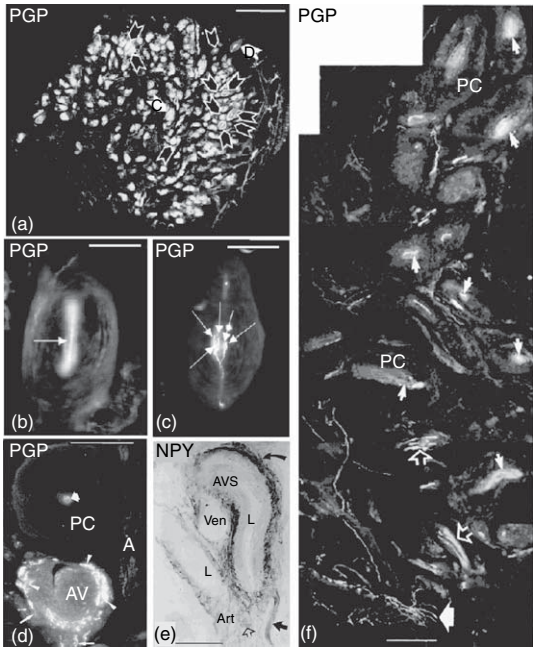

Figure 7 Immunofluorescence images of Pacinian and Golgi–Mazzoni corpuscles. (a) Monkey glabrous fingertip skin, (b) Pacinian, and (c) Golgi–Mazzoni corpuscles are located deep in the dermis (white chevrons in a) among sweat glands (black chevrons). (d,e) As seen here in the raccoon glabrous skin, Pacinian corpuscles are often closely affiliated with branches of digital arteries and arteriovenous shunts. The arteries and shunts have extensive calcitonin gene-related peptide (CGRP)-positive sensory innervation (d) and neuropeptide Y (NPY)-positive sympathetic innervation (e). (f) Numerous Pacinian corpuscles are packed against the base of the claws in the raccoon. Reproduced from Paré M. *et al.* (2002) and Rice F. L. and Rasmusson D. D. (2001).

to as Golgi–Mazzoni corpuscles, the axon terminates as several thin elongated parallel processes (Figure 7(c)). In both circumstances, the innermost Schwann cell next to the ending is anatomically and immunochemically distinct (Pawson, L. *et al.*, 2000). Experimentally, Pacinian corpuscles have been isolated from intestinal mesenteries and have been shown electrophysiologically to be low-threshold RA endings that entrain to high-frequency vibrations (Bolanowski, S. J., Jr., 1984; Bolanowski, S. J., Jr. and Zwislocki, J. J., 1984a; 1984b; Vallbo, A. B. and Johansson, R. S., 1984; Connor, C. E. and Johnson, K. O., 1992; Guclu, B. *et al.*, 2006). Whether the Golgi–Mazzoni corpuscles have a substantially different physiology is unknown. The entrainment of the Pacinian corpuscles begins at the upper end of the lower frequencies where purported Meissner corpuscles are no longer capable of maintaining their entrainments (Bensmaia, S. J. *et al.*, 2005; Leung, Y. Y. *et al.*, 2005). Thus, these two sets of endings complement each other to span a continuous range of low- to high-frequency vibration detection (Mountcastle, V. B. *et al.*, 1967; LaMotte, R. H. and Mountcastle, V. B., 1975).

Although they have a relatively high density in the fingertips, Pacinian corpuscles are very sparse compared to other endings. Their deep disposition in the dermis is consistent with the fact that they have very large receptive fields and no directional sensitivity (Connor, C. E. and Johnson, K. O., 1992). Interestingly, they are invariably in close juxtaposition to arteries (Figure 7(d)), especially arteriovenous shunts suggesting that their vibratory-detecting RA properties may respond to changes in blood flow, which would likely generate different frequencies of vibration in the arterial walls (Tuttle, R. S. and McCleary, M., 1975; Freeman, B. and Rowe, M., 1981). Pacinian corpuscles are also differentially concentrated around joints and the attachments of claws to distal phalanges (Rice, F. L. and Rasmusson, D. D., 2000) (Figure 7(f)). Both locations involve rigid tissues that would vibrate during joint movement or the scrapping of claws against objects.

Although the capsule lamellae were thought to transmit physical vibratory displacements to the sensory ending, recent intricate investigations using interference optics failed to find transmitted displacement even after indentations of the capsule well in excess of physiological relevance (Pawson, L. and Bolanowski, S. J., Jr., 2002; Guclu, B. *et al.*, 2006). This is consistent with the observation that barely detectable vibratory displacements of the skin surface can elicit activity within the Pacinian corpuscles deep in the dermis. However, the integrity of the capsule has been shown to be essential for their vibration-detecting properties, suggesting that the corpuscles are akin to a hydraulic system where incompressible fluid between the lamellae may be the force-transmitting medium, or the capsule lamellae participate in an electro chemical transducing mechanism.

6.01.2.2.4 Ruffini corpuscles

Spindle-shaped Ruffini corpuscles have long been regarded as one of the major types of innervation in the skin and have been thought to account for SA type II fibers responding particularly to stretch of the skin. Although such corpuscles have been definitively identified in the hairy paw skin of cats, both by electron microscopy (Chambers, M. R. *et al.*, 1972) and recent immunochemical techniques (Kumamoto, K. and Ebara, S., personal communication), no definitive Ruffini corpuscles have been demonstrated in recent investigations of the glabrous digital skin of raccoons, monkeys, or humans where SA type II fibers have been detected physiologically (Rice, F. L. and Rasmusson, D. D., 2000; Paré, M. *et al.*, 2002; 2003). As noted earlier, the identified SA type II fibers may actually be innervating diffuse patterns of Merkel cells. These recent studies have demonstrated that the spindle-shaped structures, interpreted as Ruffini corpuscles based on earlier reduced silver studies, are likely well-innervated segments of blood vessels (Figures 5(i) and 5(j)). Blood vessels have been shown to receive not only sympathetic innervation but also at least two types of peptidergic C fibers (Figure 7(e)) and at least one type of Aδ fiber. Conceivably these Aδ fibers may be mechanoreceptors that detect the tension in the blood vessel walls caused by blood pressure. As such, stretch of the skin might also affect the blood vessels and additionally activate these Aδ fiber endings.

6.01.2.2.5 Free nerve endings

Neither Aδ nor C fibers have been shown to terminate as endings with distinct anatomical specializations (Kruger, L. *et al.*, 1981; Mosconi, T. M. *et al.*, 1993; Kruger, L., 1996) nor have their terminations been regarded as being associated with specialized non-neuronal cells. Instead they all appear to terminate as more or less branched, nondescript endings referred to as FNE. Prior to the advent of more recent immunochemical techniques, the Aδ

and C fibers were rarely detected with the best available techniques, which were variants of reduced silver staining. As such, prior to the late 1980s, Aδ and C fibers were primarily thought to terminate diffusely in the dermis, although a few EM studies had detected them at least as far as the epidermal basement membrane but rarely into the epidermis. Thus, the epidermis was long thought to be mostly devoid of innervation. However, later immunochemical studies with antibodies against SP and CGRP revealed many terminals affiliated not only with the dermal blood vessels but also in the epidermis (Figure 8(a)) (Kruger, L., 1988; Kruger, L. *et al.*, 1989). Following the development of antibodies against a cytoplasmic enzyme, protein–gene product 9.5 (PGP9.5), which is especially concentrated in neuronal cytoplasm, far more nerve endings were revealed in the epidermis (Wang, L. *et al.*, 1990; Kennedy, W. R. and Wendelschafer-Crabb, G., 1993; Rice, F. L. *et al.*, 1993; Rice, F. L. and Rasmusson, D. D., 2000; Paré, M. *et al.*, 2007). It has now been well established that Aδ and C fibers terminate as FNE most extensively in the epidermis and in the tunica adventitia of blood vessels. These fibers also terminate in sweat glands and, as mentioned above, at many sites around hair and vibrissa follicles, as well as in Meissner corpuscles (Figures 1 and 2).

Most Aδ and C fibers are thought to mediate high-threshold mechanoreception, thermoreception, chemoreception, and nociception (Burgess, P. R. and Perl, E. R., 1967; Bessou, P. and Perl, E. R., 1969; Bessou, P. *et al.*, 1971; Koerber, H. R. and Mandell, L. M., 1992; Koerber, H. R. and Woodbury, C. J., 2002). At least some of these fibers, especially terminating in proximal hairy skin, are low-threshold mechanoreceptors (Brown, A. G. and Iggo, A., 1967; Koerber, H. R. and Woodbury, C. J., 2002). Aδ fibers are reportedly the source of D-hair low-threshold mechanoreceptors that are exquisitely sensitive to light contact with multiple hairs without a specific orientation (Koltzenburg, M. *et al.*, 1997). Recent evidence also indicates that low-threshold mechanoreceptors may be among C fiber innervation at the neck of hair follicles (Liu, Q., *et al.*, 2007). Thin-fiber low-threshold mechanoreceptors may also be

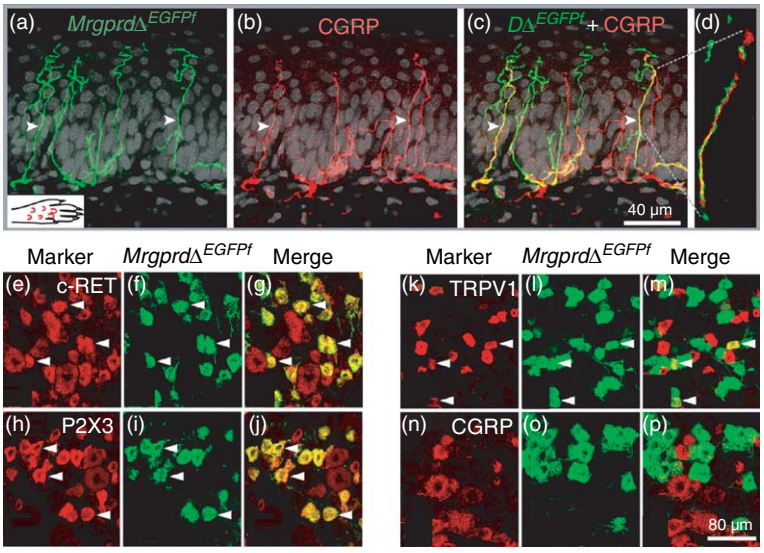

Figure 8 Mrgprd is expressed exclusively in C fibers that terminate in the epidermis and almost entirely lack calcitonin gene-related peptide (CGRP). (a–d) Green fluorescent protein expression driven from the gene locus for Mrgprd reveals that neurons expressing this G protein-coupled receptor (GPCR) supply C-fiber innervation that terminates exclusively in the epidermis and ascends through deep to superficial levels. Double labeling with anti-CGRP reveals that nearly all of the Mrgprd endings lack CGRP. CGRP-positive endings are generally located in the deep half of the epidermis and can be occasionally closely affiliated with a Mrgprd-positive ending (panel d). (e–p) Other immunochemical characteristics of Mrgprd-positive neurons in dorsal root ganglia. Many, but not all Mrgprd neurons express receptors (c-Ret) for the family of glial-derived neurotropic factors and vice versa, as well as P_2X_3. Nearly all Mrgprd neurons are TRPV1 or CGRP negative, are positive but a small proportion are positive. (Reproduced from Zylka, M.J., Rice, F.L., Anderson, D.J. 2005. Topographically distinct epidermal nociceptive circuits revealed by axonal tracers targeted to Mrgprd. Neuron 45, 17–25..

terminating at cutaneous arteries and arteriovenous shunts (Paré, M. *et al.*, 2002; Light, A. R. and Perl, E. R., 2003; Paré, M. *et al.*, 2003).

6.01.2.3 Interspecies Differences in Vibrissa Follicle–Sinus Complexes and Glabrous Fingertip Innervation

6.01.2.3.1 Rat and cat follicle–sinus complex

Although most mammalian quadrupeds have elaborate arrays of orofacial tactile vibrissae that serve the same fundamental purpose, different species use them in different environments that have different requirements (Ebara, S. *et al.*, 2002; Funfschilling, U. *et al.*, 2004; Marshall, C. D. *et al.*, 2006). For example, many species use their vibrissae in terrestrial environments, whereas others use them in aquatic environments. Although the vibrissae and their follicles differ in size, usually in proportion to body size, the basic elaborate structure of vibrissa FSC is similar among most species, including the fundamental types and locations of the innervation. In addition to Merkel and lanceolate endings described above, the FSC also have other unique types of Aβ fiber endings. These include club endings located in the mesenchymal sheath at the attachment of the ringwulst, and reticular and spiny endings located in the mesenchymal sheath at the level of the cavernous sinus. Various hypotheses have been proposed (some discussed above) regarding the function of the specific types of Aβ fiber endings; however, none have been proven (Zucker, E. and Welker, W. I., 1969; Gottschaldt, K. M. *et al.*, 1972; 1973; Lichtenstein, S. H. *et al.*, 1990; Rice, F. L. *et al.*, 1997; Szwed, M. *et al.*, 2003).

Although the basic structure and innervation are mostly the same across species, numerous interspecies differences exist in the proportions and ending branch patterns, indicating that these slight anatomical variations may be uniquely suited for the functional demands of the particular species. For example, in comparing the FSC of rats and cats, only the innervation that terminates as club endings appears to be identical, all of the other innervation terminations are different. Particularly, the ICB is densely innervated in rat FSC and includes a mix of C fiber endings and circumferentially oriented lanceolate endings supplied by Aβ fibers, whereas in the cat, the ICB is sparsely innervated only by C fibers. Merkel-related Aβ fibers at the level of the ring sinus in the rat primarily branch only at their tips to supply a local cluster of Merkel cells, whereas those in the cat branch *en passant* to supply several large contiguous territories of Merkel cells (Figures 3(a′) and 3(b′)). Presumably these differences are due to the fact that rats explore their environment by rapidly whisking their vibrissae to locate static objects (such as grain). In these animals, the ICB is located at the fulcrum where the entire FSC are rapidly rocked back and forth by the action of papillary muscles. The small terminal arbors of the Merkel endings may provide relatively high resolution for object discrimination. In contrast, cats explore their environment by protracting their vibrissae to a relatively fixed position in order to detect moving objects (such as mice). Therefore, they may lack the need for detecting rapid movement of their vibrissae, and their Merkel endings may be designed to detect more dynamic positional properties than object discrimination. As such, rats and cats presumably would have quite different vibrissal tactile perceptions.

6.01.2.3.2 Raccoon glabrous fingertips

Although raccoons have excellent tactile dexterity with their hands, the organization of their glabrous skin and its innervation is quite different than that in monkeys and humans (Figures 2 and 4–6). Instead of having fingerprints, raccoons have small, densely packed epidermal domes that each overlie a cone-shaped dermal papilla. Both raccoons and primates have Merkel innervation at the deepest epidermal locations, i.e., at the base of the epidermal domes in raccoons and at the base of the primary epidermal ridges in primates. Both species also have Pacinian corpuscles deep in the dermis. However, raccoons completely lack Meissner corpuscles. Instead, they have a second type of Merkel configuration where Aβ fibers innervate Merkel cells located in epidermal rete pegs that bulge into the sides of the dermal papillae. Moreover, raccoons also have small corpuscular endings located at the base of the epidermal domes. Although raccoons have Aβ fibers with SA and RA characteristics like those in primates, it is not known whether the unique Merkel endings on the rete pegs have SA characteristics like those typically attributed to Merkel endings in other locations, or if they have RA characteristics like those of Meissner corpuscles. Taken altogether, these examples demonstrate that different species (e.g., cat, rat, raccoon, primate) fulfill their tactile perception needs through slightly different anatomical arrangements of similar structures and innervation.

6.01.3 Molecular Basis of Tactile Sensation

The activation of sensory endings is dependent upon where they terminate, their morphology, and their chemistry. As well, tactile stimulus specificity is dependent upon the mechanisms that generate the sensory ending depolarization. Considerable research has been devoted to determining the molecular mechanisms involved in the transduction of physical stimuli into primary sensory neuron action potentials. For example, in the visual and olfactory senses, many of these transduction mechanisms have been determined, and the molecular mechanisms involved in initiating the generation of cutaneous tactile perceptions (thermal, mechanical, and chemical) are slowly being unraveled. However, particularly for mechanosensory (touch) transduction, the mechanisms are still largely unknown, although they likely involve the direct gating of ion channels (Sukharev, S. and Corey, D. P., 2004). Genetic studies in *Drosophila* and *Caenorhabditis elegans* have led to the identification of mammalian protein families that contribute directly, or indirectly, to the transduction of tactile stimulus energy to primary afferent fibers. Identified signaling protein families implicated in sensory stimuli transduction to primary afferents include the transient receptor potential (TRP) channels, the brain sodium channels/acid-sensing ion channels (BNaC/ASIC), purinergic (P_2Y, P_2X) receptors, and several others (Gillespie, P. G. and Walker, R. G., 2001; Sukharev, S. and Corey, D. P., 2004; Lumpkin, E. A. and Caterina, M. J., 2007).

6.01.3.1 Transient Receptor Potential Superfamily

The TRP ion channel superfamily encompasses a large group of cationic channels with varied structure, physiological regulation, and function that have been implicated in thermal, mechanical, and chemical sensory stimuli transduction (Gillespie, P. G. and Walker, R. G., 2001; Lumpkin, E. A. and Caterina, M. J., 2007). In particular, the TRPV1 (vanilloid family-1) channel has been implicated in thermal (hot; >43 °C) and chemical (e.g., pH, capsaicin) responsiveness, TRPM8 (melastatin-8) in thermal (cold; <25 °C) and chemical (e.g., menthol) responsiveness, and the TRPA1 (ankyrin family-1) has been implicated in thermal (noxious cold), chemical (e.g., wasabi, garlic), and mechanical (hair cells) responsiveness. TRPC1 (canonical-1) has been shown to be a membrane-stretch-activated channel, which is expressed in primary sensory neurons, and could likely mediate mechanical displacement forces impinging upon the neuronal membrane (Gillespie, P. G. and Walker, R. G., 2001; Sukharev, S. and Corey, D. P., 2004; Lin, S. Y. and Corey, D. P., 2005; Hardie, R. C., 2007; Lumpkin, E. A. and Caterina, M. J., 2007).

6.01.3.2 Degenerin/Epithelial Sodium Channel Superfamily

The BNaC/ASICs are members of the degenerin (DEG)/epithelial sodium channel (ENaC) superfamily of identified amiloride-sensitive, nonvoltage-regulated Na^+ channels with specific pore forming and transmembrane spanning region structure (Gillespie, P. G. and Walker, R. G., 2001; Sukharev, S. and Corey, D. P., 2004; Lumpkin, E. A. and Caterina, M. J., 2007). DEGs were identified in the *C. elegans* and were shown to be part of putative mechanosensitive channels in touch-responsive neurons. The structurally related mammalian ENaCs are responsible for sodium and fluid reabsorption across membranes of the kidney, lung, and colon, and have also been found in baroreceptors and somatic touch receptors where they are implicated in mechanosensation (Gillespie, P. G. and Walker, R. G., 2001; Sukharev, S. and Corey, D. P., 2004; Lumpkin, E. A. and Caterina, M. J., 2007). Specifically, the β and γ ENaC subunits, as well as the related protein, stomatin, have all been shown to be expressed within the lanceolate endings of the FSC, and β and γ ENaC subunits have been shown in Merkel and Meissner structures in rat footpad (Drummond, H. A. *et al.*, 2000; Fricke, B. *et al.*, 2000; Price, M. P. *et al.*, 2000; Garcia-Anoveros, J. *et al.*, 2001). By expression cloning, additional vertebrate homologs were discovered and initial screens detected expression primarily in mammalian brain (BNaC). Subsequent investigation demonstrated that BNaCs were sensitive to extracellular proton concentration (pH), opening under acidic conditions, thereby giving rise to the current naming scheme of ASIC (Gillespie, P. G. and Walker, R. G., 2001; Sukharev, S. and Corey, D. P., 2004; Lumpkin, E. A. and Caterina, M. J., 2007). As tissue acidosis is a hallmark of damage, several ASIC have been identified in small-caliber primary sensory neurons, presumptive Aδ and C fiber polymodal nociceptors, as well as Aδ and C fiber

innervation to dermal vasculature (Garcia-Anoveros, J. *et al.*, 2001; Molliver, D. C. *et al.*, 2005) where these channels may function in chemosensation. As well, BNaC1α (ASIC2a) is expressed within large-caliber Aβ-fiber mechanosensitive sensory endings and has been implicated as an essential molecule mediating mechanical stimulus transduction (Price, M. P. *et al.*, 2000; Garcia-Anoveros, J. *et al.*, 2001). Additionally, stomatin, an integral membrane protein shown to have high sequence homology with an adapter protein (MEC-2) identified as an essential part of the *C. elegans* mechanosensitive touch receptor, was shown to be expressed by mammalian sensory neurons (Mannsfeldt, A. G. *et al.*, 1999). Recently, it was demonstrated that null mutation of a stomatin-like protein (SLP3) eliminated mechanoreceptive responses in a substantial proportion of all types of low-threshold mechanoreceptive neurons, but left the remaining proportions functionally intact (Wetzel, C. *et al.*, 2007). This suggests that there may be subsets of functional mechanoreceptors that utilize additional molecular mechanisms. Additionally, SLP3 was shown to directly interact with ASIC2a, ASIC2b, and ASIC3 (Wetzel, C. *et al.*, 2007), further implying that these ion channels and adapter protein may function as part of a mammalian mechanoreceptor.

6.01.3.3 Purinergic Receptors

ATP is recognized as a potent co-neurotransmitter and cell-signaling intermediate, and mediates a myriad of physiological effects through two distinct receptor families (Lazarowski, E. R. *et al.*, 2003; Cockayne, D. A. *et al.*, 2005). The ATP-binding purinergic family of receptors fall into two broad classes: (1) the P_2Y family are G protein-coupled receptors (GPCRs) and generate second-messenger signaling molecules and lipid intermediates to modulate cell physiology and (2) the P_2X receptors are ion channels and directly affect cell physiology. A very wide array of signaling pathways active in the nervous, immune, endocrine, cardiovasculature, gastrointestinal, musculoskeletal, and reproductive systems utilize ATP, related ligands, and the purinergic receptor family to mediate homeostasis and response (Cockayne, D. A. *et al.*, 2005). Mechanosensitive receptive systems (hearing, vestibular sense, and touch) are largely thought to depend upon membrane-bound ion channels that are responsive to membrane deformation from mechanical forces (Sukharev, S. and Corey, D. P., 2004). In the cutaneous sensory system, expression of P_2X_2, P_2X_3, and $P_2X_{2/3}$ receptors has been found in small-caliber primary sensory neurons. These have been shown to be regulators of mechanical hyperalgesia following nerve injury, implying a role in mechanical stimulus transduction, at least following injury (Lazarowski, E. R. *et al.*, 2003; Cockayne, D. A. *et al.*, 2005). Additionally, the P_2Y_1 GPCR has been proposed to mediate mechanotransduction of light, non-noxious touch and has been shown to be expressed in large-caliber primary sensory neurons (Nakamura, F. and Strittmatter, S. M., 1996; Price, M. P. *et al.*, 2000). These results, taken with the ample literature demonstrating varied release of ATP following membrane distortions, implies a direct role of purinergic receptors (ionic and/or metabotropic) in mechanical stimulus transduction to primary afferent sensory neurons.

6.01.3.4 Ca^{2+} Ion Channels

The D-hair mechanosensitive receptor has been described as having the lowest mechanical threshold and the most dynamic sensitivity of all mechanoreceptors. Electrophysiological characterization and immunostaining of hairy skin have determined that these receptors are an Aδ medium-sized fiber, which appear to terminate as circumferentially oriented free endings around body hair follicles. Recently, a T-type Ca^{2+} ion channel, $Ca_v3.2$, was identified as a specific protein lost in $NT4^{-/-}$ mice, which do not develop the D-hair receptors. The precise location of expression and function of this channel, or the related $Ca_v3.3$, in mediating the D-hair response are currently unknown. Importantly though, these data indicate that a calcium-specific ion channel may also play a role in mechanotransduction (Shin, J. B. *et al.*, 2003).

6.01.3.5 Other Molecules

Several additional members of varied protein families are expressed within primary sensory neurons and are known to mediate or modulate important sensory functions, particularly aspects of nociception and the affective component pain. Nociception (the physiological transduction of noxious stimuli) and pain perception (the affective unpleasantness of nociceptive activation) are now known to be modulated by peripherally (as well as

centrally) acting opioids, cannabinoids, and endothelins, among others (Sawynok, J., 2003; Roosterman, D. *et al.*, 2006). For example, specific opioid receptors are found on primary sensory endings, endothelin-1 receptor A (ET-A) receptors are found in peripheral axons, and cannabinoid receptor-1 (CB-1) receptors are expressed in dorsal root ganglion (DRG) neurons (Pomonis, J. D. *et al.*, 2001; Mitrirattanakul, S. *et al.*, 2006; Roosterman, D. *et al.*, 2006). Activation of these receptors by peripherally acting ligands alters nociceptive input and pain perception (Sawynok, J., 2003). Pain is a ubiquitous sensory modality, in that pain can be brought about within each of the anatomically distinct sensory modalities. That is to say, we can detect nociceptive inputs and experience pain perceptions within each of our basic senses: sight, smell, taste, hearing, touching, and some would add even in a conscious sense, as with emotional pain. The potential roles that these pain-associated molecular families play in mediating aspects of tactile sensory transduction are unknown. However, recent evidence suggests that even large-caliber Aβ fibers associated with mechanical stimuli perception express several of these family members (Paré, M. *et al.*, 2001), and clinically, several painful neuropathic and neuropathy conditions are associated with a loss of the small-caliber C fibers, which are traditionally believed to carry nociceptive information (Petersen, K. L. *et al.*, 2002; Albrecht, P. J. *et al.*, 2006; Paré, M. *et al.*, 2007). Therefore, attributing pain, or possibly even nociception and nociceptive pathways, to any one distinct subclass of sensory neuron (i.e., small-caliber Aδ and C fibers) would appear to be a rather limited explanation of how noxious tactile stimuli are transduced and perceived as painful.

6.01.4 Peripheral Mechanisms of Sensory Integration

Rather than simplifying the link between the function and the morphology of specific types of sensory endings, the use of molecular techniques such as immunocytochemistry and null or gain of function mutations has indicated that most, if not all, sensory endings are multimodal and are potentially capable of transducing and integrating different types of stimuli. Indeed, it appears that the molecular mix of expression of various receptor/ligand systems within sensory endings determines the various response properties of that particular ending, and furthermore, the expression mixes are not static, but are likely modifiable in response to various tactile stimuli. Moreover, there is increasing evidence that nonneuronal cells such as Merkel cells, terminal glia, and epidermal keratinocytes may be sensory transducing and integrating structures that actively collaborate with the sensory endings. As well, there is evidence that some sensory endings may be directly interacting with each other in the skin.

6.01.4.1 Multimolecular Properties of Cutaneous Sensory Neurons

6.01.4.1.1 Meissner corpuscle innervation

As was described above, Meissner corpuscles in monkey glabrous fingertip skin are supplied by a mixture of branched and unbranched Aβ fibers and at least two types of C fibers (Figures 2 and 4(d)). Multiple immunolabeling combinations have revealed that these Aβ fibers, implicated as low-threshold RA mechanoreceptors, contain likely not only mechanically responsive ion channels, but also numerous other ion channels, receptors, and transmitters that have been implicated in thermal, chemical, and nociceptive transduction (Paré, M. *et al.*, 2001). These include receptors implicated both in excitatory and inhibitory mechanisms. Not only do these Aβ fiber endings contain CGRP and SP, which have been implicated in inflammatory pain mechanisms, but they also are closely associated with peptidergic C fibers and express receptors for those neuropeptides. The peptidergic C fibers also express a wide array of inhibitory and excitatory ion channels and receptors. These observations suggest that both the Aβ and peptidergic C fibers may respond to, and integrate, several varieties of stimuli, and also that the peptidergic C fibers may directly interact with the Aβ fiber endings. Anatomically, the combination of Aβ and peptidergic C fiber endings is located in segregated strata within the corpuscle, which alternate with segregated stratified terminations of a second type of C fiber that lacks neuropeptides but does express TRPV1. Furthermore, additional molecules implicated in sensory stimulus transduction are present on the terminal glia distributed in the endings. Taken together these observations indicate that Meissner corpuscles are highly complex multimodal sensory transducing and integrating structures whose known mechanoreceptive properties might be modulated by the thermal and chemical environment of skin.

6.01.4.1.2 Dorsal root ganglion neurons

The wide range of molecular properties detected by immunocytochemistry on sensory endings is consistent with the wide range of molecular properties seen in the primary sensory neuronal cell bodies in the ganglia. Although it remains extremely difficult to directly correlate particular neurons to the specific types and terminations of their endings (see Koerber, H. R. and Woodbury, C. J., 2002), numerous studies using immunolabeling of peptides and proteins, as well as assessments of mRNAs, reveal that each neuron expresses multiple channels and receptors indicating that they are all multimodal to varying degrees. This is consistent with the fact that most sensory neurons have long been known to respond to a lesser degree to stimuli other than those electrophysiologically defined as the preferred response and that appropriate combinations of stimuli had not been found to activate many sensory neurons.

Attempts at determining which molecules are consistently expressed together on the same neurons have demonstrated some common combinations. For example, a population of DRG neurons that only give rise to C fibers that terminate in the epidermis was found to specifically express a Mas1-related GPCR (Figure 8) (Zylka, M. J. *et al.*, 2005). These neurons consistently coexpressed a specific purinergic receptor (P_2X_3) and a glutamate receptor (mGluR5), but usually lack CGRP, TRPV1, and opioid receptors. In contrast, neurons that express CGRP typically coexpress SP and opioid receptors but lack purinergic receptors (Ju, G. *et al.*, 1987; Vulchanova, L. *et al.*, 1997; Olson, T. H. *et al.*, 1998; Stone, L. S. *et al.*, 1998; Guo, A. *et al.*, 1999; Koizumi, S. *et al.*, 2004; Zylka, M. J. *et al.*, 2005; Kwan, K. Y. *et al.*, 2006). However, small proportions of neurons have exceptions to these generalities. For instance, as previously noted, all the DRG neurons in mice express stomatin-like proteins implicated in mechanosensory transduction, including smaller-size neurons mostly implicated as the source of C-fiber thermoreceptors or nociceptors (Wetzel, C. *et al.*, 2007).

6.01.4.2 Potential Role of Merkel Cells and Terminal Glia in Sensory Transduction and Integration

Like Meissner corpuscles, the piloneural complexes affiliated with hair follicles may also be functionally multimodal, with the possibility that the circumferentially oriented C fiber endings interact with the Aβ fiber lanceolate endings, which themselves may have multimodal molecular properties (Rice, F. L. *et al.*, 1997; Takahashi-Iwanaga, H. and Habara, Y., 2004; Takahashi-Iwanaga, H., 2005). Importantly, within the piloneural complex, individual terminal glial cells can have processes that contact multiple lanceolate endings, including endings from two different Aβ fibers. As mentioned above, individual Merkel cells located at the mouth of hair follicles also can contact endings from more than one Aβ fiber (Ebara, personal communication). This indicates that these non-neuronal cells may not only be involved in sensory transduction, but also be coordinating activity across multiple low-threshold mechanoreceptive endings.

Electron microscopy of terminal glia and Merkel cells has revealed inclusion bodies and vesicles suggestive of some form of vesicular release (Andres, K. H., 1966b; Patrizi, G. and Munger, B. L., 1966; Iggo, A. and Muir, A. R., 1969; Iggo, A. and Andres, K. H., 1982). Immunochemical analyses are increasingly revealing that many molecules implicated in neural transmission are expressed in these accessory cells. For example, Merkel cells have been shown to express synaptophysin, neuropeptides, calcium regulatory proteins, glutamate, and tyrosine hydroxylase, as well as mechanically responsive ASICs and TRP channels (Fundin, B. T. *et al.*, 1997b; Rice, F. L. *et al.*, 1997; Price, M. P. *et al.*, 2000; Garcia-Anoveros, J. *et al.*, 2001; Tachibana, T. *et al.*, 2001; Ichikawa, H. and Sugimoto, T., 2003; Lucarz, A. and Brand, G., 2007). This indicates that the Merkel cells may likely respond to several types of physical stimuli and potentially release neurotransmitters or neuromodulators that could activate or modify the activity of Merkel endings. Terminal glial cells associated with lanceolate endings have been shown to generate Ca^{2+} signals in response to mechanical stimuli and exposure to ATP. These signals have been shown to propagate among lamellae of other terminal glia that form a network among the lanceolate endings.

6.01.4.3 Sensory Transduction and Integration Among Epidermal Keratinocytes

Although C- and Aδ-fiber FNE are not regarded as having associated non-neuronal cells (unlike Aβ fiber terminals), evidence is quickly accumulating that indicates that the FNE-innervated tissues are intimately involved in sensory processing. The majority of cutaneous FNE terminate within the epidermis or within the dermis associated with sensory structures

(e.g., hair follicles, Meissner corpuscles) or blood vessels. FNE within the epidermis terminate amongst a dense field of keratinocytes, and although direct communication junctions or synaptic contacts have not been observed between keratinocytes and primary sensory neuron endings, ultrastructural studies have shown direct membrane–membrane apposition (Wang, L. *et al.*, 1990). As well, epidermal keratinocytes have been shown to express several neural signaling mediators that can directly impact sensory endings (Khodorova, A. *et al.*, 2003; Ibrahim, M. M. *et al.*, 2005; Lumpkin, E. A. and Caterina, M. J., 2007). However, epidermal keratinocyte expression of neurotransmitter systems (e.g., adrenergic, cholinergic) and other neuromodulators (e.g., neuropeptides, cytokines, and. endocrine mediators) has largely been regarded as pertaining to the functions of the epidermis related to keratinization, barrier homeostasis (wound healing), and immunologic surveillance. More recently though, as current research continues to demonstrate that epidermal keratinocytes express and release an increasingly wide range of neuromediators, the potential functional roles that keratinocytes play in tactile sensory transduction are becoming appreciated.

For example, keratinocytes have been shown to express and to secrete the vasoconstrictive peptide, endothelin-1 (ET-1) (Yohn, J. J. *et al.*, 1993), which can bind to ET-A receptors and generate an algesic (pain-producing) response (Gokin, A. P. *et al.*, 2001; Zhou, Q. L. *et al.*, 2001). Presumably, these effects are mediated through direct receptor activation on Aδ or C fiber afferents, which have been shown to express the ET-A receptor (Pomonis, J. D. *et al.*, 2001). Keratinocytes within the deepest layer of live epidermis (stratum basalis) also express the ET-A receptor, but the function of this receptor on keratinocytes has largely been attributed to keratinocyte mitosis. However, ET-1 activation of a second ET-1 receptor, endothelin-1 receptor B (ET-B), can generate an analgesic (pain-alleviating) effect. The analgesic mechanism mediated via ET-B does not occur by direct stimulation of primary afferents, as the expression of ET-B is not found in DRG neurons. Instead, ET-B receptors are expressed among the upper live stratum of epidermal keratinocytes (Figure 9(b)), and continued investigation revealed that upon ET-B activation these keratinocytes released the endogenous opioid β-endorphin (Khodorova, A. *et al.*, 2003). Peptidergic epidermal FNE express opioid receptors and an associated inhibitory G-protein-coupled, inwardly rectifying potassium channel (GIRK2). Thus, an analgesic mechanism was established whereby stimulation of ET-B receptors on keratinocytes leads to the release of β-endorphin, which acts upon the peptidergic FNEs to inhibit the generation of action potentials via the opening of GIRK2 channels, thereby producing analgesia.

Since a mechanism involved in sensory stimuli integration and transduction is implicated for the ET-B receptor, it seems plausible that a role of the ET-A receptor in keratinocytes is also somehow involved with sensory transduction (in addition to mitosis). Likewise, the cannabinoid receptor-2 (CB-2) has been identified in the upper live stratum of epidermal keratinocytes, and specific agonists of the CB-2 receptor also activate the keratinocyte-derived β-endorphin-mediated analgesic mechanism (Ibrahim, M. M. *et al.*, 2005) (Figure 9(a)). Together, these examples of epidermal-derived mechanisms demonstrate the ability of keratinocytes to modulate sensory transduction. Additionally, there is ample indirect evidence to further substantiate a role of epidermal keratinocytes in sensory stimulus transduction and integration.

As noted above, nonpeptidergic endings in the epidermis have been shown to express purinergic receptors, and keratinocytes also express several purinergic receptors. These keratinocytes have been shown to express and release ATP after various stimulations, which further indicates that a direct signaling role from keratinocytes to primary sensory neurons likely exists, as well as a keratinocyte autocrine/paracrine signaling loop. For example, keratinocytes are known to respond to contact with specific amine-containing chemical irritants or direct mechanical stimulation via the release of ATP (Mizumoto, N. *et al.*, 2003; Koizumi, S. *et al.*, 2004). Thus, keratinocyte-mediated ATP release may facilitate the activation of FNE via P_2X receptors.

Epidermal keratinocytes have been shown to express TRPV1, TRPV3, and TRPV4 receptors each of which is known to respond to preferential ranges of physiologically relevant thermal stimuli (Peier, A. M. *et al.*, 2002; Chung, M. K. *et al.*, 2004). The TRPV1 receptor responds to noxious heat and is also expressed on FNE. The TRPV3 and TRPV4 receptors respond to non-noxious warmth and are more difficult to detect in sensory neurons. Furthermore, although dissociated sensory neurons can be activated directly by hot and cold thermal challenges, responses to warm temperatures are observed only when skin and nerve connectivity are

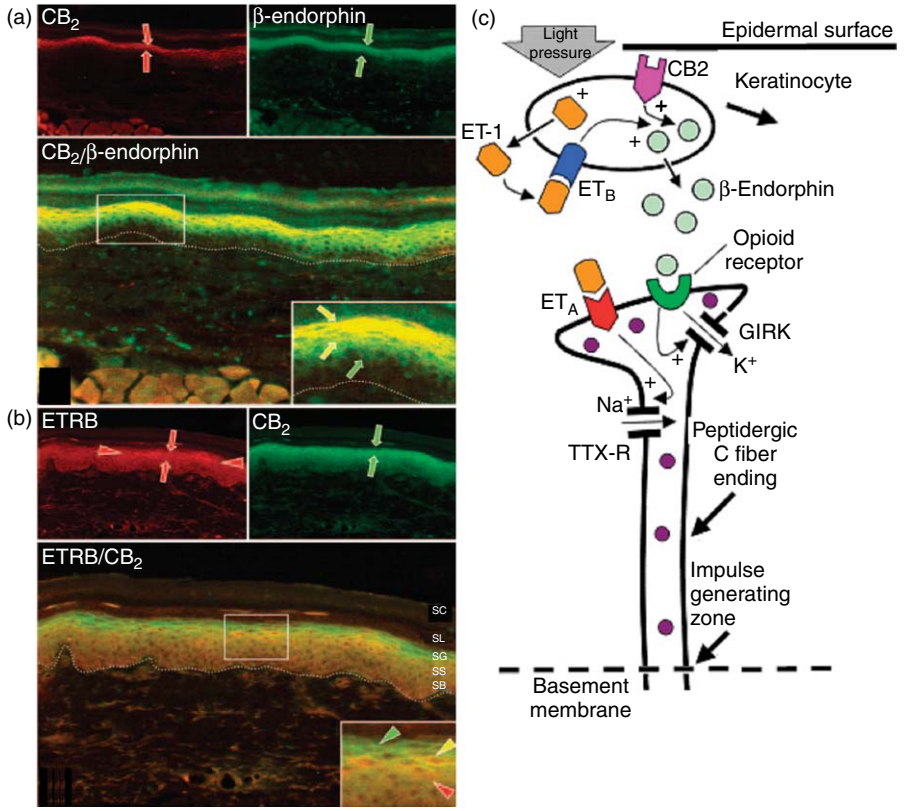

Figure 9 The keratinocytes of the epidermis can exert an analgesic effect. (a,b) Double-labeled immunofluorescence reveals that the upper stratum of keratinocytes coexpresses the endothelin receptor B (ETB) and CB2 receptors along with β-endorphin. (c) As shown schematically, ETB and CB2 activation results in an analgesic effect by releasing β-endorphin, which in turn inhibits peptidergic epidermal endings by binding to μ-opioid receptors that open GIRK2 channels.

maintained (Peier, A. M. *et al.*, 2002). Therefore, the ability to detect warmth as a tactile perception most likely involves a keratinocyte-mediated mechanism. Furthermore, expression of ENaC subunits has been demonstrated in epidermal keratinocytes (Roudier-Pujol, C. *et al.*, 1996). These sodium channels were first identified based upon their structural similarity to known mechanosensitive proteins from other species (described above), and although not directly demonstrated as yet, also imply that keratinocytes have an ability to directly respond to mechanical stimuli. How the responses of keratinocytes to these various tactile stimuli impact sensory transduction and integration is still unknown.

Interestingly, the distribution of various ligands and receptors within the epidermal keratinocytes is differentially stratified. Likewise, peptidergic endings have been shown to terminate preferentially in the deeper portion of the epidermis whereas non-peptidergic endings have been shown to terminate closer to the upper live strata (Zylka, M. J. *et al.*, 2005). Taken together, these recent discoveries strongly implicate the epidermis as a sensory transducing and integrating structure involving both excitatory and inhibitory mechanisms that in turn regulate the activity of the cutaneous sensory innervation (Figure 9(c)).

6.01.5 Summary

Skin, and particularly specialized sensory receptive structures such as vibrissa follicles and glabrous fingertips, has the capacity to rapidly detect a wide variety and range of tactile stimuli, including thermal, mechanical, and chemical. The sensitivity of these receptive functions is virtually inconceivable, and the generation of tactile perceptions is generally taken for granted. Despite over a century of research, the mechanisms responsible for these exquisite sensory capabilities are still largely unproven. Skin receives abundant primary afferent (sensory)

innervation. Cutaneous nerve anatomical and electrophysiological studies have detected a wide variety of ending types, distributions, and functions, and have determined that sensory endings are specialized to extract certain physical properties from complex cutaneous stimuli. After extracting these properties through discreet types of sensory neurons, these parallel inputs are hypothesized to recombine within the CNS circuitry to form the complex patterns of neuronal activity, which are interpreted as tactile perception. However, even the earliest electrophysiological studies recognized that among the discreet neuron populations, there were a range of sensory stimuli combinations and permutations, such that attempts to classify particular types of endings were somewhat arbitrary. It was also recognized that the preferred or optimal stimulus was based on the limitations of experimentally testable stimuli and that many sensory neurons had other less optimal stimulus response properties and still others had no detectable response.

More recent studies are demonstrating that the organization and function of cutaneous innervation has a far greater variety than was previously detected and that considerable sensory integration may be taking place within the skin and sensory endings, before inputs converge within the CNS. It is now appreciated that:

1. All sensory neurons have complex chemical properties consisting of multiple receptors and ion channels that can collectively respond to different types of physical stimulus properties. The sensory neuron properties can involve both inhibition and excitation of the sensory ending. As such, these receptors and ion channels could be regarded as the combination of synaptic inputs on typical neurons. Thus, the activation of a sensory ending under natural conditions would be due to the spatial and temporal summation of inputs from a variety of combinations.
2. Endings of a particular type (e.g., Merkel endings) may have different terminal branch patterns in the skin, which could result in different varieties of response patterns to a comparable stimulus.
3. Several varieties of sensory endings arising from Aβ, Aδ, and/or C fibers can be organized into complex ensembles such as Meissner corpuscles or piloneural complexes. These endings may function in concert with each other or interact with each other to provide an integrated output. Moreover, a single ensemble may be supplied by Aβ fibers that innervate only that ensemble and other Aβ fibers that innervate multiple ensembles.
4. Sensory transduction may be a combination of direct action of a stimulus on a sensory fiber ending and/or by indirect action mediated through accessory cells such as Merkel cells, terminal glia, or epidermal keratinocytes. The accessory cells may regulate the response property of the associated sensory ending or coordinate activity across multiple endings, and furthermore, the accessory cells, especially epidermal keratinocytes, may be primary sensory stimuli transducing and integrating structures. Peripheral mechanisms of complex sensory transduction and integration would provide an even greater variety of input to the CNS on which to construct particularly detailed tactile perceptions.

CK Cytokeratin.

6.02.1 Localization and Ultrastructure of Merkel Nerve Endings

Merkel cells are usually associated with nerve endings located in the skin and some parts of the mucosa in all vertebrates. They function as mechanoreceptors and are found in mammalian epidermis as well as the epithelium of ectoderm-derived mucosa (Merkel, F., 1875; Iggo, A. and Muir, A. R., 1969; Halata, Z. *et al.*, 2003). However, in birds they are located in the superficial layer of the dermis (Saxod, R., 1978). Occasionally, dermal Merkel cells are also found in mammals especially in man (Mahrle, G. and Orfanos, C. E., 1974).

Light microscopically, Merkel cells can be best seen using their characteristic immunohistochemical staining for cytokeratins CK8, CK18, and CK20 (Moll, R. *et al.*, 1984; 1995). In addition, Merkel cells show immunoreactivity to neuron-specific enolase, chromogranin, vasoactive intestinal polypeptide, met-enkephalin, serotonin, substance P, calcitonin gene-related peptide (CGRP), somatostatin, calcitonin protein gene product 9.5, and bombesin (Hartschuh, W. *et al.*, 1979; Hartschuh, W. and Weihe, E., 1988; Cheng Chew, S. B. and Leung, P. Y., 1991; English, K. B. *et al.*, 1992).

Electron microscopically, Merkel cells (Figure 1) can be identified by their characteristic disk-shape, large lobulated nuclei and close contact with nerve terminals. Merkel cells bear spike-like protrusions that interdigitate with the surrounding keratinocytes and are attached by desmosomes. The cytoplasm contains

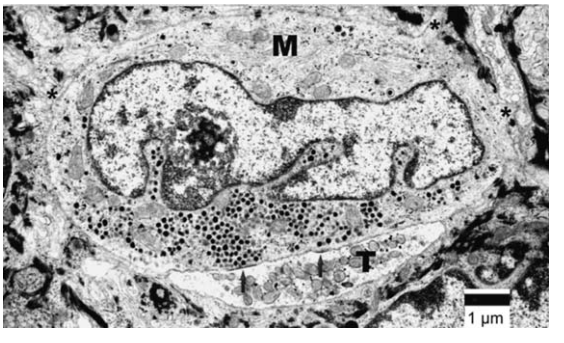

Figure 1 Ultrathin section from the planum nasale of a domestic cat. The typical Merkel nerve ending consists of a Merkel cell (M) with characteristic finger-like protrusions (*) and a discoid nerve terminal (T) containing a large number of mitochondria. Synapse-like contacts between Merkel cells and nerve terminal are marked by arrows. The cytoplasm of the Merkel cell facing the nerve terminal is packed with dense-core granules.

intermediate cytokeratin filaments and many large (50–110 nm) dense-core granules, particularly accumulated near the junction with the nerve fiber (Iggo, A. and Muir, A. R., 1969). The cytoplasmic membrane forms areas of synaptic membrane specialization with the membrane of an axonal terminal (Iggo, A. and Findlater, G. S., 1984). The nerve terminal is packed with mitochondria and optically clear vesicles.

6.02.2 Merkel Nerve Endings in Mammalian Glabrous Skin

Merkel cells in the mammalian glabrous skin are always in the basal layer of the epidermis (Figures 1 and 2). Pegged skin has solid epidermal pegs of different size anchoring the epidermis in the dermis containing blood sinus separating the epithelial pegs. Typical examples are the pig snout and planum nasale of mole and cat. Clusters of up to 40 Merkel cells are found in the basal layer of the epidermis at the base of these pegs. All Merkel cells are in synaptic contact with discoid terminals of branches of one myelinated axon (3–5 µm), losing the myelin sheath on entering the epidermis. In ridged skin (typically found in the tips of fingers and toes of primates and marsupials) clusters of up to 10 Merkel nerve endings are found at the base of the epidermal ridges near the ducts of sweat glands (Halata, Z., 1975).

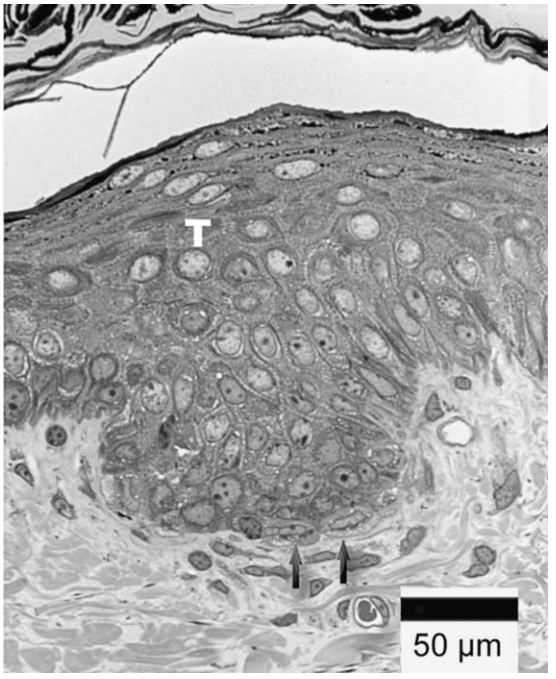

Figure 2 Semithin section of a touch dome (T) from the eyelid of a rhesus monkey. Merkel cells in the basal layer of the rete peg are marked by arrows.

6.02.3 Merkel Nerve Endings in Mammalian Hairy Skin

In hair follicles of velus hairs and guard hairs, Merkel nerve endings are found at the thickening of the follicle – the so-called bulge region – below the sebaccous gland. This part of the hair follicle does not change its form during the hair cycle and the bulge region is also a stem cell niche of the epidermis (Oshima, H. *et al.*, 2001).

Between hair follicles of the hairy skin, the epidermis forms epithelial pegs of different size and density, often referred to as touch dome (Haarscheibe; Figure 2). These are basically similar to the epithelial pegs in glabrous skin (see above), containing up to 150 Merkel nerve endings (Figure 3) supplied by one trunk nerve fiber.

6.02.4 Merkel Nerve Endings in Sinus Hairs of Mammals

Specialized large hairs (vibrissae, whiskers, or sinus hairs) are found in all mammals apart from man, arranged in groups especially in the face and

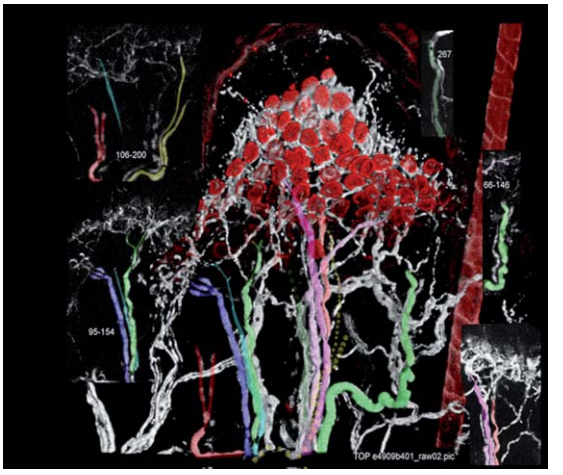

Figure 3 Touch dome from the interdigital skin of the cat paw reconstructed from confocal microscopic images. The trunk nerve fiber branches below the level of this figure into several preterminal nerve fibers (marked in different colors) before branching further into terminal nerve fibers, each making contact with 5–10 Merkel cells. In this touch dome a total of 137 Merkel cells (red) were counted. Figure kindly provided by Dr. Satomi Ebara, Kyoto, Japan.

innervated by the trigeminal nerve. They are large hair follicles embedded in blood sinus with strong sturdy hairs. Fibers of mimic muscles are inserted into the capsule of the blood sinus. The hair follicles are richly innervated with free nerve endings and a variety of different mechanoreceptors especially Merkel nerve endings. Sinus hairs of land mammals contain up to 2000 Merkel cells (Gottschaldt, K.-M. *et al.*, 1973; Ebara, S. *et al.*, 2002) while marine mammals can have up to 20 000 Merkel cells in one follicle (Dehnhardt, G. *et al.*, 2003). They have large cortical representations in somatotopically organized barrels (Woolsey, T. A. and van der Loos, H., 1970).

Merkel cells are located in the basal layer of the epithelium of the hair follicle in the thickened part below the sebaceous gland arranged like scales in a pine cone, oblique to the basal lamina (glassy membrane) sending cytoplasmic processes of about 3 µm through the glassy membrane. This area is surrounded by the ring sinus. All Merkel cells are in contact with discoid nerve terminals on the opposite side (Figure 4). The part of Merkel cells facing nerve terminals contains the typical dense-core (osmiophilic) granules. The myelinated axons (diameter about 5 µm) lose their myelin sheath and Schwann cells on penetrating the basal lamina, branching intensively supplying up to 50 Merkel cells (Ebara, S. *et al.*, 2002). Other Merkel nerve endings are found in the epidermis close to the penetration of the hair shaft in the rete pegs of the epidermis similar to the description above.

Figure 4 Ultrathin longitudinal section through the thickened portion below the sebaceous gland of a sinus hair from the upper lip of a rhesus monkey. Merkel cells (M) and nerve terminals (T) are arranged obliquely to the glassy membrane (*) like scales of a pine cone. The Merkel cell is always facing the glassy membrane. A lanceolate nerve terminal (L) in close contact with the glassy membrane is seen on the outer side.

6.02.5 Merkel Nerve Endings in the Mucosa of Mammals

In mucosa derived from the ectoderm (mouth, lips, and anal canal), Merkel cells can be found in many mammalian species. In the mouth, the so-called surrounding mucosa is not cornified and covers the surface of lips, cheeks, and the soft palate forming epithelial pegs containing numerous Merkel nerve endings at their base. Masticatory mucosa with cornified epithelium covering the hard palate and forming the surface of the gingiva has to withstand heavy mechanical loads during chewing of food. The basal layer of the epithelium forms rete ridges or rete pegs containing many Merkel nerve endings in the basal layer with identical structure as found in glabrous skin (Figure 5; Halata, Z. and Baumann, K. I., 1999). In contrast, the specialized mucosa covering the surface of the tongue with typically structured papillae and gustatory organs is free of Merkel nerve endings.

In the mucosa of the anal canal, Merkel nerve endings can be found in nonkeratinized and keratinized parts. In the nonkeratinized part, the epithelium is a flat stratified epithelium with rete pegs. In basal

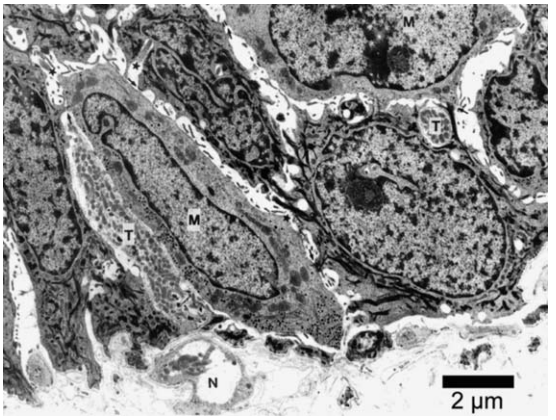

Figure 5 Ultrathin cross section through the papilla incisive of a rhesus monkey. Merkel cells (M) with cytoplasmic protrusions (*) and desmosomal contacts (arrows) with epithelial cells of the basal epithelial layer. Nerve terminals (T) from the afferent axon (N) covered by a Schwann cell.

parts of rete pegs typical Merkel nerve endings are present. Also the keratinized part shows rete pegs with numerous Merkel nerve endings (Rettig, T. and Halata, Z., 1990).

6.02.6 Merkel-Like Cells with Suggested Neuroendocrine Function

Structurally, Merkel cells resemble cells of the diffuse endocrine system found mainly in the epithelium of the gut and bronchial mucosa. Various substances were found in the osmiophilic granules of Merkel cells (see above), resulting in the classification of Merkel cells as part of the family of the amine precursor uptake and decarboxylation (APUD) system (Pearse, A. G. E., 1968; Fujita, T., 1977). These cells are believed to release neurotransmitters with paracrine function. Also in those areas where Merkel cells are usually found, pale oval cells with dense-core granules are occasionally found in the basal layer of the epidermis or mucosa of ectodermal origin. But these cells lack any contact with nerve terminals. In contrast to normal Merkel cells, these cells have oval nuclei with many nuclear pores. So far there is no evidence for exocytosis of substances from Merkel cells to support the assumption of a paracrine (Fujita, T., 1977) or neuroendocrine role (Boot, P. M. *et al.*, 1992), leaving the question about the functional role of those substances in the dense-core granules of Merkel cells widely open.

6.02.7 Merkel Cell Carcinoma

In a highly malignant type of skin tumor, cells were found with osmiophilic granules and positive immunohistochemical reaction with neuron-specific enolase (Tang, C. K. and Toker, C., 1978; Johannessen, J. V. and Gould, V. E., 1980). It is widely assumed that these tumors originate from Merkel cells, giving rise to the name Merkel cell carcinoma. However, direct evidence for this assumption is still lacking (Gould, V. E. *et al.*, 1985; Moll, R. *et al.*, 1992). Another assumption is that this tumor may originate from dermal neuroendocrine cells (Hoefler, H. *et al.*, 1985).

6.02.8 Developmental Origin of Merkel Cells

There has been a long controversy about the developmental lineage of Merkel cells. One view is that Merkel cells arise from a common ectodermal stem cell (English, K. B., 1974; Moll, I. *et al.*, 1986). This hypothesis is mainly supported by the finding of low molecular cytokeratin (CK8, CK18, and CK20) in Merkel cells of mammals (Moll, R. *et al.*, 1984; Moll, I. *et al.*, 1995; Kim, D. K. and Holbrook, K. A., 1995). In contrast, several studies suggested that they originate from the neural crest and migrate into the mammalian epidermis during the embryonic period (Hashimoto, K., 1972; Breathnach, A. S., 1978). Using the chick/quail marking system, it was shown that avian Merkel cells do not develop from ectodermal or mesodermal cells, but that they originate from the neural crest (Grim, M. and Halata, Z., 2000). In mammals, Szeder V. *et al.* (2003) examined Wnt1-cre/R26R double transgenic mice in which Merkel cells like all neural crest-derived cells are marked by the reporter gene LacZ. Thus, there is now unambiguous evidence for a neural crest origin of avian and mammalian Merkel cells.

6.02.9 Mechanoreceptor Function of Merkel Cells

Merkel's original description of touch corpuscles clearly described these complexes as mechanoreceptors (Merkel, F., 1875). They respond to punctate pressure on the skin (Iggo, A. and Muir, A. R., 1969) or bending of whiskers with long-lasting spike trains

(Gottschaldt, K.-M. *et al*., 1973). In all locations, the Merkel cells are positioned between the direction of the physiological mechanical stimulus and the nerve terminal. The surface of Merkel cells is equipped with protoplasmic protrusions anchoring between keratinocytes (Halata, Z. *et al*., 2003), which has led to comparisons with inner ear hair cells (Iggo, A. and Findlater, G. S., 1984; Baumann, K. I. *et al*., 1990) where bending of the hairs opens mechanically gated ion channels resulting in depolarization, increase of free intracellular calcium, and transmitter release (Crawford, A. C. *et al*., 1991).

There have been long controversies, whether the mechanoelectric transduction process occurs in the Merkel cell or whether the Merkel cell only directs the mechanical stimulus toward the nerve terminal. Unfortunately, the location of these receptors makes direct electrophysiological recordings with microelectrodes impossible. The slowly adapting responses of these receptors and the characteristic impulse pattern of action potentials with rather irregular interspike intervals were interpreted as an indication of a synaptic link (Iggo, A. and Muir, A. R., 1969; Horch, K. W. *et al*., 1974).

Various potential neurotransmitters were found in the dense-core granules of Merkel cells (Hartschuh, W. *et al*., 1979; Hartschuh, W. and Weihe, E., 1988; Cheng Chew, S. B. and Leung, P. Y., 1991; English, K. B. *et al*., 1992). However, attempts to impair transmission with the respective receptor blockers failed to show clear effects on receptor responses (Gottschaldt, K.-M. and Vahle-Hinz, C., 1982). Using calcium indicator dyes, increases of intracellular calcium concentration in Merkel cells during mechanical stimulation have been observed consistently in different species and locations (Chan, E. *et al*., 1996; Tazaki, M. and Suzuki, T., 1998). In spite of mechanical stimulation, no such increases are seen if the extracellular fluid is calcium free or amiloride (known to block mechanosensitive ion channels; Hamill, O. P. *et al*., 1992) is added to the solution (Halata, Z. *et al*., 2003). Further studies revealed the existence of voltage-gated calcium channels and presynaptic proteins in Merkel cells (Yamashita, Y. *et al*., 1992; Chan, E. *et al*., 1996; Haeberle, H. *et al*., 2004). Thus, mechanical stimulation causes an influx of calcium into Merkel cells, which in turn appears to trigger further release of calcium from intracellular stores (Calcium-induced calcium release; Senok, S. S. and Baumann, K. I., 1997). It has long been established that increase in free calcium is a requirement for synaptic transmitter release.

Recent experimental evidence suggests that glutamatergic transmission occurs at Merkel cell receptors although the specific type of glutamate receptor involved is still unclear (Fagan, B. M. and Cahusac, P. M. B., 2001; Hitchcock, I. S. *et al*., 2004; Haeberle, H. *et al*., 2004; Cahusac, P. M. B. *et al*., 2005). This synaptic transmission is probably essential for the slowly adapting responses during maintained mechanical stimuli (Ogawa, H., 1996; Senok, S. S. and Baumann, K. I., 1997).

6.03.1 Introduction

The human body is covered by skin which, together with the special senses, forms our interface with the environment. Most of the body is covered by hairy skin but the palms of the hands and the soles of the feet are covered by glabrous skin, which does not have hairs. Sensation from both types of skin is mediated by a large number of specialized sensory receptors. These fall into three major categories, namely thermoreceptors, nociceptors, and mechanoreceptors. Thermoreceptors in the hand inform us of the temperature or thermal properties of objects we handle (a cold windowpane or a bath of warm water) whereas thermoreceptors in hairy skin play a crucial role in temperature regulation. Nociceptors alert us to stimuli that cause, or potentially cause, tissue damage and are critical to our survival. Thermoreceptors and nociceptors are covered in separate chapters of this encyclopedia.

Cutaneous mechanoreceptors, which respond to low-threshold or non-noxious mechanical stimuli, provide us with information about our environment; the complexity, richness, and importance of this information in our daily lives is often underestimated. In hairy skin, the sensory functions of whisker systems in navigation for animals like rodents and seals have long been appreciated. More recently, the role of hairy skin receptors in affective aspects of touch has been revealed.

The significance of glabrous skin to humans is far greater than suggested by the fact that it forms only a small proportion of human skin. This is because glabrous skin, which covers the front surface of the hand, is engaged in the myriad manipulations that are central to human existence. There are countless examples of hand function ranging from common everyday tasks, such as lifting a glass of water, shelling a pea, or peeling an orange, to complex contemporary tasks such as performing a liver transplant or driving a car. Such tasks are dependent on information from the cutaneous mechanoreceptors.

In this chapter we will first discuss, in some detail, neural signals from the glabrous skin of the hand.

Only primates have hands and therefore much of the data related to glabrous cutaneous mechanoreceptors were gathered in humans or monkeys. We will then discuss, more briefly, neural signals from hairy skin. Data on primate hairy skin mechanoreceptors is not extensive and much of our knowledge of these receptor properties stems from work done in other animals that have hairy skin, particularly for the complex signals in the whisker system, which is covered elsewhere.

6.03.2 Glabrous Skin

6.03.2.1 Receptors

Human glabrous skin (Figure 1) contains four classes of mechanoreceptors which vary in their structural complexity and in their location in the skin (Halata, Z., 1975). Meissner corpuscles and Pacinian corpuscles are mechanically complex, comprising repeating layers of fluid bounded by connective tissue or nerve terminals, resulting in a mechanical filter interposed between the stimulus and the mechanosensitive nerve terminals. Ruffini endings and Merkel complexes are simpler in that the mechanosensitive nerve terminals are not surrounded by a laminated filter. Meissner corpuscles in the uppermost part of the dermis and Merkel complexes at the epidermal–dermal junction are relatively close to the surface of the skin. Ruffini endings located in the mid part of the dermis and Pacinian corpuscles locate deep in the dermis, or subcutaneously, are further from the surface than Merkel or Ruffini endings.

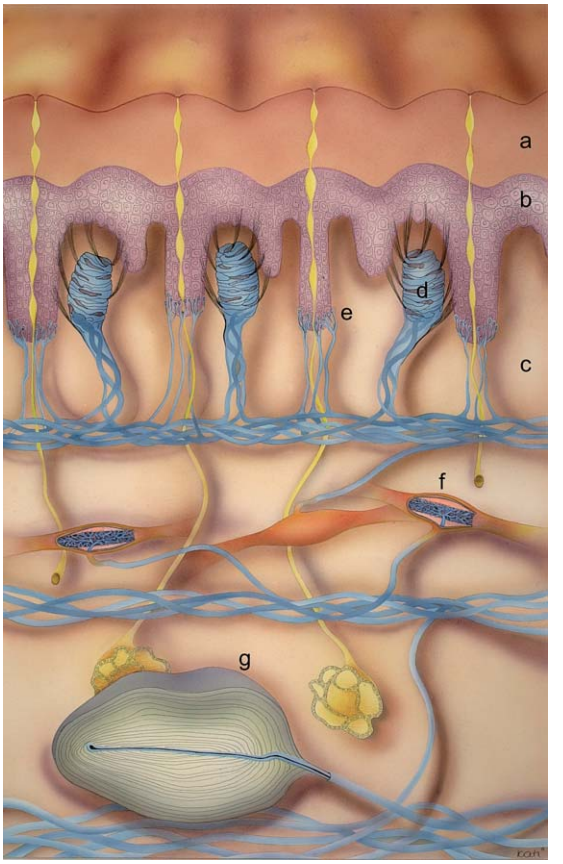

Figure 1 A cross-section through glabrous skin. Fingerprint patterns reflect the wavelike structure of the dermis (c), the epidermis (b), and the covering keratin (a). Peripheral nerve fibers, shown in blue, innervate four types of mechanoreceptors: the Meissner corpuscles (d), the Merkel endings (e), the Ruffini organs (f), and the Pacinian corpuscles (g). Reproduced with permission from Ian Darian-Smith.

6.03.2.2 Classification of Innervating Fibers

The mechanoreceptors are innervated by large myelinated axons belonging to the Aβ group. They range in diameter from 7–14 μm and have conduction velocities in the range of 15–60 m s^{-1} (Vallbo, A. B. and Johansson, R. S., 1984; Brink, E. E. and Mackel, R. G., 1993). These primary afferent axons, which are part of the sensory component of peripheral nerves, have cell bodies in the dorsal root ganglia; their proximal terminals enter the spinal cord via the dorsal roots. The anatomical relationship between primary afferent axons and mechanoreceptors differs for different receptors. For axons terminating on Merkel complexes, a single axon typically innervates several Merkel complexes (Pare, M. *et al.*, 2002). Similarly, many Meissner corpuscles may be innervated by the same axon, and a single Meissner corpuscle may be innervated by more than one axon (Quilliam, T. A., 1978). This contrasts with Pacinian corpuscles, each of which is supplied by a single unbranched axon (Quilliam, T. A., 1978). Ruffini ending have been studied mainly in hairy skin or structures like the joints, where the evidence is that each ending is innervated by a single axon and a single axon may innervate a number of endings (Iggo, A. and Andres, K. H., 1982).

Primary afferent fibers innervating glabrous skin fall into four classes which are easily defined by the afferents' responses to indenting probes. Rigorous classification requires machine-controlled probes but even simple hand-held probes allow unambiguous classification (Vallbo, A. B. and Johansson, R. S., 1984).

For two of the classes, afferents respond when the probe is pressing into or lifting out of the skin, the dynamic component, and also when indentation of the probe is maintained without change, the static component. These are termed slowly adapting (SA) afferents. For one class of SA afferents the receptive fields are spatially confined; there is a central small area, of the order of square millimeters, where thresholds are low, surrounded by an area where thresholds rise rapidly (Figure 2). These are termed SA type I (SAI) afferents. For the second group, the SA type II (SAII) afferents, thresholds rise more slowly with distance from the receptive field center so that the receptive fields are less confined and larger than those of SAI afferents. An additional property of SAII afferents is that they respond well to lateral stretch of the skin, for example when two points of skin on either side of the receptive field are pulled away from each other.

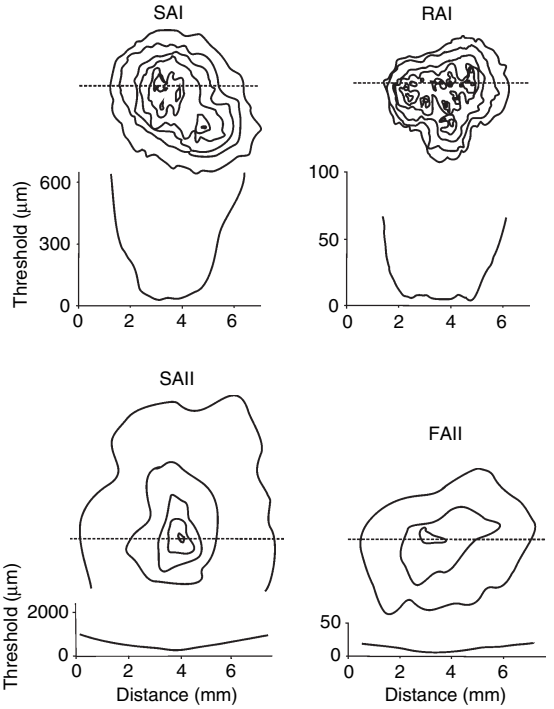

Figure 2 Receptive field structure for the four classes of mechanoreceptive afferents innervating glabrous skin. For each class, the lower figure shows threshold as a function of distance along a line through the receptive field center. The upper figures are contour plots showing thresholds along both dimensions of the receptive field. SA, slowly adapting; FA, rapidly adapting (adapted from Johansson, R. S. 1976. Receptive field sensitivity profile of mechanosensitive units innervating the glabrous skin of the human hand. Brain Res. 104, 330–334).

Fibers in the remaining two classes respond only to the dynamic component of probe indentation and are referred to as fast adapting (FA) afferents. Again, one class has relatively small and confined receptive fields whereas the other has larger more diffuse receptive fields. These are termed FA type I (FAI) and FA type II (FAII) afferents, respectively.

There is evidence, both direct and indirect, that SAI and FAI afferents terminate on the more superficial Merkel complexes and Meissner corpuscles, respectively, while SAII and FAII afferents innervate the deeper Ruffini endings and Pacinian corpuscles, respectively (Vallbo, A. B. and Johansson, R. S., 1984).

Monkey glabrous skin is similar in structure to human glabrous skin. It contains Merkel endings, Meissner corpuscles, and Pacinian corpuscles and the properties of monkey SAI, FAI, and FAII afferents are similar to those in humans. A major difference is that monkey glabrous skin does not appear to contain Ruffini endings and no SAII afferents have been reported (Pare, M. *et al.*, 2002).

Innervation density is not uniform over the hand (Johansson, R. S. and Vallbo, A. B., 1979). For SAI and FAI afferents, the density increases in a distal direction reaching a peak in the fingertips of about 0.7 and 1.4 afferents mm^{-2}, respectively. The proximal–distal gradient is less pronounced for SAII and FAII afferents which have lower densities than the type I afferents (0.09 and 0.22 mm^{-2}, respectively).

6.03.2.3 Afferent Responses to Ramps and Vibration

By using a machine to control the indentation of a probe, it is possible to specify either the force of indentation or the displacement of the probe. In addition, the temporal waveform of the indentation can be varied.

Trapezoids are a commonly used temporal waveform because they allow independent variation of the static component of indentation (the height of the trapezoid) and the dynamic component (the slope of the trapezoid) corresponding to the velocity of indentation. SAI afferents, which respond principally to the depth of indentation, have a range of threshold amplitudes (depths); the least sensitive fibers have thresholds about 10 times those of the most sensitive fibers (Knibestol, M., 1975). FAI afferent responses depend on both the depth and the velocity of indentation; depth threshold varies from 0.05 to 1.65 mm and velocity thresholds range from 0.4 to 39.3 mm s^{-1} (Knibestol, M., 1973). Response

thresholds for FAII afferents also depend on both the depth and velocity of indentation (Knibestol, M., 1973).

An effective way of studying FAI and FAII responses is to use sinusoidally vibrating probes, which clearly show the difference in their adaptation characteristics (Talbot, W. H. *et al.*, 1968). FAI afferents respond best (have minimum thresholds) for vibratory frequencies around 30 Hz. In contrast, thresholds of FAII afferents are minimum at frequencies around 300 Hz. The layered structure of Meissner and Pacinian corpuscles forms a mechanical filter which accounts, at least in part, for the dynamic characteristics of the FA afferent responses. There may also be a component of adaptation in the neural transduction process (French, A. S., 1992).

6.03.2.4 Activation of Cutaneous Afferents during Manipulation

Responses of the primary afferents to simple, but precisely controlled, indenting probes have provided invaluable information about the fundamental nature of the transduction process (Leung, Y. Y. *et al.*, 2005). However, such experiments do not provide a ready appreciation of the rich and complex information signaled to the central nervous system by those afferents when we manipulate the range of objects encountered daily.

Any form of manipulation requires motor output and it results in sensory input from a range of sources including cutaneous mechanoreceptors. There are various degrees of sensorimotor interaction depending on the nature of the task. In some tasks the sensory component dominates. For example, when determining the roughness of a piece of sandpaper, the purpose is to extract sensory information and the relatively simple role of the motor system is to engage the cutaneous mechanoreceptors with the surface being explored. Most manipulations are of a more complex nature. As an example, when picking an apple, the precise hand movements required rely on sensory information about parameters such as the size and shape of the apple. During such a task, the sensory input is used in two ways. First, in conscious perception; we are aware of factors such as the texture of the apple and its degree of slipperiness. Second, the sensory information is used by the motor control system either in a feedback manner, to optimize the hand movements, or to update memory, which can be used in a feedforward manner for similar tasks in the future. (Witney, A. G. *et al.*, 2004)

In general, input to the brain is multisensory. In the case of picking an apple, visual and proprioceptive information is obviously involved. What is easily overlooked is the importance of the cutaneous mechanoreceptors in such tasks. There are many pointers to their crucial role. For many finely controlled hand movements, such as doing up a button in the dark, visual input is absent and we rely entirely on cutaneous mechanoreceptive input and proprioception. Also, it is well established that blocking the cutaneous afferents with local anesthetic severely compromises complex manipulations or makes them impossible (Monzee, J. *et al.*, 2003).

What parameters of the object being manipulated, or of the manipulation itself, are potentially signaled to the central nervous system by the cutaneous mechanoreceptors? Candidates include: the local shape of the object, the position of contact on the skin, the texture of the surface, the contact force (which is three-dimensional and includes forces normal to the skin and forces tangential to the skin), the compliance or softness of the object, the coefficient of friction, and slip during the manipulation.

In order to characterize the information relayed by the cutaneous afferents during manipulation, it is necessary to use stimuli that are more complex than simple indenting probes. Stimuli that can be directly related to naturally occurring stimuli are particularly informative.

6.03.2.5 Spatial Resolution of Single Afferents

Single indenting probes provide limited information on the spatial resolving capacity of the four classes of cutaneous mechanoreceptive afferents. A more direct measure of spatial resolution can be obtained by stepping square-edged gratings of alternating grooves and ridges across the receptive fields of primary afferent fibers. The resulting afferent responses are modulated by the position of the stimulus in the receptive field (Phillips, J. R. and Johnson, K. O., 1981). Gap width is the principal determinant of response and modulation decreases as the spatial period of the grating decreases (Figure 3). Measured in this way, acuity is greatest for SAI afferents, which can resolve gap widths of around 1 mm. Acuity for FAI afferents is considerably less.

Measuring resolution with an indenting grating, with no lateral movement, is appropriate in the context of hand movements where there is no lateral motion between the skin and the surface, such as

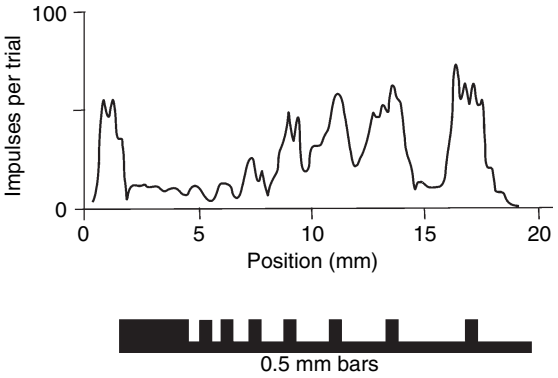

Figure 3 Responses of a single slowly adapting type I (SAI) afferent to a grating indenting the skin. The grating, with an incrementing spatial period (lower figure), was stepped across the receptive field between indentations. Upper curve shows response as a function of the position of the grating in the receptive field (adapted from Phillips, J. R. and Johnson, K. O. 1981. Tactile spatial resolution. II. Neural representation of bars, edges, and gratings in monkey primary afferents. J. Neurophysiol. 46, 1192–1203).

grasping an object with a rough surface. For manipulations where there is lateral motion, a more suitable stimulus comprises patterned surfaces scanned over the receptive field. There have been many such studies with a range of patterned surfaces including gratings of alternating grooves and ridges, raised dots analogous to Braille, and embossed letters (Goodwin, A. W. and Morley, J. W., 1987; Phillips, J. R. *et al.*, 1990; Blake, D. T. *et al.*, 1997; Yoshioka, T. *et al.*, 2001). Such stimuli are considerably more complex than an indenting stimulus and comprise both spatial and temporal components. All four afferent types respond in some way to patterned surfaces scanned across the skin. FAI and SAI afferents both respond vigorously (Figure 4), and the variation in response of single afferents is correlated with the perceived roughness of the surfaces. This relationship is more consistent for the SAI than the FAI afferents.

6.03.2.6 Interpreting Resolution of Single Afferents

Is the spatial resolution of a single afferent a meaningful concept? Consider the task of touching a grating of alternating grooves and ridges using a single vertical contact without lateral motion of the finger. Clearly information about the spatial properties of the grating is contained in the combined activity of the entire array of cutaneous afferents activated. Thus, any analysis of the spatial properties of a stimulus relayed by the mechanoreceptors necessitates a population analysis, even if only of an implicit nature. Figure 3 depicts the responses of a single SAI afferent when the grating shown is stepped across the afferent's receptive field. The direct way of interpreting this curve is as a receptive field profile, which shows the responses of a single fiber to a stimulus applied at increasing distances from the receptive field center. But the curve can also be

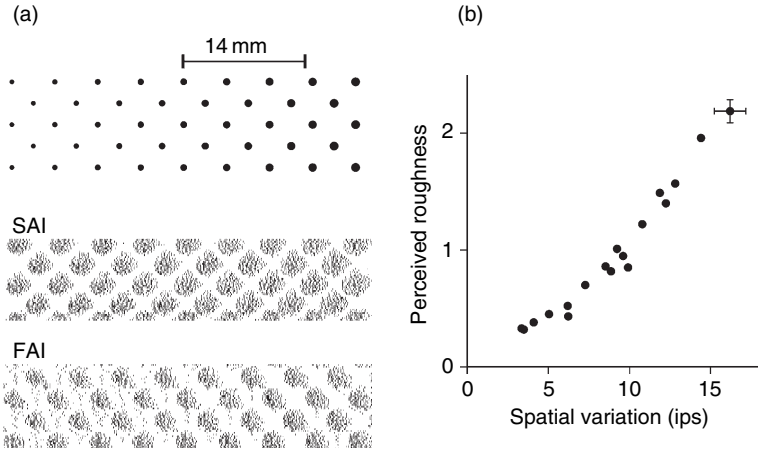

Figure 4 Responses to a pattern of dots, with incrementing spatial period, swept across the fingerpad. (a) Impulse patterns in a single fast adapting type I (FAI) afferent (bottom) and a single slow adapting type I (SAI) afferent (middle) are isomorphic with the dot pattern in the stimulus (top). (b) Human perception of roughness correlates with a measure, spatial variation, extracted from the SAI impulse patterns (adapted from Blake, D. T., Hsiao, S. S., and Johnson, K. O. 1997. Neural coding mechanisms in tactile pattern recognition: the relative contributions of slowly and rapidly adapting mechanoreceptors to perceived roughness. J. Neurosci. 17, 7480–7489).

viewed as the profile of responses across a population of afferents with receptive field centers located at increasing distances from center of the stimulus contact point. This interpretation of the data is necessary for any postulates about the nature of spatial information relayed to the brain. As will be discussed in a later section, there are many inherent simplifying assumptions in such an interpretation that are not valid.

A similar argument applies to interpreting responses to surfaces scanned across the skin. A common approach has been to generate spatial event plots, such as those illustrated in Figure 4 where the pattern of dots was swept across the receptive field of a single SAI afferent and a single FAI afferent. For each successive sweep, the stimulus is shifted, at right angles to the direction of scanning motion, by a small amount so that eventually the entire pattern is scanned over the receptive field center. The two-dimensional spatial event plots show the occurrence of action potentials in a single afferent. Each plot can by interpreted directly as the response of a single afferent to the stimulus located in a variety of different positions in its receptive field. But this is not as useful as the alternative view that the plot shows the responses of a two-dimensional population of afferents transmitting the spatial pattern of the surface to the brain. Again the simplifying assumptions about the population are potentially problematic.

6.03.2.7 Responses to the Shape of an Object

When stepping square-edged stimuli across the receptive fields of SAI afferents, it was observed that responses were more vigorous when an edge was located at the receptive field center than when a flat part of the object was located there (left part of Figure 3). The enhanced edge response suggests that the cutaneous afferents have the capacity to transmit information about the local shape of handled objects. This has been studied directly in experiments in which objects with defined and controlled local shapes were indented into or scanned across the skin.

A number of simple shapes have been used effectively to characterize tactile sensation. The local shape of an object (the shape at a particular point on the object) can be described by two orthogonal curvatures at that point. A sphere is perhaps the simplest shape; the curvature is the same in both orthogonal directions and is the same all over the object. Thus, a sphere can be described by a single parameter; either its radius or, more conveniently, its curvature, which is the reciprocal of the radius. A toroidal surface is defined by two orthogonal curvatures which are different, but each is constant over the entire surface. A cylinder is a special case of a toroid in which the curvature in one direction is zero (infinite radius) and the curvature in the orthogonal direction is nonzero and constant. Because such surfaces are simple to characterize mathematically and are easily manufactured, they have been used extensively to examine cutaneous mechanoreceptor responses.

Figure 5(a) shows the responses of a single SAI afferent when spheres of different curvature were indented into a monkey's fingerpad, contacting the afferent's receptive field center (Goodwin, A. W. *et al.*, 1995). The monotonic relationship confirms that SAI afferents are signaling information about the local shape of the object. Little information about shape was evident in the responses of FAI afferents. Similar results were obtained with sinusoidally shaped surfaces (Srinivasan, M. A. and LaMotte, R. H., 1987) and toroids (Khalsa, P. S. *et al.*, 1998).

For an indenting object, the nature of the contact is equivalent to that occurring when an object is grasped. To simulate the type of contact that occurs when an object is actively explored by the hand, which results in tangential motion between the skin and the object, simple surfaces such as toroids were scanned across the afferent's receptive field (LaMotte, R. H. *et al.*, 1998). Here too it is clear that SAI afferents are responsive to the shape of the object while FAI afferent responses are less shape sensitive.

Experiments in humans, using indenting spheres, show that with contact forces comparable in magnitude to those used in everyday manipulations, afferents innervating glabrous skin all over the distal segment of the finger are activated (Jenmalm, P. *et al.*, 2003). Responses of SAI, FAI, and SAII afferents are influenced by the curvature of the stimulus.

6.03.2.8 Responses to Contact Force

When grasping and manipulating an object, the cutaneous mechanoreceptors are activated by the contact forces exerted on the skin. Commonly, experimenters resolve the forces into two components and deal with them separately. The first component, the grip force, is normal to the skin surface. The second component, the load force, is tangential to the skin surface and may be at any angle in the tangential

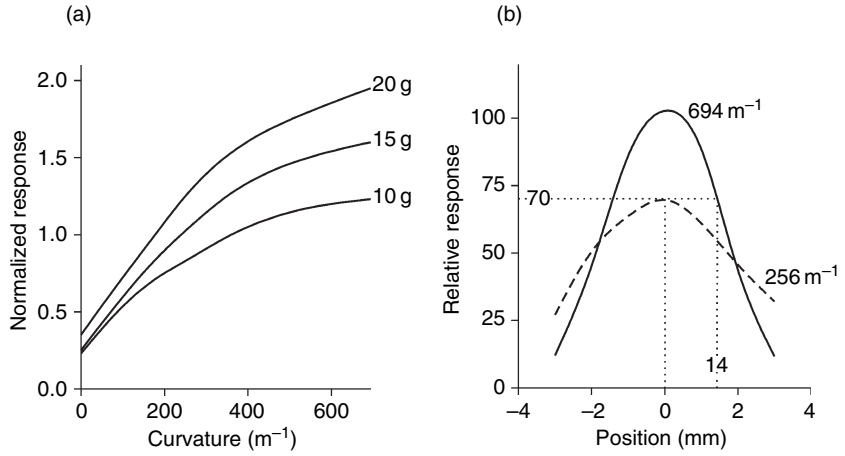

Figure 5 Responses of a single slow adapting type I (SAI) afferent to spheres indented in the receptive field. (a) Response increased with increasing curvature of the sphere and increased when contact force increased from 10 to 15 to 20 g. (b) Response as a function of position in the receptive field for a sphere of curvature 694 m^{-1} compared with that for a sphere of curvature 256 m^{-1}. Dotted lines demonstrate the ambiguity of a response of 70 imp s^{-1} (adapted from Goodwin, A. W., Browning, A. S., and Wheat, H. E. 1995. Representation of curved surfaces in responses of mechanoreceptive afferent fibers innervating the monkey's fingerpad. J. Neurosci. 15, 798–810).

plane. It has been known for some time that increasing the depth of indentation of a punctuate probe, which increases the force normal to the skin, results in an increase in responses of SAI and FAI afferents (Vega-Bermudez, F. and Johnson, K. O., 1999). The effect of controlled normal force on a single SAI afferent's responses is illustrated in Figure 5(a).

There are few studies of afferent responses to tangential or load forces. In the human it has been shown that responses of SAI, FAI, and SAII afferents are modulated by the direction of the tangential force (Birznieks, I. *et al.*, 2001). The alternative, and equivalent, interpretation is that all three afferent types are modulated by the three-dimensional force vectors.

6.03.2.9 Position in the Receptive Field

Machine-controlled punctuate probes lend themselves to field studies in which afferent responses can be measured when the probe is presented at a range of different positions in the receptive field. For the SAI illustrated in Figure 5(b), the solid line shows the receptive field mapped using a probe with a spherical tip of curvature 694 m^{-1} (radius 1.4 mm). There is a single point of maximum sensitivity, when the probe is located at the receptive field center, and responses decrease progressively as the probe is located further and further from the center. A similar profile holds for FAI afferents (Wheat, H. E. *et al.*, 1995). For SAII and FAII afferents, the receptive field profiles show a more gradual decrease in response with distance (Figure 2). Using finer probes (0.4 mm diameter) the receptive fields of SAI and FAI afferents show multiple points of high sensitivity within the central plateau region (Figure 2), suggesting that multiple mechanoreceptors converge on the single primary afferent fiber, which is consistent with their structure described above.

A crucial point is that the receptive field is not uniform, but rather is characterized by a profile of varying sensitivity or responsiveness. Moreover, the profile is stimulus dependent. When the receptive field of the SAI afferent in Figure 5(b) is mapped (broken line) with a more gently curved sphere of curvature 256 m^{-1} (radius 3.9 mm), the receptive field profile changes and is lower in amplitude and broader in width than the profile mapped with the more curved sphere.

For stimuli that are scanned across the skin, the equivalent to the receptive field map is the spatial event plot.

6.03.2.10 Signaling Must Be Viewed in Terms of Population Responses

Responses of single primary afferent fibers change when any one of several stimulus parameters change. Thus, it is not possible to determine the details of the stimulus from the response of a single afferent. For example, in Figure 5(b), the SAI afferent response of 70 imp s^{-1} could result from either a sphere of

curvature 256 m^{-1} located at position 0, or a sphere of curvature 694 m^{-1} located at position 1.4 mm (or even −1.4 mm). Such ambiguities are resolved in the responses of populations of neurons, which have the capacity to relay, with precision, multiple parameters of the stimulus.

Consider the simple task of grasping a sphere with the fingertips (comparable to grasping an apple). Psychophysics experiments have shown that the cutaneous mechanoreceptors in the fingertips convey to the brain high resolution and independent information about the shape or curvature of the sphere, the contact or grip force used, and the position of the contact on the skin (Goodwin, A. W. *et al.*, 1991; Wheat, H. E. *et al.*, 1995; Wheat, H. E. *et al.*, 2004). Humans can make accurate judgments about each of these parameters and the feedback is important for motor control.

Ideally, characterizing the population response requires that activity in each of the afferents of the population are recorded simultaneously, but technical limitations preclude this currently. A compromise approach is to synthesize an approximation to the population response as follows.

In Figure 5(b) a sphere of curvature 694 m^{-1} was indented into the receptive field of an SAI afferent at locations along a line through the receptive field center. This curve shows the effect of one parameter of the stimulus, the position of contact, on the response of the fiber. As explained above, this curve can be interpreted as an ideal one-dimensional population response. By indenting the probe at points over the two-dimensional receptive field, the two-dimensional receptive field profile, or ideal population response, can be obtained as shown in Figure 6(a). This shows the responses of a two-dimensional population of fibers with the sphere contacting the skin at a position arbitrarily defined as $x = 0$ and $y = 0$. If the position of contact on the skin changes, then the whole population response shifts a corresponding amount as illustrated in Figure 6(c) for a shift of 1 mm.

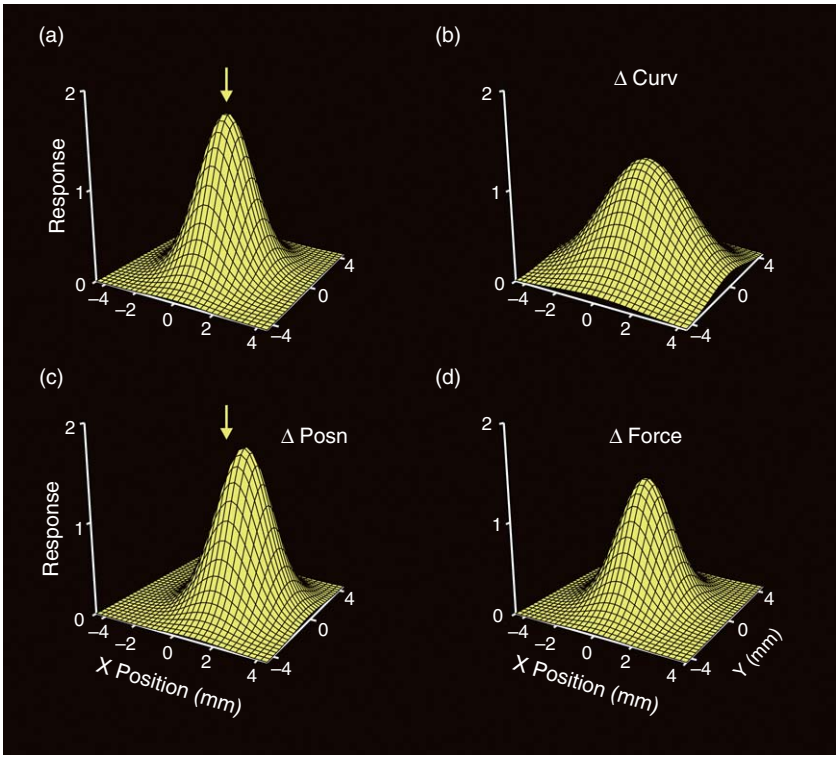

Figure 6 Ideal population responses for slowly adapting type I (SAI) afferents responding to spheres indented in the receptive field. (a) A sphere with curvature 694 m^{-1} indented at position $x = 0$, $y = 0$ on the skin. (b) Effect of changing the stimulus shape to a curvature of 256 m^{-1}. (c) Shifting the stimulus by 1 mm results in the population response shifting by 1 mm (compare responses to fixed arrows). (d) A reduction in contact force scales the entire response correspondingly. Compare responses in (b), (c), and (d) with response in (a) (adapted from Goodwin, A. W. and Wheat, H. E. 1999. Effects of nonuniform fiber sensitivity, innervation geometry, and noise on information relayed by a population of slowly adapting type I primary afferents from the fingerpad. J. Neurosci. 19, 8057–8070).

How do changes in a second stimulus parameter, the curvature of the sphere, affect the SAI afferent responses? The one-dimensional receptive field profile of the single SAI afferent for a less curved sphere, curvature 256 m^{-1}, is shown in Figure 5(b) and the two-dimensional profile for this sphere is shown in Figure 6(b). For the less curved sphere, the profile is reduced in height and is broader.

A third stimulus parameter is the contact force or grip force. For a sphere of any particular curvature, applied at any particular point in the receptive field, the response of a single SAI afferent increases with an increase in contact force (Figure 5(a)). In terms of the idealized population response in Figure 6(a), decreasing contact force decreases the response at all points as shown in Figure 6(d).

From inspection of the population response in Figure 6 it is evident how all three parameters of the stimulus are represented. The shape or curvature of the sphere is represented in the shape of the population response profile, the contact position is represented by the spatial location of the profile, and the contact force affects the overall scaling of the response. It is also apparent that the value of all three parameters can be extracted, without ambiguity, from the single population response.

In a similar way, the orientation of a cylinder indented into the skin can be seen in the ideal SAI population responses, constructed from two-dimensional receptive field profiles, depicted in Figure 7(a).

An analogous approach has been used for shaped objects scanned across the receptive field. With this mode of stimulation the relative motion between the skin and the object is equivalent to that when humans move their hands over objects during exploration or manipulation. The equivalent of the

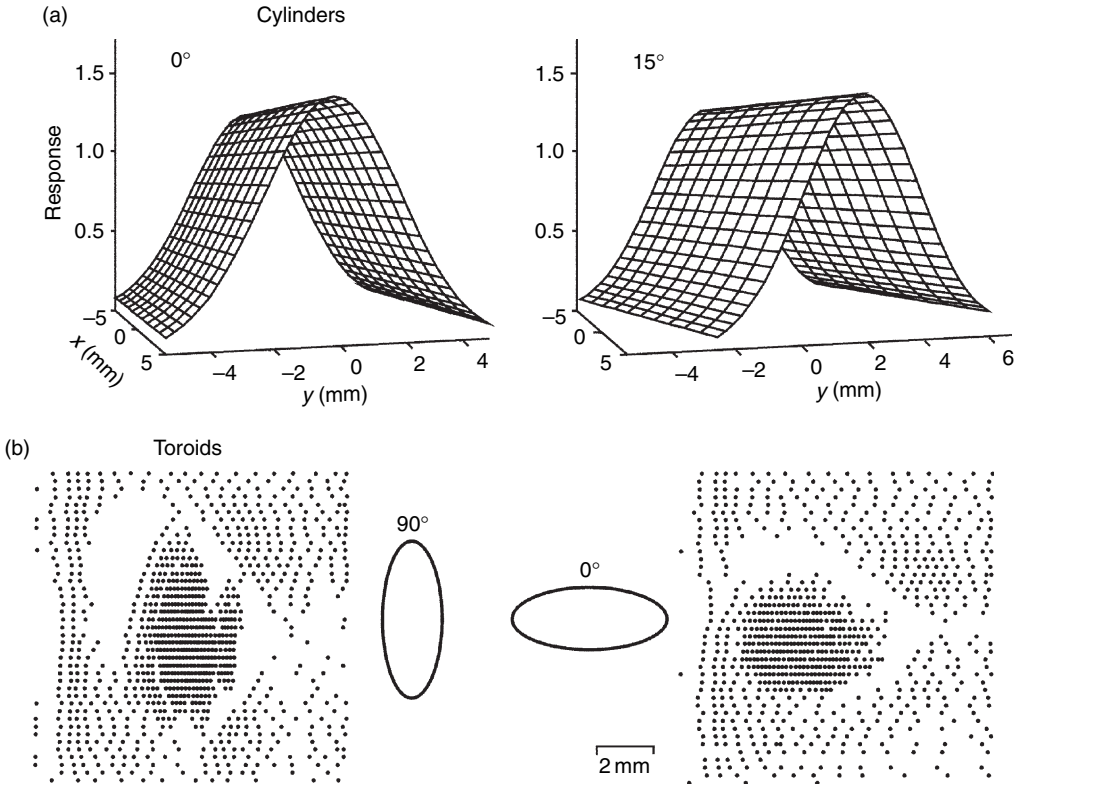

Figure 7 Ideal population responses of slowly adapting type I (SAI) afferents in a monkey's fingerpad. (a) Two-dimensional receptive field profiles reveal the orientation of a cylinder indented into the fingerpad. The cylinder, with a curvature of 172 m^{-1}, was oriented at 0° or 15°. Modified from Dodson M. J., Goodwin A. W., Browning A. S., and Gehring H. M. 1998. Peripheral neural mechanisms determining the orientation of cylinders grasped by the digits. J. Neurosci. 18, 521–530. (b) Spatial event plots show the orientation of a toroid scanned over the fingerpad. The 1 × 5 mm toroid was oriented at 90° or 0° (redrawn from LaMotte, R. H., Friedman, R. M., Lu, C., Khalsa, P. S., and Srinivasan, M. A. 1998. Raised object on a planar surface stroked across the fingerpad: responses of cutaneous mechanoreceptors to shape and orientation. J. Neurophysiol. 80, 2446–2466).

two-dimensional receptive field profile for indenting objects is the two-dimensional spatial event plot for scanned objects, which can also be viewed as an ideal population response. Shaped objects used have included spheres, toroids, and sinusoidal steps (LaMotte, R. H. and Srinivasan, M. A., 1987; LaMotte, R. H. *et al.*, 1998; Friedman, R. M. *et al.*, 2002). In Figure 7(b) the orientation of scanned toroids is reflected in the orientation of the spatial event plots.

6.03.2.11 More Realistic Population Responses

Real population responses are affected by a number of factors that are not apparent in the ideal reconstructions illustrated above. These factors have a significant impact, particularly when quantifying stimulus representation and resolution.

The ideal reconstructions are based on the implicit assumption that all afferents in the population have the same stimulus-response characteristics and, in particular, all have the same sensitivity or responsiveness. However, it is known that this is not the case; for example, the responsiveness of SAI afferent sensitivities vary over a 10-fold range (Knibestol, M., 1975; Goodwin, A. W. *et al.*, 1995). Variation in sensitivity results in distortion of the ideal profiles as illustrated in Figure 8. The broken line shows the ideal population response to a sphere of curvature 256 m^{-1}. Two more realistic population responses, where the constituent afferents have varying sensitivities, are shown by the solid lines; the sensitivities have a distribution matching the experimentally measured distribution. The profiles for the two more realistic populations differ from the ideal profile and differ from each other. In the case of stimuli scanned across the skin, there would be an equivalent distortion of the spatial event plots and the isomorphism between the plots and the stimulus apparent in Figure 4 would be reduced.

The second inherent assumption in most representations of ideal population responses is infinite innervation density, which is obviously not the case. For example, the profiles and dot plots in Figure 7 are sampled by a grid of a finite number of afferents. Estimates of the SAI and FAI afferent densities at the fingertip are 0.7 and 1.4 afferents mm^{-2}, which corresponds to a spacing between afferent receptive field centers of 1.2 and 0.85 mm, respectively (Johansson, R. S. and Vallbo, A. B., 1979; Darian-Smith, I. and Kenins, P., 1980).

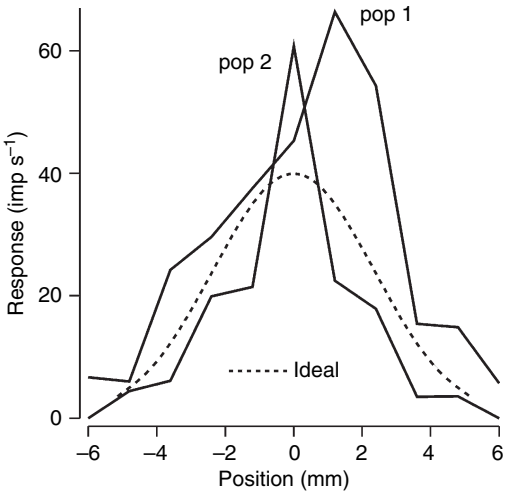

Figure 8 Variation in sensitivity distorts the slowly adapting type I (SAI) afferent population response to a sphere contacting the skin. Broken line shows an ideal population, where all afferents have the same sensitivity. Solid lines show two more realistic and different populations, where afferent sensitivities vary (redrawn from Goodwin, A. W. and Wheat, H. E. 1999. Effects of nonuniform fiber sensitivity, innervation geometry, and noise on information relayed by a population of slowly adapting type I primary afferents from the fingerpad. J. Neurosci. 19, 8057–8070).

Considering the spatial scale of the population response (of the order of millimeters to tens of millimeters) the consequences of receptive field spacing of this magnitude cannot be ignored. There are three additional complicating factors pertaining to innervation density. First, the estimates are derived from a single study in humans, backed up by a single study in monkeys, and are based on a number of assumptions and thus may be imprecise. Second, the pattern of innervation is not known and it may not be uniform. Third, during aging, and as a result of common diseases such as peripheral neuropathies, some primary afferents degenerate and this reduces the sampling density, perhaps unevenly. In Figure 9, estimates are shown for the effect of afferent density or receptive field spacing on the resolution of position in a population of SAI afferents.

A third assumption in ideal population reconstructions is that the neurons are free from noise. It is assumed that if the same stimulus is applied several times, then any particular neuron will respond identically each time. In fact, all neurons have some degree of variability or noise. In general, the

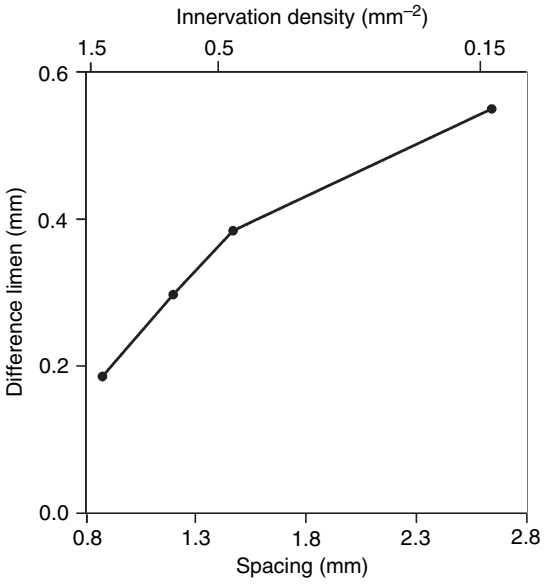

Figure 9 Decreasing innervation density results in decreasing resolution of position in the slowly adapting type I (SAI) population response, indicated by an increase in the difference limen for position. As density decreases, the spacing between receptive field centers increases (adapted from Goodwin, A. W. and Wheat, H. E. 1999. Effects of nonuniform fiber sensitivity, innervation geometry, and noise on information relayed by a population of slowly adapting type I primary afferents from the fingerpad. J. Neurosci. 19, 8057–8070).

primary afferents themselves have only a low level of noise (Jenmalm, P. *et al.*, 2003), but the central neurons processing the population responses have considerable noise (Lee, D. *et al.*, 1998). Such noise distorts the population responses. Multiple applications of the same stimulus will result in a range of different population responses; equivalently, there will be some uncertainty in the population response expected from a particular stimulus. In terms of human perception, this is one of the factors leading to the well-documented variability in discrimination (Galanter, E., 1984).

To redress the considerable limitations of ideal population responses, it is necessary to reconstruct more realistic population responses (Goodwin, A. W. and Wheat, H. E., 2004). Such reconstruction must take into account the inherent characteristics of the population including: varying sensitivity, pattern and density of innervation, and neural noise. A variety of mathematical and statistical approaches have been used. Computer simulations are relatively simple and particularly effective for exploring how the various population parameters affect the population response.

6.03.2.12 Measures of Stimulus Parameters

It may be possible to see how the various stimulus parameters are represented if the population responses are essentially isomorphic with the stimulus as in Figure 7 but, as explained above, in real populations the isomorphism is distorted. Even for isomorphic representations, any further quantitative analysis requires that some measure of the stimulus parameter is extracted from the population response. For example, any rigorous comparison with human behavior, or any tests of hypotheses about neural coding mechanisms, require quantitative measures of stimulus representations, including their resolution.

From Figure 6 it is evident that when the position of an object in contact with the skin shifts, there is a corresponding shift in the population response. But can this lead to a quantitative measure of object position, and how precise is such a measure given the distortions produced by the population parameters? To answer such questions it is necessary to hypothesize potential neural measures of the stimulus parameters. For example, one hypothesis for a measure of the position of contact of the stimulus on the skin is the centroid of the population response. Note in Figure 8 that the location of the peak of the population response is not a robust measure because it is highly susceptible to error from sensitivity variation, noise, and sampling. In contrast, the impact of these factors on the centroid are minimized by averaging.

By comparing proposed parameter representations with measured human behavior it is possible to reject hypotheses that result in a mismatch (Blake, D. T. *et al.*, 1997; Friedman, R. M. *et al.*, 2002). As an illustration, the correspondence between human roughness perception and a measure of roughness representation in the SAI afferents, spatial variation, is shown in Figure 4(b). The same correspondence does not hold for the FAI population.

When measures of stimulus representation are extracted from ideal populations, whether derived from receptive field profiles for contacting stimuli or spatial event plots for scanned stimuli, they do not take into account the significant differences in real populations. For this, simulations of more

realistic population responses are needed (Goodwin, A. W. and Wheat, H. E., 1999).

6.03.2.13 Complex Geometry of the Fingers

Glabrous skin is not a flat sheet. Moreover, the stresses and strains in skin are dependent on the characteristics of the underlying tissues, including bone. Consider the fingertips, which are the parts of the hand most commonly engaged in precise manipulations (Christel, M., 1993). The curvature of the fingertip varies, being relatively flat on the fingerpad and being highly curved on the distal and lateral parts. Bone, forming the distal phalanx, is incompressible and the subcutaneous tissues between the bone and the skin are nonuniform. Also, the skin is more mobile on the pad than it is close to tethering points such as the interphalangeal joints or creases. Finally, when comparing behavior or afferent responses in humans and monkeys, the difference in scale (Figure 10) must be considered.

There are two ways in which the geometry of the hand or fingers affects the responses of the cutaneous mechanoreceptors. At the simpler level, the nonuniform mechanics may result in quantitative differences in stimulus–response characteristics of identical mechanoreceptors located at different parts of the finger or hand, even when the stimulus is applied to the receptive field center in all cases. Less obviously, the curved fingers mean that during manipulation a large number of mechanoreceptors remote from the stimulus are active and convey information to the brain about the stimulus parameters. If grasping an object results in contact at the central part of the fingerpad, it is obvious that mechanoreceptors in the vicinity of the contact region on the fingerpad will be active. What is not so obvious, but true, is that mechanoreceptors all over the fingertip, including the curved lateral and distal portions may be active (Bisley, J. W. *et al.*, 2000). One approach to capture this wide-spread activity is to reconstruct the population response by applying the stimulus to a single common point on the fingertip while recording, in a number of experiments, from afferents innervating all parts of the fingertip (Khalsa, P. S. *et al.*, 1998; Birznieks, I. *et al.*, 2001). There are advantages and disadvantages to this approach.

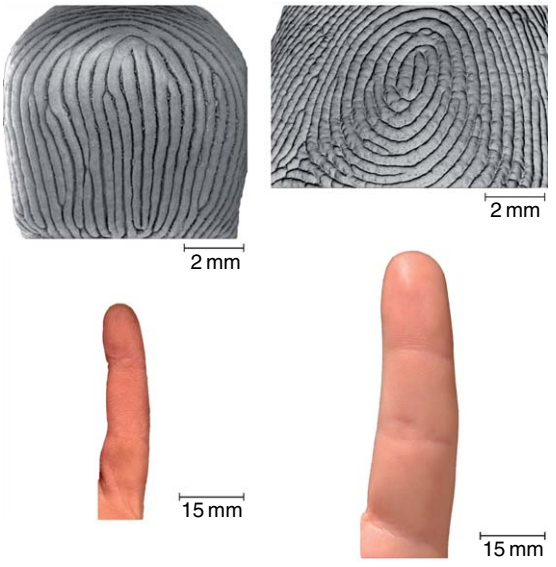

Figure 10 Comparison of monkey (left panel) and human (right panel) fingers. Whole index fingers (bottom) show the relative sizes of typical monkey and human fingers; there is of course considerable variation amongst individuals. Scanning electron micrographs (top) show fingerprint patterns. All our monkeys had the same linear proximal–distal pattern; humans have highly variable and unique patterns.

6.03.3 Hairy Skin

Although hairy skin is more extensive than glabrous skin, much less is known about the properties of its mechanoreceptors and their afferents than is the case for glabrous skin. There are a number of reasons for this. First, not all hairy skin is the same. Even in humans, receptive field properties of afferents innervating the arm differ from those of afferents innervating the dorsum of the hand or the face (Johansson, R. S. *et al.*, 1988; Edin, B. B. and Abbs, J. H., 1991; Vallbo, A. B. *et al.*, 1995). Second, much of the research on hairy skin has been performed on nonprimate species which are likely to have further differences from humans. An obvious example is the whisker system, which is highly developed in rodents, seals, and other mammals but is of little importance to humans (Zucker, E. and Welker, W. I., 1969; Dehnhardt, G. *et al.*, 1998). Third, stimuli used in hairy skin studies have usually been handheld and not well controlled. Fourth, unlike the obvious role played by glabrous skin mechanoreceptors during grasp and manipulation, the functional role of mechanoreceptors in human hairy skin appears to be more diffuse and is yet to be fully characterized.

6.03.3.1 Classification of Innervating Fibers

Mechanoreceptors in hairy skin may be located in hair follicles or in the skin between hairs. Large myelinated afferent fibers innervating these mechanoreceptors have been classified into five groups in numerous mammals, including humans (Burgess, P. R. *et al.*, 1968; Iggo, A. and Andres, K. H., 1982; Vallbo, A. B. *et al.*, 1995).

Two of the five classes of myelinated afferents are slowly adapting (Vallbo, A. B. *et al.*, 1995). SAI afferents innervate Merkel cells located in touch domes (Figure 11; Reinisch, C. M. and Tschachler, E., 2005).

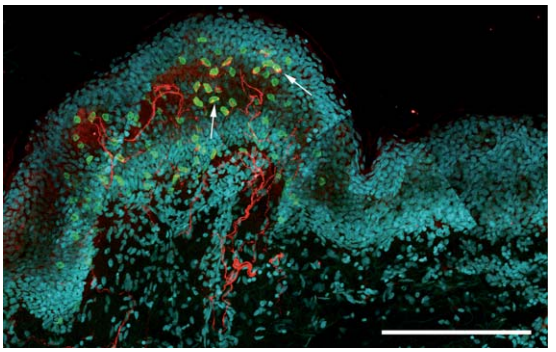

Figure 11 A touch dome in human hairy skin. Arrows mark contact zones between neurofilament (NF) positive nerve fibers and Merkel cells. Nuclei were counterstained with Hoechst. Scale bar = 200 μm (Reinisch, C. M. and Tschachler, E. 2005. The touch dome in human skin is supplied by different types of nerve fibers. Ann. Neurol. 58, 88–95).

Typically, SAI receptive fields contain a number of regions of high sensitivity (Figure 12(a)) indicating that each afferent innervates a cluster of Merkel cells, analogous to the innervation of SAI afferents in glabrous skin. SAII afferents innervate Ruffini organs and, as in glabrous skin, their receptive fields usually have a single zone of maximum responsivity.

Of the three rapidly adapting classes (Vallbo, A. B. *et al.*, 1995), the Pacinian units are similar to Pacinian afferents in glabrous skin with a single zone of maximum sensitivity in their receptive fields; they respond to taps on the skin remote from the receptive field center. The remaining two classes of rapidly adapting units have no counterpart in glabrous skin. These are the hair units innervating follicles, and the field units innervating skin between hairs. Hair units can often be activated by deflection of single hairs but they usually innervate many follicles, resulting in large receptive fields. Field units (Figure 12(b)) have large receptive fields with a number of zones of high sensitivity.

Hairy skin is also innervated by unmyelinated low-threshold mechanoreceptive afferents which, in humans, appear to mediate the emotional aspects of touch (Olausson, H. *et al.*, 2002).

6.03.3.2 Responses to Stroking

An effective method of activating hairy skin mechanoreceptors in a controlled way is by using a

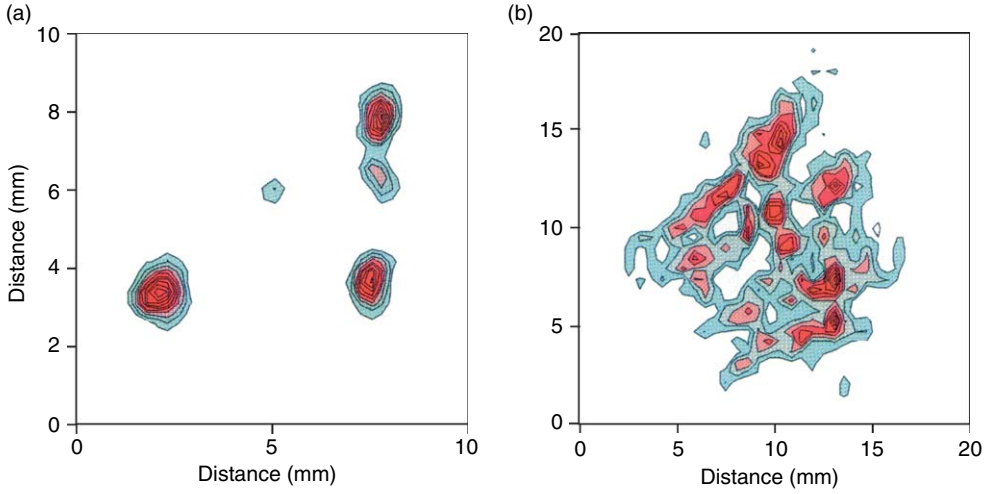

Figure 12 Color-coded contour plots showing two-dimensional receptive field structure for human hairy skin units. Sensitivity is graded from zero (white) to maximum (red). (a) A slowly adapting type I (SAI) afferent with a small number of confined regions of sensitivity. (b) A field unit with a large receptive field and multiple zones of sensitivity (redrawn from Vallbo, A. B., Olausson, H., Wessberg, J., and Kakuda, N. 1995. Receptive field characteristics of tactile units with myelinated afferents in hairy skin of human subjects. J. Physiol. 483, 783–795).

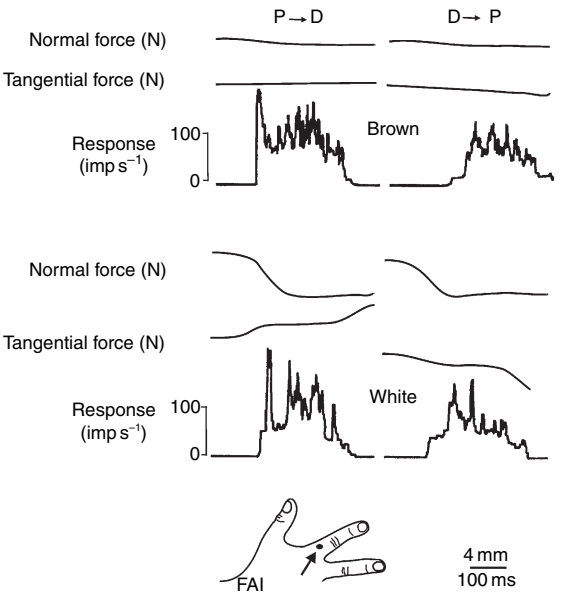

Figure 13 Responses of a fast-adapting unit in hairy skin to controlled brushing. The white brush resulted in higher forces than the brown brush. Stroking was in the proximal–distal direction on the left and in the distal–proximal direction on the right (adapted from Edin, B. B., Essick, G. K., Trulsson, M., and Olsson, K. Å. 1995. Receptor encoding of moving tactile stimuli in humans. I. Temporal pattern of discharge of individual low-threshold mechanoreceptors. J. Neurosci. 15, 830–847).

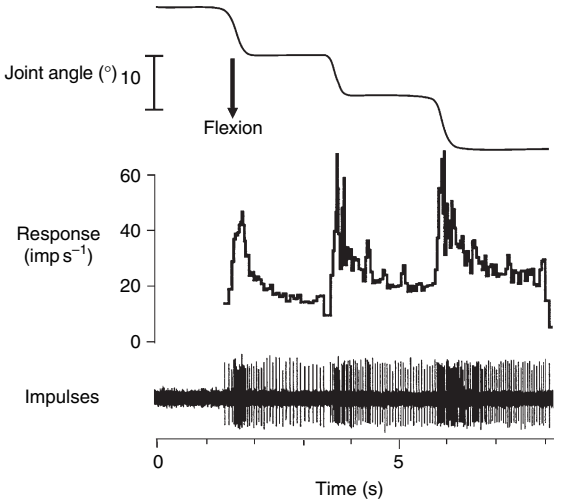

Figure 14 Responses of a slowly adapting type II (SAII) unit located in the hairy skin on the metacarpophalangeal joint of the index finger. Increasing flexion of the joint (top trace) resulted in an increased dynamic and static response of the unit (middle trace and bottom impulses) (adapted from Edin, B. B. and Abbs, J .H. 1991. Finger movement responses of cutaneous mechanoreceptors in the dorsal skin of the human hand. J. Neurophysiol. 65, 657–670).

mechanically driven brush. In some ways this simulates the natural contact that humans, and particularly other animals, make with the environment.

When human forearm skin is brushed, responses of both slowly and rapidly adapting units are modulated by the force, the velocity and the direction of brushing (Edin, B. B. *et al.*, 1995; Essick, G. K. and Edin, B. B., 1995). These responses (Figure 13) can explain the human ability to locate stimuli on the skin, determine their direction of movement, and discriminate the forces and velocities of movement.

6.03.3.3 Proprioception

Relatively recently it has become clear that mechanoreceptors in hairy skin are well situated for signaling the angles and movements of joints. Their role in proprioception for the hand contributes to primates' capacities to manipulate objects. At other joints, such as the knee, they are thought to play a key role in the control of posture and movement.

Whenever a joint moves, hairy skin for considerable distances around the joint are stretched or relaxed and the resultant stresses and strains activate the mechanoreceptors. For the finger joints (Figure 14), the hairy skin receptors provide graded information about joint angle (Edin, B. B. and Abbs, J. H., 1991). Electrical stimulation of these afferents, or stretching the skin on the dorsum of the hand in a controlled way, leads to the illusion of finger joint movement (Collins, D. F. and Prochazka, A., 1996). Similarly, afferents from hairy skin near the knee respond to knee position and movement (Edin, B. B., 2001), and stretching the skin around the knee or elbow leads to illusions of movement of those joints (Collins, D. F. *et al.*, 2005).

It is still to be determined how proprioceptive information from cutaneous and muscle spindle afferents are combined or what their relative importance is.

Glossary

adaptation The change in firing rate to a constant stimulus. Rapidly adapting neurons produce action potential only during the onset or offset of the stimulus. Slowly adapting neurons show a slow decline in firing rate during the sustained portion of the stimulus.

cutaneous Of or relating to the skin. The term cutaneous is typically used to refer to low-threshold mechanoreceptive afferents and their central connections.

isomorphic representation An one-to-one mapping between the spatial configuration of the stimulus and its neural representation.

kernels A set of mathematical functions that map one feature space into another.

mechanoreception The process of converting a deformation of the skin into neural signals. Cutaneous receptors have mechanoreceptive channels.

neural representation Spatial or temporal activity in a population of neurons that carries the information about a specific aspect of a stimulus or behavior.

proprioception The perception of the location and movement of body parts. For example, proprioception underlies the ability to perceive the conformation of the hands.

stress/strain Stress denotes a force per unit area; strain is the change in length per total length.

6.04.1 Introduction

Although object shape perception has been studied extensively in both vision and touch, the neural mechanisms underlying this ability have remained elusive. In vision, object recognition is based on inferring the 3D structure of objects from 2D images that originate from the retinas. These images flow centrally where they are combined and processed by neurons along the visual ventral stream to ultimately activate neurons in the inferotemporal (IT) cortex that are tuned to complex shapes such as faces. The problem of 3D shape processing in vision is difficult. First the visual system must segment images into

figure and ground. Then the 3D shape of the object must be inferred from disparity and image cues represented in the two 2D images. The problems that the tactile system faces in object perception are different. In touch, the hand has direct access to local 2D features from cutaneous signals at places where the skin contact the object and information about its global shape from proprioceptive signals that specify where those points of contact lie in 3D space. Tactile shape perception thus seems to rely on central mechanisms that integrate cutaneous inputs from the finger pads with proprioceptive inputs to produce central representations of objects. In both touch and vision, object perception is the product of matching transformed neural inputs against previously stored representations.

Recognizing objects with our hands is effortless, does not require visual input and is based on our ability to integrate information about the shape (e.g., sphere, cube), size (e.g., golf ball, basketball), and texture (e.g., tennis ball, baseball) to form a coherent representation. These features are processed independently and contribute to our ability to tactually identify objects. Object recognition begins with the activation of mechanoreceptive and proprioceptive afferents that innervate the skin, joints, and muscles of the hand and arm. A number of psychophysical and neurophysiological studies carried out over the past 30 years or so have led to an understanding of the organization of the peripheral afferent inputs and the roles they play in form and texture perception (for a detailed review, see Johnson, K. O., 2001). However, little is known about how and where these inputs are integrated in the central nervous system for object perception:

1. What are the central pathways and circuits that transform the peripheral inputs into the representations upon which perception is based?
2. What algorithms are used at each step of processing to represent objects and textures?
3. How is this transformed representation matched against previously stored representations?

In this chapter we first discuss the psychophysics and neurophysiology of 2D form and texture perception and review studies showing how form and texture are represented and coded in the responses of the peripheral afferents. We then discuss the central pathways of form and texture perception and review the current literature about how peripheral inputs are integrated in cortex to represent 2D shape and 3D objects.

6.04.2 Peripheral Coding of 2D Shape and Texture

6.04.2.1 Coding of 2D Shape

The processing of 2D spatial patterns presented to a single finger pad has been the focus of numerous psychophysical and neurophysiological studies (for a review, see Hsiao, S. S., *et al.*, 2003). These studies suggest that the somatosensory system, like the visual system, has two separate streams for processing spatial information. The slowly adapting type 1 (SA1) system is responsible for processing information related to texture and form, and the rapidly adapting (RA) system is responsible for processing information related to local movement on the skin (Johnson, K. O., 2001). Evidence that the SA1 system, which receives its inputs from Merkel cells, is responsible for 2D spatial form comes from studies showing that these afferents densely innervate the glabrous skin of the hand (about 100 afferent fibers per cm^2 at the fingertip in man and monkey) (Johansson, R. S. and Vallbo, A. B., 1979; Darian-Smith, I. and Kenins, P., 1980) and have small receptive fields (about 2–3 mm in diameter) and, because of their high sensitivity to skin strain (Phillips, J. R. and Johnson, K. O., 1981b; Sripati, A. P. *et al.*, 2006a), these afferents resolve the fine spatial details of patterned stimuli (down to about 0.5 mm) (Phillips, J. R. and Johnson, K. O., 1981a). Further, SA1 afferents have linear responses to skin indentations over a wide range (Blake, D. T. *et al.*, 1997b; Vega-Bermudez, F. and Johnson, K. O., 1999; Johnson, K. O. *et al.*, 2000), and are highly sensitive to local curvature and edges indented into the skin (LaMotte, R. H. and Srinivasan, M. A., 1996; Blake, D. T. *et al.*, 1997b; Goodwin, A. W. *et al.*, 1997; Wheat, H. E. and Goodwin, A. W., 2001). The responses of these afferents to spatial stimuli is only minimally affected by changes in scanning velocity (Hsiao, S. S. *et al.*, 1996; DiCarlo, J. J. and Johnson, K. O., 1999).

An example of the response of an SA1 afferent to scanned embossed letters is shown in Figure 1. The figure shows that the initial representation of 2D form in the SA1 population response is a crisp isomorphic neural image (i.e., has the same shape as the stimulus) that is minimally affected by changes in contact force or velocity. Evidence from neural coding studies show that this system underlies the ability of humans to recognize fine spatial patterns (Johnson, K. O. and Phillips, J. R., 1981; Vega-Bermudez, F. *et al.*, 1991). The SA1 system is the tactile processing system for 2D patterns and is analogous to the parvocellular pathway in vision (Hsiao, S. S., 1998).

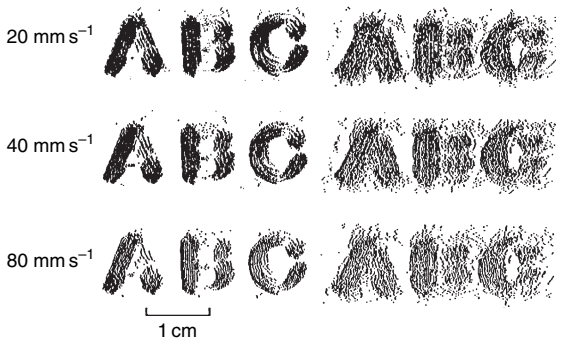

Figure 1 Responses of typical slowly adapting type 1 (SA1) (left) and rapidly adapting (RA) peripheral afferents to scanned embossed letters (8.0 mm high) at three scanning velocities. The figure shows that the SA1 afferents provide a crisp isomorphic representation of spatial patterns to the central nervous system.

The RA system, which receives its inputs from Meissner corpuscles also innervates the skin densely (about 150 afferents per cm^2 in man and monkey) (Johansson, R. S. and Vallbo, A. B., 1979; Darian-Smith, I. and Kenins, P., 1980). This system also sends to the central nervous system an isomorphic representation of spatial stimuli (Figure 1). However, the images are less crisp and evidence suggests that it only provides a crude sense of spatial form (Johnson, K. O. and Hsiao, S. S., 1992). In fact, recent studies have suggested that the RA system can actually interfere with fine form processing (Bensmaia, S. J. *et al.*, 2006). This system is thought to be responsible for the perception of low-frequency vibrations (called flutter) and the perception of tactile motion. RA afferents have intermediate spatial acuity, respond well to movement across the skin (Gardner, E. P. and Palmer, C. I., 1990) and are responsible for signaling microslips that occur when lifting objects (Johansson, R. S. and Westling, G., 1987; Westling, G. and Johansson, R. S., 1987; Srinivasan, M. A. *et al.*, 1990). The RA system is the tactile motion system and is analogous to the magnocellular system in vision (Hsiao, S. S., 1998).

The ability of the peripheral SA1 afferents to resolve the spatial details of stimuli comes from their high sensitivity to mechanical strain. Stimuli that are indented into the skin produce patterns of stresses and strains in the subcutaneous tissues beneath the surface of the skin that activate mechanoreceptive channels in the receptor endings of the afferent fibers. Continuum mechanics models (Phillips, J. R. and Johnson, K. O., 1981b; Johnson, K. O. and Hsiao, S. S., 1992; Sripati, A. *et al.*, 2006a) have shown that when a stimulus is indented into the skin the stresses are greatest at the edges where there is less tissue over which forces exerted at the skin surface can be distributed. Under the stimulus edges, then, the SA1 firing rates are much higher, which leads to an enhancement of the peripheral representation of features such as edges and corners. In contrast, RA afferents show little to no enhanced responses to edges (Sripati, A. *et al.*, 2006a). (see Chapter Physiological Responses of Sensory Afferents in Glabrous and Hairy Skin of Humans and Monkeys for a detailed discussion of the responses of the peripheral afferents to stimuli of varying curvature.)

6.04.2.2 Coding of Surface Texture

Like size and shape, information about surface texture plays a major role in tactile object recognition (e.g., baseball vs. an orange) and can be important when manipulating objects. For example, a ball made of foam is manipulated very differently than a ball made of steel. Multidimensional scaling studies show that texture perception is multidimensional and includes three main dimensions, namely, roughness/smoothness, hardness/softness, stickiness/slipperiness, and possibly a fourth dimension of warmth/coolness (Hollins, M. *et al.*, 1993; 2000; Bensmaia, S. J. and Hollins, M., 2005). Below, we discuss the neural coding mechanisms of the three main dimensions of texture.

6.04.2.2.1 Roughness/smoothness

By far the most widely studied aspect of texture is the sense of roughness. The subjective sense of roughness (and smoothness) varies along a single dimension and is not readily predicted by the surface properties. Psychophysical studies report that roughness increases linearly with particle size for sandpapers (Ekman, G. *et al.*, 1965) and increases with spatial period and groove width for gratings (Chapman, C. E. *et al.*, 2002). In studies using embossed dot patterns it has been shown that perceived roughness has an inverted U-shaped function with spatial period (increasing as dot spacing increases from 1.0 to 3.2 mm and decreasing as dot spacing increases to 6.2 mm), decreasing as dot diameter increases (from 0.5 to 1.0 mm) and increasing as dot height increases (from 280 to 620 μm) (Connor, C. E. *et al.*, 1990; Blake, D. T. *et al.*, 1997a).

In a series of studies pairing human psychophysics with macaque neurophysiology (see Johnson, K. O. *et al.*, 2002 for a review), Johnson, Hsiao and co-workers set out to establish the peripheral neural code underlying roughness perception (Connor, C. E. *et al.*, 1990;

Connor, C. E. and Johnson, K. O., 1992; Blake, D. T. *et al.*, 1997a; Yoshioka, T. *et al.*, 2001). Their approach consisted of devising and testing a set of hypotheses linking the activity in populations of peripheral afferent fibers evoked by a wide range of textured surfaces (embossed dot patterns, see above) to estimates of perceived roughness obtained from human subjects. These estimates, obtained for a variety of dot patterns, were plotted against predictions derived from each putative neural code. A hypothesis was eliminated if it failed to show a consistent relationship between the roughness estimates and the putative neural code. They rejected all neural codes based on:

1. the mean firing rate elicited by any of the mechanoreceptive afferents fibers;
2. all codes based on temporal variability in the firing of a given population of mechanoreceptive afferent fibers; and
3. all codes based on the firing of RA and Pacinian (PC) afferents.

The only remaining code that stood up against the entire battery of stimuli was one based on a measure of the spatial variation in firing rates among SA1 afferents (Figure 2). According to this hypothesis, there are populations of neurons in the central nervous system whose receptive fields comprise excitatory and inhibitory subregions, spaced about 2.0 mm apart, which is approximately the distance between two primary afferent spacings. Johnson, Hsiao, and co-workers showed that, as textured patterns like the ones shown in Figure 2 are scanned across the finger pad; populations of neurons with these kinds of receptive fields compute a measure of spatial variation in firing rate that closely matches the psychophysical data (Figure 2). For example, Connor C. E. *et al.* (1990) showed that closely spaced dots which equally excite the excitatory and inhibitory subregions produces low firing rates. Similarly, widely spaced dots also produced low firing rates because neurons were only rarely excited by the dots. Dots with intermediate spacings produced the highest firing rates and correspondingly elicited high subjective roughness magnitude estimates. The correlation between the psychophysics and the spatial variation measure in this study was about 0.98. Similar correlations between this neural measure and human psychophysics were found for patterns composed of fine textures (Yoshioka, T. *et al.*, 2001), patterns that varied in dot diameter (Blake, D. T. *et al.*, 1997a), and patterns that systematically altered the spatial and temporal (variation in firing rate

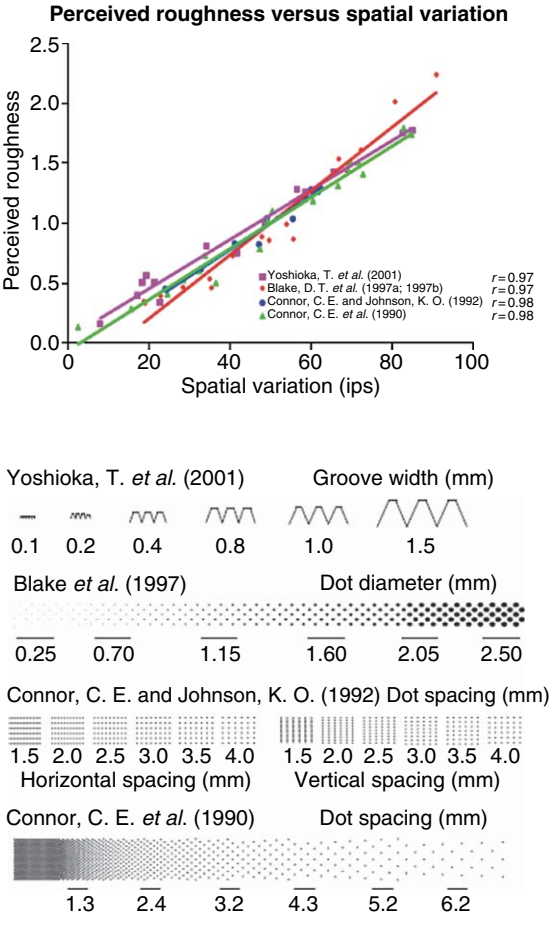

Figure 2 Summary of four neural coding studies of roughness perception. In all the four studies, human subjects performed roughness magnitude estimates of the surfaces shown at the bottom. These same surfaces were used as stimuli in neurophysiological experiments of the peripheral afferents of macaque monkeys. All neural codes that were tested were rejected except for a measure of spatial variation of firing in slowly adapting type 1 (SA1) afferents. The results are shown at the top where perceived roughness is plotted against the spatial variation measure. The plot shows that there is a consistent relationship between the neural measure and perceived roughness. The plot also shows that there is a linear relationship between perception and the neural code upon which it is based.

across time) variation in the afferent discharge (Connor, C. E. and Johnson, K. O., 1992). In all cases, roughness perception was linearly related to the SA1 spatial variation measure.

The predicted receptive field structures are exactly like the measured receptive fields of a subset neurons in area 3b (DiCarlo, J. J. *et al.*, 1998; DiCarlo, J. J. and Johnson, K. O., 1999; 2000) suggesting that roughness is derived from the mean firing rate of neurons in primary somatosensory cortex (SI).

Hollins and co-workers studied fine textures with spatial periods below about 200 μm and found that roughness for these fine surfaces correlates well with vibratory intensity and hypothesized that PC afferents may play a role in roughness perception for very fine surfaces (Hollins, M. *et al.*, 2001; 2002; Bensmaia, S. J. and Hollins, M., 2003; 2005).

6.04.2.2.2 Hardness/softness

Hardness/softness is the subjective continuum associated with the compliance of an object. Softness perception has been shown to rely primarily on cutaneous cues: eliminating kinesthetic information has no effect on subjects' ability to discriminate softness (Srinivasan, M. A. and LaMotte, R. H., 1995). As the hand is pressed against a compliant object, it conforms to the contour of the skin in proportion to the contact force. The compliance (and the softness) of the object appears to be signaled by the rate of growth of the area over which the skin contacts the object as the contact force increases, as well as the increase in the reaction force exerted by the object on the skin across the contact area. Softness perception likely relies on signals from SA1 afferents (Srinivasan, M. A. and LaMotte, R. H., 1996).

6.04.2.2.3 Stickiness/slipperiness

Stickiness/slipperiness is the sensory continuum associated with the friction between skin and surface. Indeed, magnitude estimates of stickiness have been shown to closely match the measured kinetic friction between skin and surface, that is, the ratio between the force exerted normal to the surface to that exerted parallel to the plane of the surface (Smith, A. M. and Scott, S. H., 1996). Furthermore, when judging stickiness, subjects do not substantially vary the normal forces they apply on the surface, but the applied tangential forces tend to vary across surfaces, suggesting that tangential forces are intimately linked with the perception of stickiness. The neural basis for stickiness is not known.

6.04.3 Coding of 3D Size and Shape

6.04.3.1 Psychophysical Studies of 3D Size and Shape

In the absence of visual input, tactile object recognition using a single hand is highly accurate and improves as the number of digits used to contact objects increases (Davidson, P. W., 1972; Kappers, A. M. L. and Koenderink, J. J., 1996). Interestingly, accuracy seems to decrease if two hands are used (Kappers, A. M. L. and Koenderink, J. J., 1996). Klatzky R. L. *et al.* (1985) showed that blindfolded subjects perform with an accuracy of 96% and a mean response time of less than 5 s when asked to identify 100 common objects. Further, Lederman S. J. and Klatzky R. L. (1993) showed that, when subjects explore objects, they use stereotypical movement patterns, which they call exploratory procedures (EPs). Among the eight kinds of EPs, two are critical for extracting information concerning object shape. The first, called enclosure, involves dynamic molding of the palm and/or fingers to the contours of the object. The second, called contour following, involves tracing the edges of objects with the fingers. Both procedures require that information about hand position (i.e., proprioception) be combined with tactile information from the skin (i.e., mechanoreception). In a similar study, Loo C. K. *et al.* (1983) showed that purely cutaneous information was sufficient for the discrimination of small objects but proprioceptive information is needed for the discrimination of large objects. Large objects are recognized more effectively when touched from the back (which is the natural way we grasp an object) than when touched from the front (Newell, F. N. *et al.*, 2001). Voisin J. *et al.* (2002a; 2002b) showed that the discrimination of an angle requires both cutaneous and proprioceptive input. Furthermore, Davidson P. W. (1972) showed that subjects are less successful at identifying 3D curved surfaces when tracing them with a single finger than when they contact surfaces simultaneously with multiple fingers.

Relatively, little is known about how information is integrated across fingers or even across finger pads of the same digit. Some psychophysical studies suggest that interactions between fingers are minimal. Loomis J. M. *et al.* (1991) tested the ability of human subjects to identify objects either visually or by touch and found that while performance improved considerably when the size of the visual field was doubled (simulating touching a surface with two fingers), subjects showed little improvement in performance when two, rather than one, fingers were used to explore the complex 3D patterns. Similarly, Craig J. C. (1985) reported that patterns presented to a single finger pad are identified more accurately and rapidly than when the same patterns are divided in half and presented to separate fingers on the same hand. In contrast, psychophysical evidence suggests that there are considerable interactions when tactile information is presented to multiple digits on the same and opposite hands. Evans P. M. *et al.* (1992) showed that

performance in identifying a spatial pattern is high when identical stimuli are presented to two fingers and low if a conflicting stimulus is presented to an adjacent finger even when subjects are told to ignore stimulation of the adjacent finger. The effect occurs regardless of whether the two fingers are adjacent or nonadjacent but does not occur if the patterns are presented to opposite hands. Pont S. C. *et al.* (1999) tested the ability of subjects to detect curvature using static and dynamic touch and found that discrimination using multiple fingers is better than discrimination using a single finger.

Proprioceptive input provides information about the location of the digits in space and information about hand conformation. A simple demonstration of the importance between hand conformation and cutaneous perception is the Aristotle illusion. In this illusion, a continuous edge feels like a single edge when the two fingers are next to each other but feels like two separate edges (with different orientations) when touched with the fingers crossed (Benedetti, F., 1985; Craig, J. C., 2003). Other studies have demonstrated that hand conformation affects motion perception. Rinker M. A. and Craig J. C. (1994) found that the perception of stimuli presented to a single finger pad is dramatically affected by hand conformation. In their study, subjects were asked to report the direction of stimuli moving across the thumb while a non-target-moving stimulus was presented to the index finger. They showed that when the hand is placed flat, stimuli moving in the opposite directions on the index finger interfere with perception on the thumb. However, if the hand conformation is changed such that the index finger and thumb are opposed (precision grip configuration used when grasping objects), then the identical motion on the index finger that interfered with direction perception now improves performance. The perception of shape can also be affected by the orientation of the hand. Oldfield S. R. and Phillips J. R. (1983) showed that the perception of letters changed when subjects pronated or supinated their hand. Thus an embossed lower case "d" pressed into the skin changes to a lower case "b" as the wrist is rotated. The most plausible explanation for these findings is that perception from the finger pads is not based simply on the perception of local features but rather is based on cutaneous features in the context of hand conformation and orientation.

Recently, Berryman L. J. *et al.* (2006) showed that the perception of object size is dependent on both proprioceptive and mechanoreceptive input. They showed that the perceived size of an object is based on the spread of the digits at initial contact. Further, they showed that size perception is independent of contact force and contact area and somehow takes into account the textural properties of objects. Thus, the softness of an object does not affect its perceived size.

6.04.3.2 Cortical Neurophysiological Studies of 3D Shape

6.04.3.2.1 Ascending pathways

As shown in Figure 3, there are two principal pathways that carry somatosensory information from the

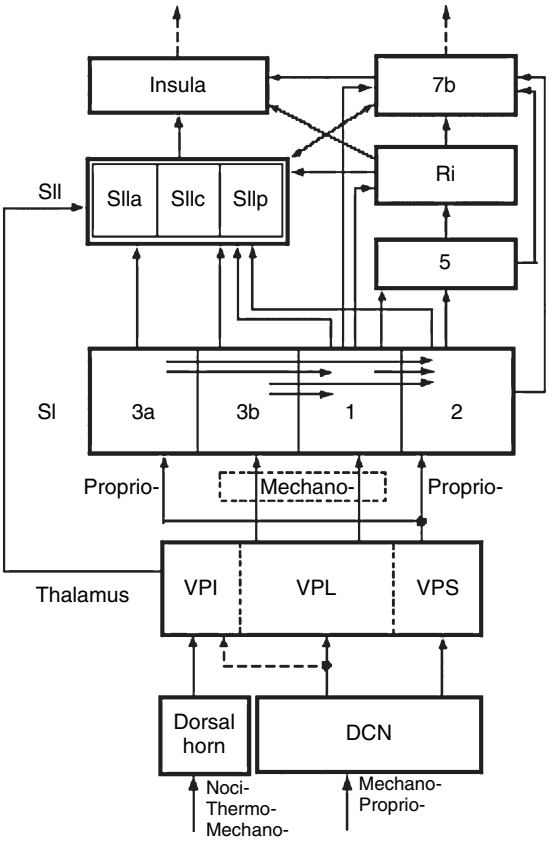

Figure 3 Functional organization of the somatosensory system. The pathway underlying form and texture processing starts with mechanoreceptive and proprioceptive afferents, which project to the dorsal column nuclei (DCN). These neurons then send their projections to the ventrobasal complex of the thalamus that has three subnuclei. The pathway then progresses to areas 3a, 3b, 1 and 2 of primary somatosensory cortex (SI) and then to the anterior, central, and posterior fields of the second somatosensory cortex (SII). The pathway for form and texture processing after SII cortex is largely unknown. VPI, ventroposterior lateral nucleus.

periphery to the cortex. One pathway, called the spinothalamic tract, carries information about nociception, temperature, and itch and does not play a role in object perception. The other pathway, called the dorsal column medial lemniscal pathway, carries information from the large diameter afferent fibers and is the critical pathway for conveying information from cutaneous and proprioceptive afferents. The information from mechanoreceptive and proprioceptive inputs remains segregated along this pathway.

6.04.3.2.2 Primary somatosensory cortex

The first cortical processing stage for somatosensory information is SI cortex, which consists of four areas (Kaas, J. H. *et al.*, 1979): Area 3a receives inputs from the shell region of the ventrobasal (VB) complex of the thalamus and neurons in this area respond to joint position (Burchfiel, J. L. and Duffy, F. H., 1972; Jones, E. G. and Porter, R., 1980; Friedman, D. P. and Jones, E. G., 1981) (Figure 3). Area 3b receives inputs from the core region of VB and 3b neurons tend to have slowly adapting RA responses with small receptive fields composed of excitatory and inhibitory subregions (Bankman, I. N. *et al.*, 1990; Hsiao, S. S. *et al.*, 1996; DiCarlo, J. J. *et al.*, 1998; Sripati, A. P. *et al.*, 2006b). Animals with lesions of area 3b show severe deficits in practically all aspects of tactile perception including form, texture, and shape perception (Randolph, M. and Semmes, J., 1974; Semmes, J. and Turner, B. H., 1977). Area 1 also receives cutaneous inputs from VB; however, the projection to area 1 is less dense than to 3b, and area 1 also receives projections from area 3b (Jones, E. G. and Powell, T. P. S., 1969). Neurons in area 1 have larger receptive fields than those in area 3b (Iwamura, Y. *et al.*, 1993), tend to have both slowly adapting and RA responses (Sur, M., 1980), and respond well to motion (Gardner, E. P., 1984). Lesions of area 1 are less devastating than lesions of area 3b, with animals showing mild but specific deficits in making rough–smooth and hard–soft discriminations (i.e., texture discriminations) (Randolph, M. and Semmes, J., 1974).

Area 2 receives both deep and cutaneous inputs from VB; neurons in this area have more complex responses than neurons in the other three areas of SI (Iwamura, Y. *et al.*, 1985). Besides receiving inputs from VB, area 2 also receives inputs from areas 3a, 3b, and 1, making it a prime candidate for being the initial processing stage for 3D shape processing (Pons, T. P. and Kaas, J. H., 1985; Porter, L. L. and Izraeli, R., 1993). Animals with lesions of area 2 are unable to discriminate gross object features (i.e., to judge objects as concave or convex, or square or diamond) (Randolph, M. and Semmes, J., 1974). Neurophysiological studies of area 2 provide strong evidence that this region is involved in 3D form perception (Iwamura, Y. and Tanaka, M., 1978; Gardner, E. P. and Costanzo, R. M., 1981; Koch, K. W. and Fuster, J. M., 1989; Debowy, D. J. *et al.*, 2001). Iwamura Y. and Tanaka M. (1978) reported that a large fraction of the neurons responded to simultaneous manipulation of the joints and punctate stimuli, and that some neurons appeared to be tuned to specific textures or shapes. They showed, for example, that some neurons in area 2 responded selectively to balls or cylinders but not to edges.

Several studies show that neurons in area 3b show selective responses to particular features of spatial stimuli (DiCarlo, J. J. *et al.*, 1998; DiCarlo, J. J. and Johnson, K. O, 1999; 2002; Sripati, A. P. *et al.*, 2006b). These studies report that neurons in area 3b have receptive fields composed of a central excitatory region with one or more inhibitory regions surrounding the excitatory region. The onset of the inhibitory subregion lags the excitatory input suggesting that it is of cortical origin. These excitatory and inhibitory subregions become fully elaborated approximately 20 ms following stimulus onset. Both of these regions are then rapidly followed by a larger replacing inhibition that lasts approximately 60 ms following stimulus onset. The regions of excitation and inhibition explain why neurons in 3b show feature selectivity. Peripheral neurons, which have mainly simple excitatory receptive fields, do not show orientation selectivity (Hsiao, S. S. *et al.*, 2002), however, a large fraction (70%) of the neurons in area 3b have asymmetric receptive field and consequently show orientation-tuned responses. One way of viewing these neurons is to think of them as spatiotemporal filters that are selective to particular features of the stimuli. These studies support the notion that area 3b lies at an intermediate step along a pathway where 2D spatial form is transformed from the isomorphic responses shown in Figure 1 to an altered representation that underlies perception of spatial form and the perception of roughness (DiCarlo, J. J. *et al.*, 1998; Chapman, C. E. *et al.*, 2002). The role of the replacing inhibition is to insure that the neurons are relatively insensitive to changes in scanning velocity. That is, the spatial response properties of the neuron are rapidly inhibited by the replacing inhibition thus limiting the degree of temporal smear that occurs with scanning.

Neurons in area 1 which receives inputs from both the thalamus and from area 3b appear to have larger but similar receptive field structures as area 3b neurons, although the responses are not as linear.

6.04.3.2.3 Areas 5 and 7 (tactile dorsal pathway)

Two principal processing streams diverge from SI cortex (Figure 3). One processing stream is directed caudally from SI to areas 5 and 7. Animals with lesions of areas 2 and 5 were unable to perform a wide range of form discrimination tasks. However, if area 2 is spared, animals show only a mild deficits in their ability to perform tactile discrimination tasks (Murray, E. A. and Mishkin, M., 1984). Similarly, animals with lesions of area 7 show only mild deficits in form discrimination (Semmes, J. and Turner, B. H., 1977). These results suggest that areas 5 and 7 are not involved in representing object shape. However, Sakata H. and Iwamura Y. (1978) reported that neurons located in the anterior bank of the intraparietal sulcus (area AIP), which is near the border between areas 2 and 5, exhibited shape-tuned responses: some neurons responded to rectangular blocks or straight edges but not to cylinders, whereas other neurons responded selectively to cylindrical bottles or apples. More recently, Koch K. W. and Fuster J. M. (1989) reported that neurons in areas 2 and 5 responded similarly to object shapes. One hypothesis is that areas 5 and 7 are involved in the perception of the immediate extrapersonal space and are responsible for representing the location of the body in space, for guidance of the body and hand, and for directing the attentional focus to targets in that space (Mountcastle, V. B. *et al.*, 1975; Sakata, H. and Iwamura, Y., 1978; Gardner, E. P. *et al.*, 2007a; 2007b). Further, neurons in these areas may play a role in matching hand grips with the characteristics of objects, since accurate positioning of the finger pads on an object surface is a prerequisite for subsequent handling and manipulation (Jeannerod, M. *et al.*, 1995). (See the chapter by Gardner, E. P., 1984 for further details on the roles of areas 5 and 7 in haptic processing.)

6.04.3.2.4 Second somatosensory cortex (tactile ventral pathway)

The other processing stream is directed ventrally toward the second somatosensory cortex (SII) and the insula and is concerned with object form perception (Murray, E. A. and Mishkin, M., 1984; Pons, T. P. *et al.*, 1992; Disbrow, E. *et al.*, 2001) and maybe closely linked with motor functions (Hinkley, L. B. *et al.*, 2007). Although SII also receives a direct projection from VB, several lines of evidence suggest that SII lies at a higher processing stage than SI cortex. First, lesions of SI cortex render neurons in SII silent (Pons, T. P. *et al.*, 1992). Second, while neurons in area 3b of SI cortex have small receptive fields restricted to single digits, neurons in SII tend to have larger receptive fields that often encompass multiple digits or the entire hand, with many neurons having bilateral receptive fields (Robinson, C. J. and Burton, H., 1980b; Hsiao, S. S. *et al.*, 1993; Fitzgerald, P. J. *et al.*, 2006). Third, 90% of the neurons in SII are affected by the attentive state of the animal (Hsiao, S. S. and Vega-Bermudez, F., 2002). Fourth, SII cortex, like SI cortex, is important for object and texture processing since animals with ablations of SII are unable to perform tactile tasks involving form and texture discriminations (Ridley, R. M. and Ettlinger, G., 1978; Murray, E. A. and Mishkin, M., 1984). Finally, neural responses in SII to scanned letters are significantly more complex and less isomorphic than are the responses of neurons in area 3b (Hsiao, S. S. *et al.*, 2003).

The functional organization of SII cortex is not well understood. Early reports suggested that it was composed of two areas (Robinson, C. J and Burton, H., 1980a; Burton, H. *et al.*, 1995; Krubitzer, L. A. *et al.*, 1995). Recent studies, however, suggest that it is composed of at least three fields (Fitzgerald, P. J. *et al.*, 2004) and possibly more in humans (Eickhoff, S. B. *et al.*, 2006). Fitzgerald P. J. *et al.* (2004) found that in monkeys, neurons in the anterior and posterior fields of SII cortex respond best to both proprioceptive and cutaneous input, whereas neurons in the central field respond primarily to cutaneous input. One possibility is that different tactile functions are distributed among the three fields and that different aspects of object shape are represented in each of the three fields. Another possibility is that SII cortex is more closely related to cognitive processing within the somatosensory system, which could explain why over 90% of the neurons in SII are affected by the animal's focus of attention (Hsiao, S. S. *et al.*, 1993; Jiang, W. *et al.*, 1997; Steinmetz, P. N. *et al.*, 2000; Meftah, E. M. *et al.*, 2002; Keysers, C. *et al.*, 2004).

Hsiao and co-workers (Hsiao, S. S *et al.*, 2002; Fitzgerald, P. J. *et al.*, 2006) have demonstrated that a large fraction of neurons in the somatosensory cortex show orientation tuning and that the representation of orientation is elaborated as one proceeds from SI to SII cortex. While neurons in the periphery do not show orientation tuning, about 70% of the neurons in area 3b and about 30% of the neurons in

the three areas of SII show tuned responses. In both SI and SII, the orientation tuning properties of the neurons (aspect ratio and bandwidth) are similar to those found in the visual system (Fitzgerald, P. J. *et al.*, 2006) suggesting that these neurons are involved in form processing. Neurons in SII have receptive fields that range from simple receptive fields, confined to a single finger pad, to large and complex receptive fields, comprising combinations of finger pads and exhibiting tuned, untuned excitatory, and untuned inhibitory pads (Fitzgerald, P. J. *et al.*, 2006). Furthermore, the tuning of individual neurons is highly similar across pads (Figure 4). In further studies, they report that many neurons in SII have positionally invariant responses to bars placed anywhere in the finger pad (Thakur, P. H. *et al.*, 2006).

The results from these studies suggest that neurons in SII cortex are ideally suited for coding features of large objects that span multiple finger pads. One hypothesis is that these receptive fields represent processing kernels that underlie the representation of 3D objects. Orientation-tuned pads may be responsible for detecting edges or corners of patterns and untuned excitatory pads for detecting the flat part of objects.

A working hypothesis for 3D object perception, supported by neural imaging studies (Roland, P. E. *et al.*, 1988; Seitz, R. J. *et al.*, 1991), is that surface features are extracted by neurons in areas 3b and 1, and primitives for object shape and size are extracted by neurons in area 2 (Bodegard, A. *et al.*, 2001; Ostry, D. J. and Romo, R., 2001). The processing then proceeds to the three areas that make up SII cortex, where the primitives are combined to form more elaborate representations of objects. Little is known about where the processing proceeds beyond SII. Candidate areas include AIP, supramarginal gyrus (Bodegard, A. *et al.*, 2001), and possibly visual areas like IT cortex (Sadato, N. *et al.*, 1996; Zangaladze, A. *et al.*, 1999; Merabet, L. *et al.*, 2004).

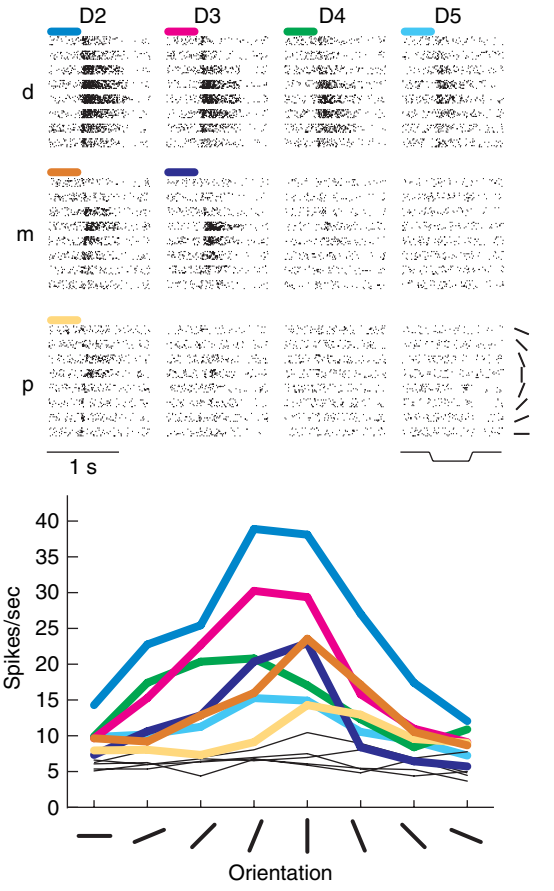

Figure 4 Receptive field of a neuron in SII cortex that has six orientation-tuned pads. D2, D3, D4, and D5 stand for the index, middle, ring, and pinky; d, m, and p stand for the distal, middle, and proximal finger pads. Each raster shows the occurrence of action potentials from an oriented bar indented into the finger pad at eight orientations (legend for the orientations is to the right of the raster for D5p. The bottom graph shows the tuning curves for all 12 pads. Adapted from Fitzgerald, P. J., Lane, J. W., Thakur, P. H., and Hsiao, S. S. 2006. Receptive field (RF) properties of the macaque second somatosensory cortex: RF size, shape, and somatotopic organization. J. Neurosci. 26, 6485–6495.

6.04.4 Conclusion

While much is known about the peripheral afferent systems that underlie somatic sensation, little is known about how information from those systems leads to perception. Emerging evidence suggests that the pathway for object perception progresses from area 3b to area 2 and then to SII cortex, where cutaneous inputs are combined in a stagewise manner with proprioceptive inputs to form representations of the 3D structure of objects. The pathway for texture processing is less clear. Clearly, spatial processing by the SA1 afferents plays the major role in roughness and hardness perception; however, the peripheral representation of stickiness has not been established. Evidence also suggests that areas 3b, 1, and possibly SII also play a major role in texture perception. Further studies are needed to investigate how objects are represented in cortex beyond SII cortex.

Glossary

action-phase controller Represents a sensorimotor control policy for reaching a subgoal of an overall action plan by using sensory information and predictions in a specific way, each. As such, it is conceptually related to the notion of internal models in motor control that involve neural circuits that mimic the behavior of the motor system and environment and capture the mapping between motor outputs and sensory inputs (Wolpert, D. M. *et al.*, 2001).

grasp stability control The control of grip forces such that they are adequate to prevent accidental slips but not so large as to cause unnecessary fatigue or damage to the object or hand.

haptic Refers to the ability to experience the environment through active exploration, typically with our hands, as when palpating an object to gauge its shape and material properties.

microneurography A method using metal microelectrodes to investigate directly neural signals in efferent and afferent peripheral nerves *in situ* in conscious human subjects, able to participate in sophisticated and cooperative experimental tests. Tungsten microelectrodes with an epoxy resin-insulated shaft having diameter of about 200 μm, a tip diameter of about 5 μm, and an impedance around 500 kΩ measured at 1 kHz are generally used for recording action potentials in single axons. For an early review detailing this technique see Vallbo, Å. B. *et al.* (1979).

precision grip The grip formed when grasping an object with the distal tips of digits. Usually refers to grasping with the tips of the thumb and index finger on either side of an object.

sensorimotor control points Contact events that denote completion of action goals and give rise to discrete and distinct sensory signals in one or more sensory modalities.

sensorimotor control The use of both predicted and unexpected sensory information in the control of action.

tactile Refers to signals conveyed to the brain by low-threshold mechanoreceptive afferent neurons that innervate the skin and subcutaneous tissues in glabrous skin areas and oral mucosa, i.e., body areas used primarily for object interactions.

6.05.1 Organization of Object Manipulation Tasks

Most natural object manipulation tasks involve a series of actions or phases where each phase accomplishes a specific goal or subgoal of the overall task. Distinct mechanical contact events typically signify goal attainments. For example, consider the task of lifting, holding, and replacing a box on a tabletop. This task involves a series of action phases separated by contact events that involve either the making or the breaking of contact (Figure 1(a)) (Johansson, R. S. and Westling, G., 1984a). Thus, the goal of the initial reach phase is marked by the digits contacting the box and the goal of the subsequent load phase, during which forces are applied under isometric conditions to overcome object weight, is marked by the breaking of contact between the object in hand and the support surface. These and subsequent contact events give rise to distinct and discrete sensory signals in the tactile modality and, in many cases, other modalities (Figure 1(a)). These sensory signals not only provide information about the timing of the events but also about the characteristics of the mechanical interaction. Thus, a given object manipulation task can be represented as a sensory plan specifying a sequence of sensory goals in one or more sensory modalities (Flanagan, J. R. *et al.*, 2006). The implementation of such a plan requires the selection and execution of a corresponding sequence of basic actions, or action-phase controllers, to achieve the sensory goals (Figure 1(a)).

The task of each action-phase controller is to generate motor commands that will lead to the successful attainment of the sensory goal. When possible, the controller uses knowledge of object properties, combined with information about the current state of the system (including the motor apparatus and objects in the environment), to predictively tailor motor commands to the task at hand. For example, during the load phase of lifting, people normally scale the rate of change of force output to the predicted weight of the object. At the same time, the controller generates predictions about the sensory consequences of the motor output, including sensory signals associated with contact events. By comparing predicted and actual sensory feedback, task progression can be monitored (Figure 1(a)). If a mismatch occurs, the brain can launch learned task- and phase-specific corrective actions (or smart reflexes) that are part and parcel of the controller (Figure 1(a)). If the mismatch is due to erroneous predictions about object properties, memory representations related to these properties can be updated so as to improve predictive control in subsequent phases of the task and in other tasks with the same object.

Predictions about the terminal sensory state of each action phase provide initial state information for the next action-phase controller. In the absence of such predictions, this state information would have to be obtained by a peripheral afferent signal at the start of each phase. This would prevent smooth transitions between action phases because of substantial time delays in sensorimotor control loops. Due to delays associated with receptor transduction and encoding, afferent and efferent neural conduction, central processing, and muscle activation, it takes approximately 100 ms before signals from tactile sensors in the digits can bring about meaningful adjustments of fingertip actions. Even longer delays, in excess of 200 ms, are usually required to transform visual events into purposeful fingertip actions. Anticipatory control policies support dexterous object manipulation by avoiding these long time delays.

6.05.2 Sensory Systems Supporting Object Manipulation

In addition to multiple motor systems (arm, hand, postural), most natural object manipulation tasks engage multiple sensory systems. Vision can provide important information for planning and controlling task kinematics. For example, vision is used to locate target objects and to identify contact sites that are both stable and advantageous for actions we want to perform with the grasped object. Furthermore, visual cues about the identity, size, and shape of an object can be used for predictively adapting fingertip forces. For example, visual cues related to object weight and mass distribution can be used to predict force magnitudes and visual cues about shape to predict stable force directions. However, vision is of limited utility when objects are out of sight or partially occluded and for assessing contact sites for digits contacting the backside of objects. Furthermore, vision only provides indirect information about mechanical interactions that is based on statistical correlations learned through experience. Similarly, proprioception can only provide indirect information about contact mechanics. For example, signals related to muscle length, joint angle, and muscle force do not directly code the contact state between the hands and objects, and the sensitivity of nondigital

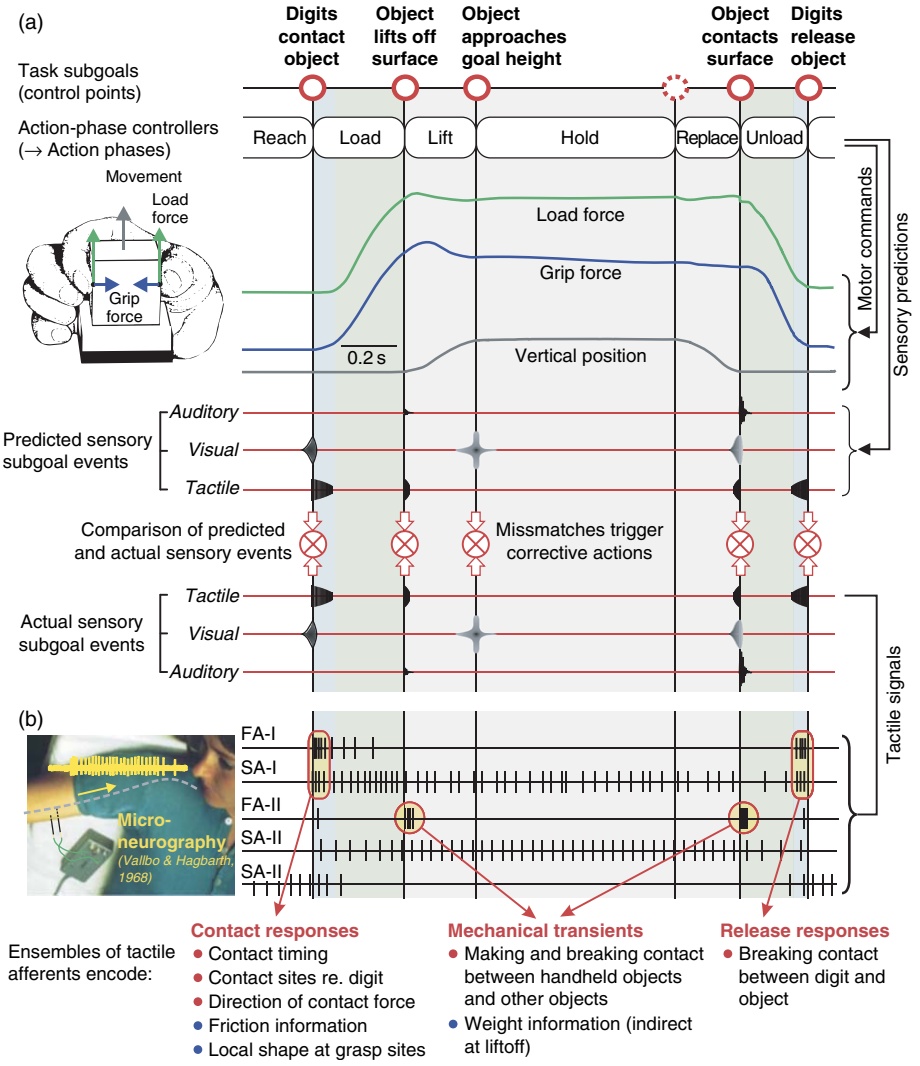

Figure 1 A person grasps and lifts an instrumented test object from a table, holds it in the air, and then replaces it, using the precision grip. (a) The contact events shown at the top define subgoals of the task (i.e., goals of each action phase). Sequentially implemented action-phase controllers generate motor commands that bring about the required action phases. After digits contact the object, the grip force increases in parallel with the tangential (load) force applied during isometric conditions to the object to overcome gravity. When the load force overcomes the force of gravity, the object lifts off. After the object is replaced such that it contacts the support surface, the load and grip forces decline in parallel until the object is released. In conjunction with generating motor command, the action-phase controllers predict internally the sensory consequences of these commands in one or more modalities (predicted sensory subgoal events) whereas the actual sensory consequences are signaled in one or more modalities (actual sensory subgoal events). For example, when the object is replaced on the surface, the contact between the object and the surface gives rise to tactile, visual, and auditory sensory events. By comparing predicted and actual sensory events, the sensorimotor system can monitor task progression and detect mismatches used to bring about corrective actions tailored to the action phase (see Figures 7 and 8). The predicted sensory events from each action phase can be used to provide initial state estimates for the next phase (not illustrated). (b) Schematic illustration of signals in four types of tactile afferents innervating the human fingertips as recorded from the median nerve at the level of the upper arm using the technique of microneurography. At four points corresponding to subgoal events of the task, tactile afferents show distinct burst discharges: (1) contact responses preferentially in fast-adapting type I (FA-I) and slowly adapting type I (SA-I) afferents when the object is first contacted, (2) responses in the fast-adapting type II (FA-II) afferents related to the mechanical transients at liftoff, and (3) when objects contact the support surface, and (4) responses primarily in FA-I afferents when the object is released (goal of the unloading phase). In addition to these event-related responses, slowly adapting type II (SA-II) afferents and many SA-I afferents show ongoing impulse activity when forces are applied to the object. Some spontaneously active SA-II units are unloaded during the lift and cease firing. (a) Compiled from data presented in Westling, G. and Johansson, R. S. 1987. Responses in glabrous skin mechanoreceptors during precision grip in humans. Exp. Brain Res. 66, 128–140. (b) From Vallbo, Å. B. and Hagbarth, K.-E. 1968. Activity from skin mechanoreceptors recorded percutaneously in awake human subjects. Exp. Neurol. 21, 270–289.

mechanoreceptive afferents (e.g., musculotendinous afferents) to fingertip events is very low in comparison to that of tactile sensors (*cf.* Macefield, V. G. and Johansson, R. S., 1996; Macefield, V. G. *et al.*, 1996; see also Häger-Ross, C. and Johansson, R. S., 1996).

Conversely, the tactile sensors directly provide information about mechanical interactions and thus play a pivotal role in the control of dexterous manipulation. The importance of tactile afferent signals in manipulation tasks is most apparent in people with impaired digital sensibility who have great difficulty with routine tasks even under visual guidance. For example, they often drop objects, may easily crush fragile objects, and have tremendous difficulties with everyday activities such as buttoning a shirt or picking up a match. About 2000 tactile afferents innervate each fingertip and some 10 000 afferent neurons innervate the remaining glabrous skin on the volar surface of the digits and the palm. As discussed below, these afferents provide various types of contact information critical for the control of the hands in dexterous object manipulation (see also Figure 1(b)). Because tactile information in object manipulation is used in control processes that generally operate automatically, transiently, and quickly, traditional studies of tactile sensory mechanisms, where perceptual (declarative) phenomena are examined in psychophysical experiments, provide limited information about the function of these mechanisms in manipulation.

6.05.2.1 Tactile Sensory Innervation of the Human Hand

Microneurography recordings of signals in single peripheral neurons in humans have shown that four different types of tactile afferents supply the inside of the hand (Johansson, R. S. and Vallbo, Å. B., 1983; Vallbo, A. B. and Johansson, R. S., 1984). Figure 2 summarizes characteristic features of these four types of afferents. Two types, termed fast-adapting type I (FA-I) and fast-adapting type II (FA-II) afferents, respond only during dynamic phases of tissue deformation. The other two types, called slowly adapting type I (SA-I) and slowly adapting type II (SA-II) afferents, respond to sustained skin deformation with a graded sustained discharge.

The type I afferents (FA-I and SA-I) terminate in end organs located at the dermal–epidermal margin. If delineated by weak point indentations of the skin, both types have small and well-defined cutaneous receptive fields ($\sim$10 mm^2), which in humans comprise multiple ($\sim$4–17) highly sensitive zones corresponding to individual terminal branches of the afferent axon (Johansson, R. S., 1978; Phillips, J. R. *et al.*, 1992). The receptive fields of both types exhibit enhanced representations of spatial discontinuities with comparable spatial resolution when tested with edge contours indenting the skin (Johansson, R. S. *et al.*, 1982b) and embossed dots scanned over the receptive field (Phillips, J. R. *et al.*, 1992). Their density in the skin increases stepwise in the distal direction of the hand (Figure 2(a)) and is especially high in the very tips of the digits where there are $\sim$140 FA-I afferents and $\sim$70 SA-I afferents per square centimeter of skin area (Figure 2). Hence, these afferents can transmit detailed spatial information about mechanical fingertip events, including the location and distribution of contact events. The FA-I and SA-I afferents provide complementary temporal information, with the SA-Is encoding static tissue deformations and deformation changes of lower frequencies (Johansson, R. S. *et al.*, 1982a). Accordingly, intraneural microstimulation of FA-I afferents typically evokes subjective sensations akin to wobbling, fluttering, or tapping feelings that are sharply delimited on the skin surface whereas stimulation of SA-I afferents typically evokes sensations of light pressure located more diffusely slightly below the skin surface (Vallbo, A. B. *et al.*, 1984; Torebjörk, H. E. *et al.*, 1987).

The predominance of FA-I afferents in the hand, and especially in the fingertips, indicates the premium placed on extracting with high-fidelity spatiotemporal features of dynamic mechanical events. Such events occur when objects are contacted and are often superimposed on low-frequency and large forces typically present when holding and maneuvering objects, including tools. Indeed, there is a predominance of FA-I afferents (or afferents similar to FA-Is) on other body areas used for accurate object interactions, such as the lips, the tip of the tongue (Trulsson, M. and Essick, G. K., 1997), and the sole of the foot (Kennedy, P. M. and Inglis, J. T., 2002). In contrast, hairy skin areas have no Meissner corpuscles (i.e., no FA-I sensors) and a predominance of slowly adapting sensors (Nordin, M. and Hagbarth, K. E., 1989; Edin, B. B. and Abbs, J. H., 1991; Edin, B. B. *et al.*, 1995; Vallbo, A. B. *et al.*, 1995).

The type II afferents (FA-II and SA-II) innervate the hand with a lower and more uniform density compared to the type I afferents. Their cutaneous receptive fields are an order of magnitude larger (Johansson, R. S., 1978), presumably partly because they terminate in the deeper dermal and subdermal

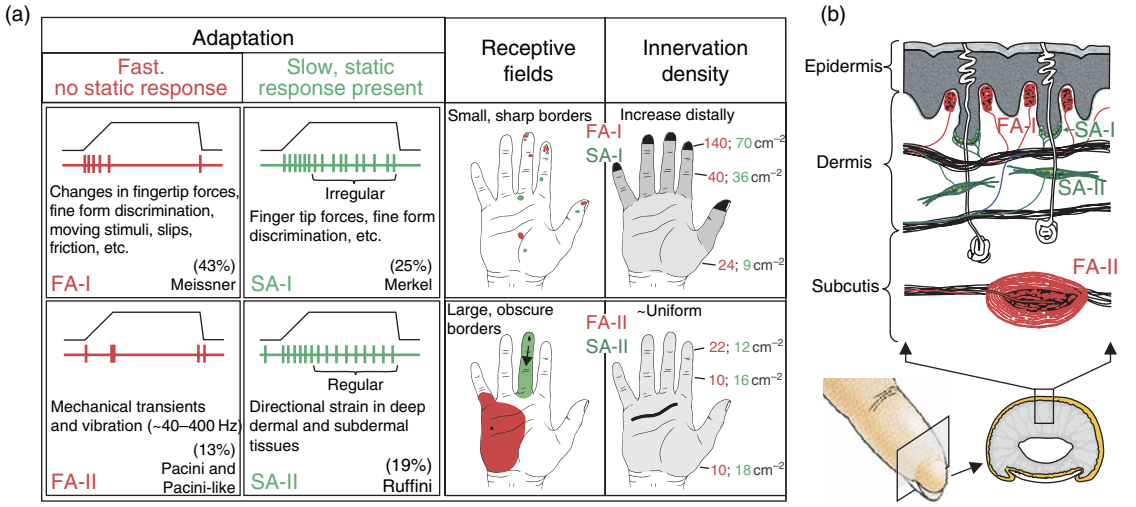

Figure 2 Types of tactile (mechanoreceptive) sensors in the glabrous skin of the inside of the human hand. (a) Graphs schematically show the impulse discharge (lower traces) to perpendicular ramp indentations of the skin (upper traces) for each sensor type. Two types (fast-adapting type I (FA-I) and fast-adapting type II (FA-II)) show fast adaptation to maintained tissue deformation, i.e., they only respond to deformation changes. These afferents were originally termed RA (rapidly adapting) and PC (Pacinian). Two types adapt slowly (slowly adapting type I (SA-I) and slowly adapting type II (SA-II)), that is, they show an ongoing response related to the strength of maintained tissue deformation. The type I sensors (FA-I and SA-I) have small and well-defined cutaneous receptive fields (typically 10 mm^2) when defined by light pointed stimuli (patches in the drawing of the hand represents the fields of 15 different sensors). The density of these sensors increases stepwise in the proximo-distal direction of the hand, with one step from the palm to the main parts of the digits and one at the border between the proximal to the distal half of the distal phalanx (see the rightmost drawing of the hand where the number of afferents per square centimeter of skin area is indicated for the fingertips, fingers, and palm, respectively). In contrast, the fast-adapting type II (FA-II) and SA-II sensors show lower and about uniform densities over the hand and their receptive fields are larger and less well defined. The FA-IIs are especially responsive to mechanical transients that propagate through the tissues whereas the SA-IIs sense strain in the dermal and subdermal fibrous tissues, often with a remote origin. The relative frequency of occurrence in the glabrous skin and the probable morphological correlate are indicated for each type of sensor. (b) Diagrammatic vertical section of a fingertip showing the organized nerve terminals corresponding to the four types of tactile sensors. Compiled from data reviewed in Johansson, R. S. and Vallbo, Å. B. 1983. Tactile sensory coding in the glabrous skin of the human hand. Trends Neurosci. 6, 27–31 and in Vallbo, A. B. and Johansson, R. S. 1984. Properties of cutaneous mechanoreceptors in the human hand related to touch sensation. Hum. Neurobiol. 3, 3–14.

tissues (Figure 2(b)). The FA-II afferents efficiently encode transient mechanical events containing high frequencies (~40–400 Hz) because of high-pass filtering properties of their end organs (Pacinian and Pacinian-like corpuscles) (Loewenstein, W. R. and Skalak, R., 1966). Such events arise in manipulation tasks when handheld objects form and break contacts with other objects and give rise to traveling waves in the tissues that can excite FA-II afferents located remotely from the contact areas. For example, it has been estimated that some 500–1000 FA-II afferents respond at liftoff and at support contact when objects are lifted and replaced, as illustrated in Figure 1 (Westling, G. and Johansson, R. S., 1987). The SA-II afferents sense directional strain in deep dermal and subdermal tissues (Johansson, R. S., 1978), including shear strain generated by forces tangential to the skin in object manipulation tasks (Westling, G. and Johansson, R. S., 1987). The fact that afferents with functional and structural properties akin to the type II afferents of the hand terminate in all fibrous tissues in the body, e.g., interosseous membranes, muscle fascias, and joint capsules and ligaments, suggests that they constitute a general mechanoreceptive system that supports proprioceptive in addition to tactile function.

6.05.2.2 Deformational Properties of the Fingertips and Coding of Tactile Information in Ensembles of Afferents

Signals in ensembles of afferents from the entire distal phalanx can contribute to the encoding of tactile information in natural object manipulation tasks because the interaction between the fingertips and objects typically causes widespread distributions of complex stresses

and strains throughout the engaged fingertips, including in the skin (Birznieks, I. *et al.*, 2001; Jenmalm, P. *et al.*, 2003). Hence, afferents that terminate outside regions of direct contact with objects can be vigorously excited, including FA-I and SA-I afferents, and constitute a part of the population code (Figure 3(b)). This applies, for example, to the encoding of fingertip force direction. Firing rates of individual tactile afferents distributed over the fingertips are tuned broadly to a preferred direction of fingertip force and this preferred direction varies amongst afferents such that ensembles of afferents can encode force direction (Figure 3(c) and 3(d)) (Birznieks, I. *et al.*, 2001). Directional preferences of individual afferents of specific types could, for example, be combined in population models such as the vector model of direction proposed for neurons in the motor cortex (Georgopoulos, A. P. *et al.*, 1986) and for encoding the direction of tooth loads by periodontal mechanoreceptors (Trulsson, M. *et al.*, 1992). In a similar vein, it has been proposed that the centroid of the population response can encode the position of a stimulus on the skin surface (Goodwin, A. W. and Wheat, H. E., 2004).

Firing rates in ensembles of tactile afferents also encode shape of contacted surfaces. Most studies of neural encoding of shape have concerned fine form

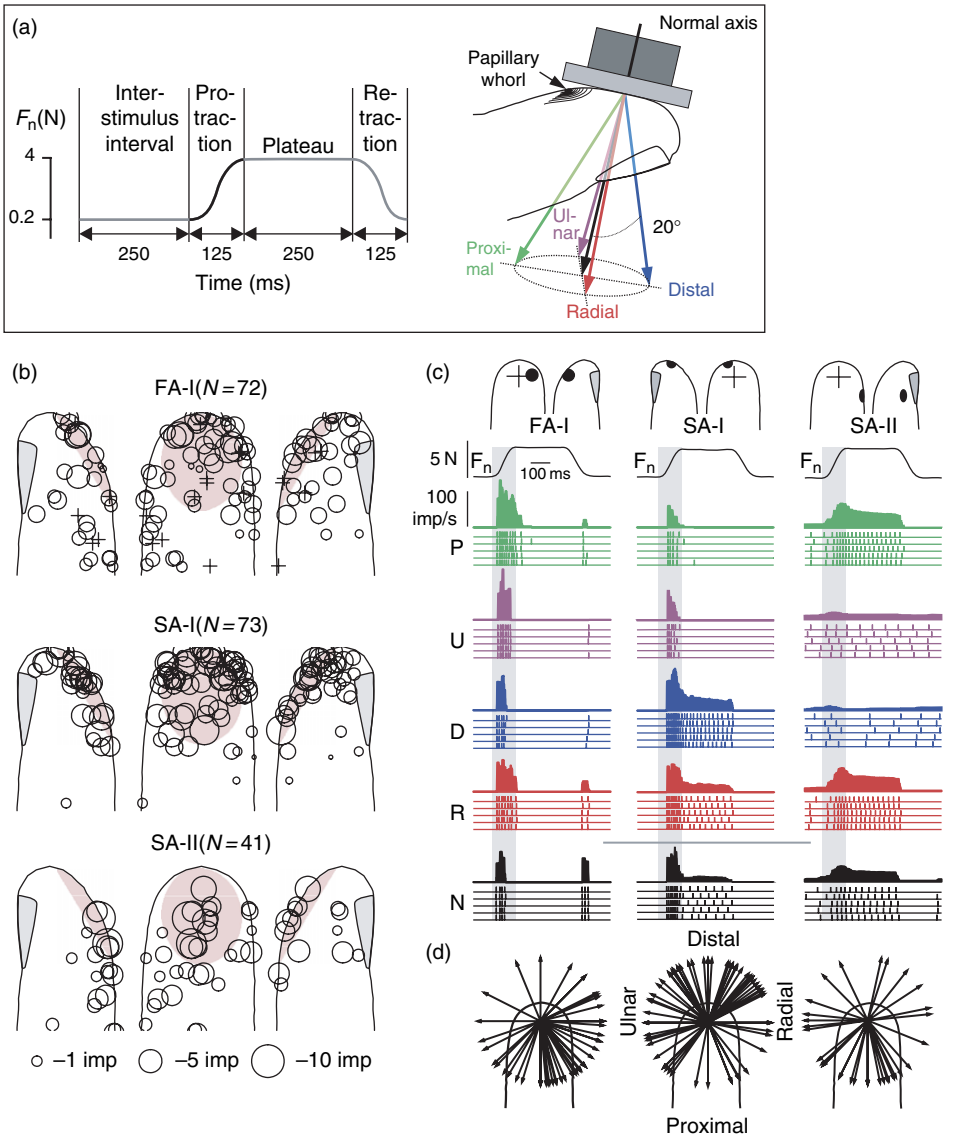

Figure 3 (*Continued*)

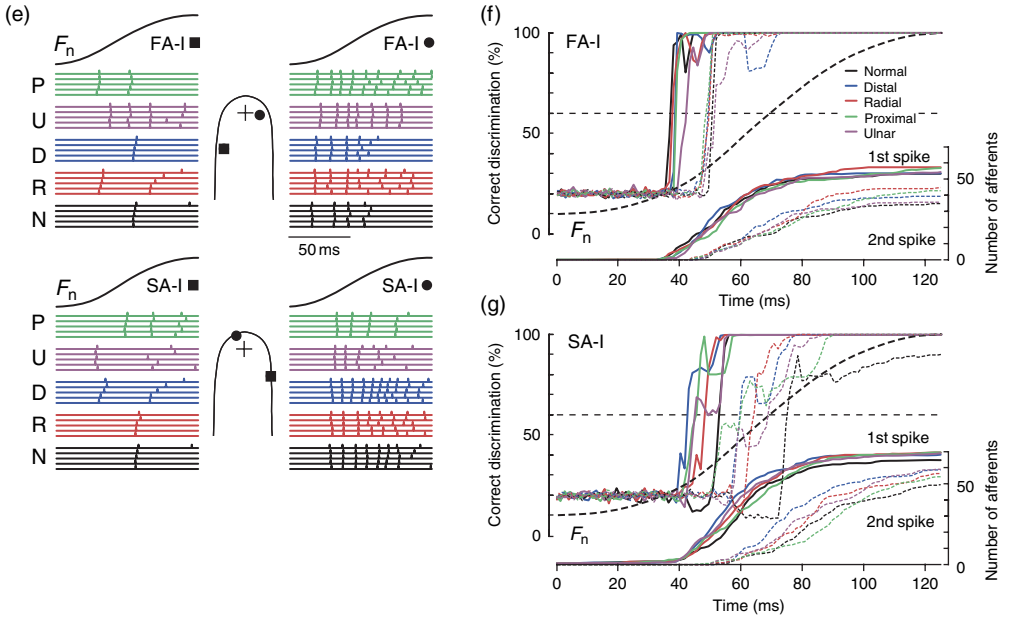

Figure 3 Signals in human tactile afferents under stimulation conditions representative for object manipulation tasks: Encoding of direction of fingertip forces. (a) Superimposed on a 0.2 N normal force (F_n), force was applied to the fingertip in the normal direction only (N), together with tangential components in the proximal (P), ulnar (U), distal (D), or radial (R) directions. Each stimulus consisted of a force protraction phase (125 ms), a plateau phase (4 N force), and a retraction phase (125 ms) and was applied with a flat contact surface at a standard site on the fingertip that serves as a primary target for object contact in grasping and manipulation of small objects. (b) The centers of the circles mark the location of the centers of the receptive fields of 186 tactile afferents, and the area of the circles represents the number of impulses evoked during the protraction phase with stimuli in the normal direction only. Nearly all afferent responded; crosses indicate locations of sampled afferents that did not respond. Pink zone represents the area of contact at 4 N normal force. (c) Impulse ensembles exemplifying responses in a single highly responsive fast-adapting type I (FA-I), slowly adapting type I (SA-I), and slowly adapting type II (SA-II) afferent to repeated force stimuli ($n = 5$) applied in each force direction (P, U, D, R, and N). Traces above show the instantaneous discharge frequency averaged over the five trials. Top traces show the normal force component (F_n) superimposed for all trials. Circles on the finger indicate the location of the afferents' termination and the cross the primary site of stimulation. (d) Distributions of preferred direction of tangential force components for 68 SA-I, 53 FA-I, and 32 SA-II afferents from the fingertip shown as unit vectors (arrows) with reference to the primary site of stimulation. These afferents terminate at various locations on a terminal phalanx (*cf*. (b)). Preferred directions were estimated by vector summation of the mean firing rates during the force protraction phase (gray zone in (c)) obtained with different directions of the tangential force component. (e–g) Discrimination of force direction by FA-I and SA-I afferents based on the relative timing of first spikes and on first-interspike intervals. Impulse ensembles in (e) exemplify responses during the force protraction phase in two FA-I and two SA-I afferents to repeated force stimuli ($n = 5$) applied in each of five force directions (see (a)). Force direction influenced consistently the first-spike latencies of all of these afferents. (f and g) Top graph: Solid curves show the probability of correct discrimination of stimuli in each of the five force directions (coded by different colors) by afferents' recruitment sequence as a function of time during the force protraction phase; dashed curve shows the development of the normal force component (F_n). Horizontal line indicates the probability for one-half of the stimuli being discriminated correctly, i.e., with force direction a probability of 60% given that chance performance is 20% (i.e., five force directions). Thin dashed curves show the time-varying probability of correct discrimination based on first-interspike intervals. Bottom graph: Solid curves give the number of sampled afferents recruited as a function of time for stimuli in each force direction, i.e., cumulative distributions of first-spike latencies. Thin dashed curves show the corresponding data for the second spike. (a–d) Adapted from Birznieks, I., Jenmalm, P., Goodwin, A., and Johansson, R. 2001. Encoding of direction of fingertip forces by human tactile afferents. J. Neurosci. 21, 8222–8237 and (e–g) from Johansson, R. S. and Birznieks, I. 2004. First spikes in ensembles of human tactile afferents code complex spatial fingertip events. Nat. Neurosci. 7, 170–177.

geometric features (e.g., Braille-like patterns and gratings), including markedly curved surfaces (radii $<\sim 5$ mm, i.e., curvatures $>\sim 200\ m^{-1}$), gently stimulating the fingertips in monkeys (Johnson, K. O., 2001; Goodwin, A. W. and Wheat, H. E., 2004). Such stimuli primarily engage afferents that terminate in the area of contact. However, objects that humans grasp in most everyday situations (e.g., cups, knobs, handles,

pens, fruit) involve larger curvatures (curvatures $\leq \sim 200\ m^{-1}$), and the control of fingertip actions in dexterous object manipulations depends critically on tactile information about these gross geometrical features (Jenmalm, P. and Johansson, R. S., 1997; Jenmalm, P. *et al.*, 2000). Recent findings in humans suggest that, in contrast to the encoding of fine form shapes, encoding of gross shapes engages ensembles of afferents terminating over the entire terminal phalanx (Jenmalm, P. *et al.*, 2003). Shape changes robustly influence firing rates in the majority of responsive SA-I, SA-II, and FA-I afferents, including afferents that terminate at the sides and end of the fingertip. For each afferent type, roughly half the afferents for which response intensity correlate with curvature showed a positive correlation and half a negative correlation (Figure 4(a) and 4(b)); afferents terminating at the sides and end of the fingertip tend to show negative correlations. Consequently, there is a curvature contrast signal within the populations of tactile afferents. This contrast signal may aid curvature recognition even though the overall discharge rates of afferent populations are influenced by various factors, e.g., the magnitude, direction, and rate of change of the contact force and changes in viscoelastic properties of the fingertip related to previous interactions with objects. Although the FA-I, SA-I, and SA-II afferents

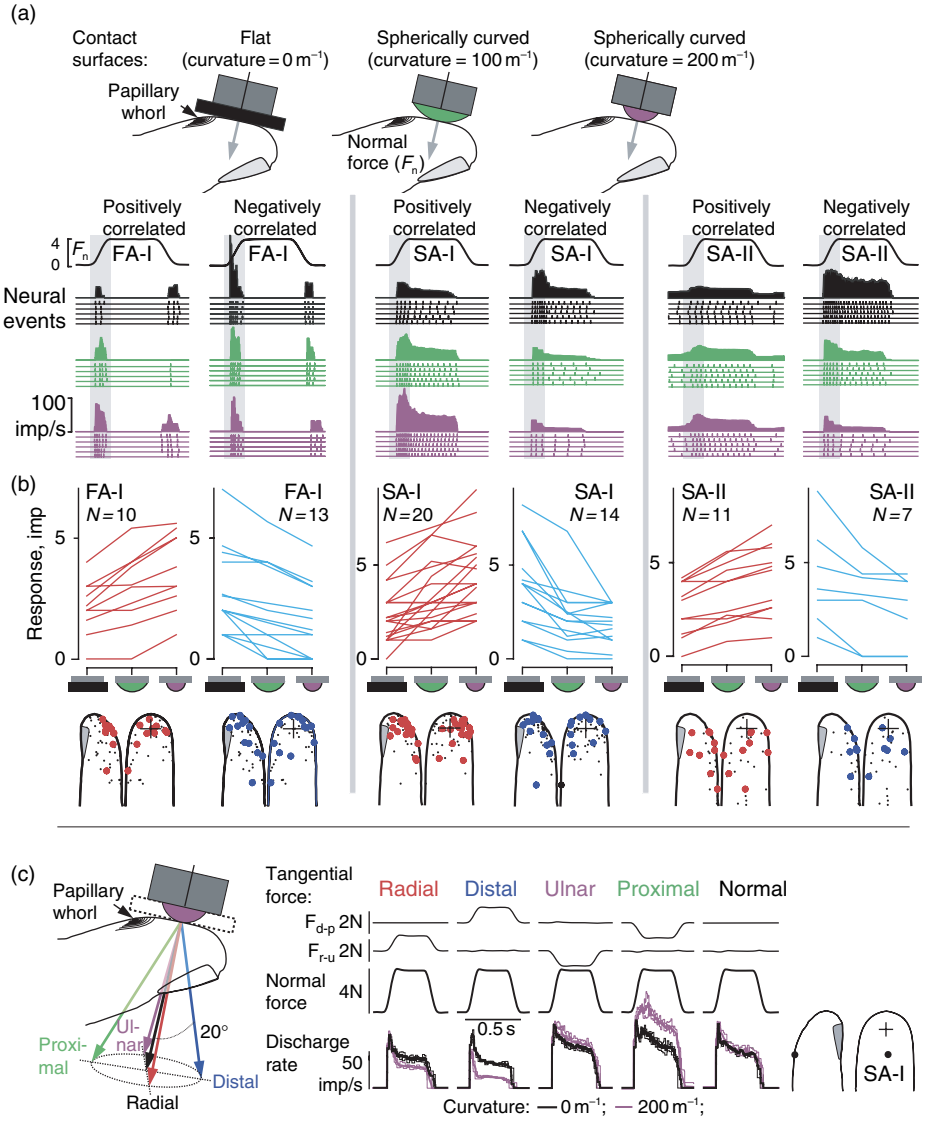

Figure 4 (*Continued*)

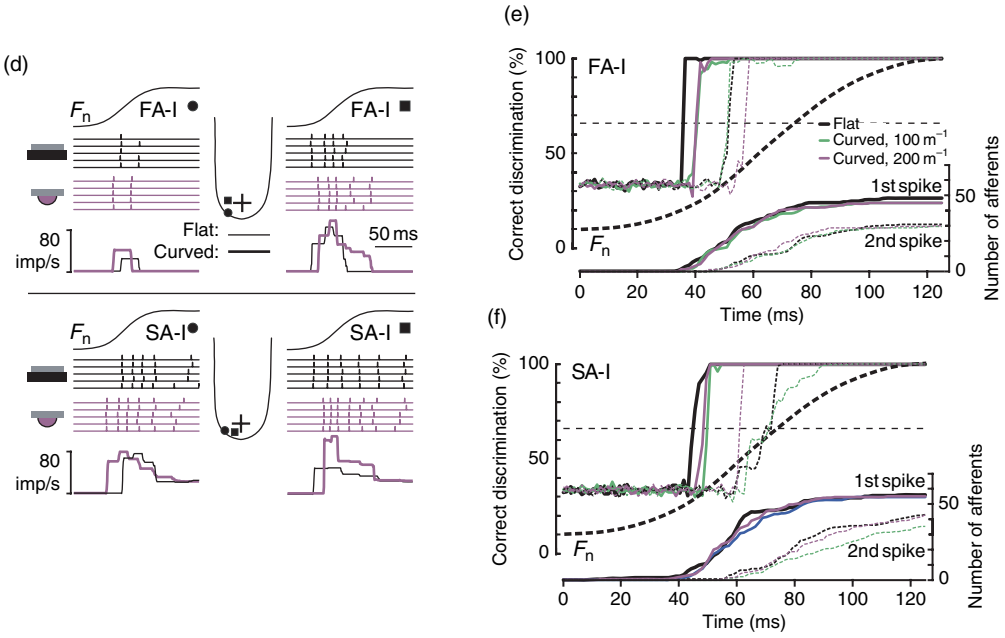

Figure 4 Signals in human tactile afferents under stimulation conditions representative for object manipulation tasks: Encoding of shape of spherically curved surfaces contacting the fingertips. (a) Impulse ensembles show responses to repeated stimuli ($n = 5$) of two single fast-adapting type I (FA-I), slowly adapting type I (SA-I), and slowly adapting type II (SA-II) afferents with forces applied in the normal direction with each of three surface curvatures 0, 100, and 200 m^{-1} (force stimulation as in Figure 3(a)). Traces above show the instantaneous discharge frequency averaged over the five trials. Top traces show the normal force. Left and right panels for each afferent type represent afferents for which response intensity increased (positively correlated) and decreased (negatively correlated) with an increase in curvature. (b) Left and right panels show, for each type of afferent, afferents with responses positively and negatively correlated with surface curvature, respectively; response is represented as the mean number of impulses evoked during the protraction phase (gray zone in (a)) with each curvature. Solid circles on the fingertip indicate the location of the receptive field centers of the afferents and the cross the stimulation site; the side view of the fingertip includes afferents located on either side of the finger. (c) Interaction effects between curvature and force direction on afferent responses illustrated by responses in one SA-I afferent during stimulation with forces in five directions (see Figure 3(a)) with the flat (0 m^{-1}) and most curved (200 m^{-1}) surface. Force profiles shown for the normal force component and for the tangential force components ($F_{d\text{-}p}$, $F_{r\text{-}u}$); radial, distal, ulnar, and proximal refer to the direction of the tangential force component. Profiles of instantaneous discharge frequency show responses to the 0 and 200 m^{-1} curvature; the center line indicates the mean instantaneous firing rates averaged over repeated stimuli ($n = 5$) and the thin lines represent the recorded maximum and minimum of the five rates. The dots on the fingertip indicate the afferents' receptive field center, the cross marks the stimulation site. (d–f) Discrimination of shape of stimulus surface by FA-I and SA-I afferents based on relative timing of the first spikes evoked in ensembles of tactile afferents and on the first-interspike intervals. (d) Impulse ensembles illustrate the effect of shape of stimulus surface on first-spike latencies of two single FA-I and SA-I afferents during five normal force stimuli with the flat (0 m^{-1}) and the most curved surface (200 m^{-1}). Traces above show normal force (F_n) and traces below instantaneous discharge frequency averaged over the five trials. Surface influenced consistently the first-spike latencies of all of these afferents. (e and f) Solid curves in the top graph show the probability of correct discrimination of each shape (coded by different colors) based on afferents' recruitment sequence as a function of time during the force protraction phase. Thin horizontal line indicates the probability for one-half of the stimuli being discriminated correctly, i.e., a probability of 66.5% given that chance performance is 33.3%. See caption of Figure 3(e–g). (a–c) Adapted from Jenmalm, P., Birznieks, I., Goodwin, A. W., and Johansson, R. S. 2003. Influences of object shape on responses in human tactile afferents under conditions characteristic for manipulation. Eur. J. Neurosci. 18, 164–176 and (d–f) from Johansson, R. S. and Birznieks, I. 2004. First spikes in ensembles of human tactile afferents code complex spatial fingertip events. Nat. Neurosci. 7, 170–177.

might all contribute information on object shape and contact forces, the SA-II population likely provides coarser information than the SA-I and especially the FA-I populations because of the lower innervation density of SA-II afferents.

Because tactile afferents respond to the complex patterns of strain/stress that occur in the fingertip when objects are contacted, various contact parameters can show complex interaction effects on the afferent responses. Interactions between force

direction and object shape on the responses of SA-I, SA-II, and FA-I afferents have been demonstrated (Jenmalm, P. *et al.*, 2003). That is, changing the direction of force generally affects an afferent's sensitivity to curvature and *vice versa*. Figure 4(c) illustrates such an interaction for a single SA-I afferent. How the brain deals with interactions among different parameters of fingertip stimulation in natural tasks poses important problems for future research. Presumably, many computational requirements for decoding tactile messages in manipulation tasks are satisfied by the somatosensory pathways functionally modeling the mechanics of the fingertips in the tactile sensory domain by, in effect, filtering information predictively in a manner that depends on context, task, and task phase. For example, corollary discharges associated with the execution of action plans (Sommer, M. A. and Wurtz, R. H., 2002) could, through descending corticothalamic, corticocuneate, and corticospinal projections, dynamically control the signal processing in ascending somatosensory pathways (Harris, F. *et al.*, 1965; Adkins, R. J. *et al.*, 1966; Ergenzinger, E. R. *et al.*, 1998). As such, there is ample evidence that the processing of sensory stimuli is controlled by top-down influences that constantly create predictions about forthcoming sensory events (Engel, A. K. *et al.*, 2001) including contract events (Bays, P. M. *et al.*, 2005).

6.05.2.3 Relative Spike Timing Provides Fast Information about Mechanical Fingertip Events

Traditionally, it is posited that tactile information is coded by the firing rates of afferents. To estimate firing rates, at least two impulses in a given neuron are required and given the stochastic properties of interspike intervals, reliable rate estimation may require that neural responses be averaged over a substantial time window and over several trials. However, in manipulation, typically, the brain quickly extracts information from dynamic tactile events and expresses this information in fingertip actions faster than can be readily explained by rate codes. Recent findings indicate that the relative timing of impulses from ensembles of individual different afferents conveys information about important contact parameters faster than the fastest possible rate code and fast enough to account for the use of tactile signals in natural manipulation (Johansson, R. S. and Birznieks, I., 2004). Specifically, the sequence in which different afferents initially discharge in response to discrete fingertip events provides information about the direction of fingertip force and the shape of the contacted surface. Presumably, the order of recruitment of members of the populations of tactile afferents can code other parameters of tactile stimuli used in the control of manual actions as well.

The relative timing of the first spikes contains information about force direction and object shape because changes in either of these parameters differentially influences the first-spike latency of individual afferents rather than having systematic effects on the latencies within an afferent population (Figures 3(e) and 3(g) and 4(d) and 4(f)). For example, with a single stimulus delivered to the fingertip in a given force direction, the responsive afferents will be recruited in a particular order. With another force direction, the order will be different because some afferents are recruited earlier and others later. The efficacy of this code for conveying early information to the brain depends on the variability and noise in first-spike latencies and the speed of recruitment of afferents. The FA-I population provide correct discrimination faster than the SA-I afferents of both force direction (*cf.* Figure 3(f) and 3(g)) and surface curvature (*cf.* Figure 4(e) and 4(f)). Effective discrimination takes place after as few as some five FA-I afferents are recruited, which occur a few milliseconds after the appearance of the first impulse in the population response (Figure 3(f) and 3(e)). For the SA-Is, about twice as many (but still very few) afferents had to be recruited for reliable discrimination primarily because of a larger variability in first-spike latencies. Even under the most favorable conditions, discrimination based on firing rates (first-interspike rate) takes on average 15–20 ms longer than discrimination based on first-spike latency (*cf.* dashed and solid curves in Figure 3(f) and 3(g) and 4(e) and 4(f)). Populations of SA-II are much poorer in discriminating force direction or object shape based on both first-spike latencies and firing rate, in part because of the background discharge in many of these afferents. Encoding and decoding of sensory information based on the timing of neural discharges, rather than (or in addition to) their rate, has received increasing attention in the past decade and it has become clear that the timing, with precision in the order of milliseconds or even less, of individual spikes can carry far more information than average rates alone (Heil, P., 2004; VanRullen, R. *et al.*, 2005).

6.05.3 Predictions and Control Points in the Tactile Modality

6.05.3.1 Control of Reach

Most manipulation tasks require that we first reach for the object to grasp it. One goal of this reach phase is to place the fingertips on the object in locations that will allow the development of a stable grasp in the context of the actions that will be performed with the object. Likewise, it is usually important that the fingertips contact the object at around the same time and that the fingertip force vectors sum to zero. These and other features of the contacts between the fingertips and object are robustly encoded by tactile signals. For each digit, contact responses in ensembles of afferents convey information about contact timing, the contact location on the digit, and the direction of contact force (Figure 1(b) and 3). Thus, the initial contact events represent control points where predicted and actual sensory feedback related to object geometry, location, and orientation can be compared. Mismatches between predicted and actual contact responses can be used to calibrate and uphold calibration of future reach commands (Gentilucci, M. *et al*., 1997; Lackner, J. R. and DiZio, P. A., 2000; Rao, A. K. and Gordon, A. M., 2001; Monzée, J. *et al*., 2003; Säfström, D. and Edin, B. B., 2004).

6.05.3.2 Control of Grasp Stability

After contact is obtained with an object, most manipulation tasks require application of forces tangential to the contacted surfaces (load forces). For example, to lift an object with the digits at the sides, vertical load forces must be applied to overcome the weight of the object (Figure 1(a)). If we lift a bar from one end, we must also apply tangential torque to prevent it from rotating when lifted. To deal with these potentially destabilizing tangential forces, the motor system generates grip forces normal to the grasped surface that are synchronous with, and proportional to, the tangential loads applied (Figures 1(a) and 5) (Johansson, R. S. and Westling, G., 1984a; Goodwin, A. W. *et al*., 1998; Johansson, R. S. *et al*., 1999). The grip forces are strong enough to prevent the object from slipping (either linearly or rotationally), while at the same time not excessive. This coordination of grip and load force supports grasp stability in virtually all maneuvers that we perform with objects. For example, it operates at the level of individual digits when people use two or more digits of the same or both hands to lift and further manipulate objects (Edin, B. B. *et al*., 1992; Flanagan, J. R. *et al*., 1999). Likewise, grip forces predict changes in load forces on a hand-held object that occur when we jump up and down (Flanagan, J. R. and Tresilian, J. R., 1994) and in bimanual tasks where the hands have different and complementary roles, such as when we use one hand to add things into, or remove things from, a receptacle held by the other hand (Johansson, R. S. and Westling, G., 1984a; 1988b). Coupling between grip and load forces also operates when we move objects with different complex dynamics (combinations of inertial, elastic and viscous loads) even though this involves altering the mapping between motor commands that generate load forces and those that generate grip forces (Flanagan, J. R. and Wing, A. M., 1997).

The control of grasp stability requires, however, that the balance between the grip and load forces be adapted to the properties of the contacted surfaces. Indeed, irrespective of surface friction and object shape, people typically use grip forces that exceed the minimum required to prevent slips by a safety margin of 10–40% of the applied grip force (gray areas in the force coordination plots of Figure 5). By varying the ratio between grip force change and load force change, people parametrically adapt to different frictional conditions and use greater grip forces with more slippery surfaces (Figure 5(b)). In the same vein, they adapt the grip-to-load force ratio to the shape of the contacted surface. For example, when lifting tapered objects, a greater grip-to-load force ratio is required when the grip surfaces are tapered upward as compared to downward (Figure 5(c)). Similarly, the greater the curvature of a spherically curved grasp surface, the larger the grip force required to generate a given tangential torque (Figure 5(d)).

Tactile signals are critical for forming, updating, and upholding predictions used by action-phase controllers when adapting forces to object surface properties. Indeed, people with digital sensory impairments fail to adapt grip-to-load force ratios to object surface properties and, instead, consistently use large grip forces (*cf.* Figure 6(b) and 6(c)) (Johansson, R. S. and Westling, G., 1984a; Westling, G. and Johansson, R. S., 1984; Jenmalm, P. and Johansson, R. S., 1997; Jenmalm, P. *et al*., 2000; Monzée, J. *et al*., 2003; Nowak, D. A. *et al*., 2004). Signals in ensembles of tactile afferents – primarily in FA-Is – rapidly convey information related to

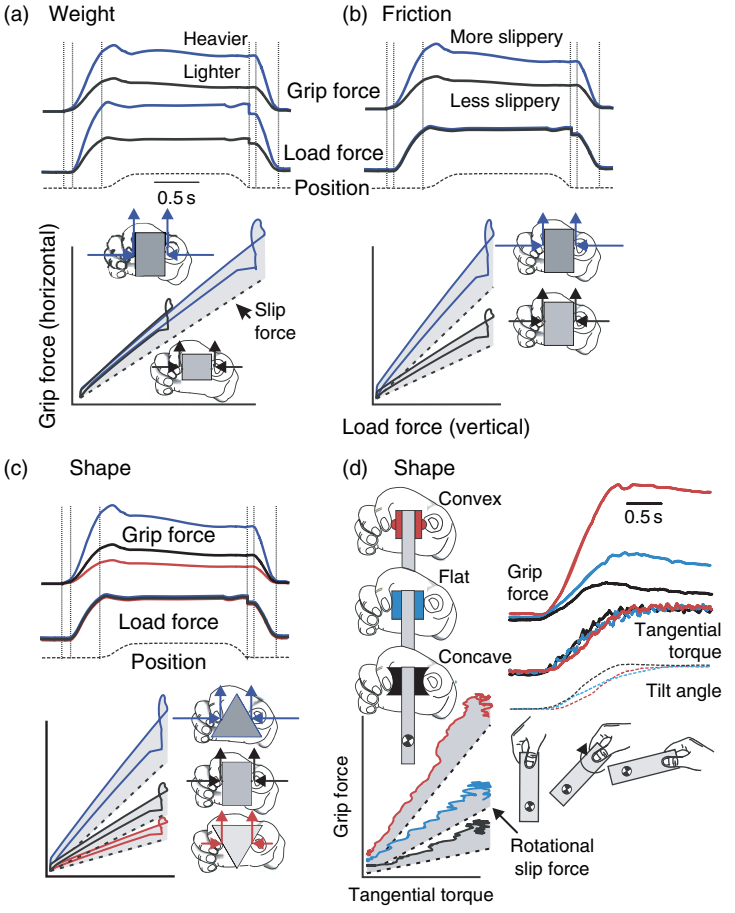

Figure 5 Parametric adjustments of fingertip forces to object weight, friction between the object and skin, and shape of the contact surface. (a–c) Subject lifts an instrumented test object from a table, holds it in the air, and then replaces it, using a precision grip (*cf*. Figure 1). Upper graphs show the horizontally oriented grip force, the vertically oriented load force (lift force), and the object's vertical position as a function of time for superimposed trials, indicated by differently colored curves. The lower graphs show the grip force as a function of the load for the corresponding data. Dashed lines indicate the minimum grip force to prevent slips; the safety margin against slips is indicated by hatching. (a) With weight variations the parallel change in grip and lift forces coordinated by the action-phase controllers ensures grasp stability when lifting objects of different weights. (b) The balance between grip force and load force is adjusted to deal with changes in friction. (c) A similar scaling of the grip-to-load force ratio is observed when object shape is varied. In either instance, the coordination of grip and load force ensures an adequate safety margin against slips. (d) An already lifted object is tilted by 65° around the grip axis, which caused tangential torques at the grasp surfaces. The three superimposed curves (color coded) refer to a trial with a spherically convex grip surface (radius 5 mm; curvature 200 m^{-1}), a flat (curvature 0 m^{-1}), and a spherically concave surface (radius 20 mm; curvature 50 m^{-1}). The top traces show the grip force, the tangential torque, and the tilt angle against time. Note the effect of surface curvature on the coordination between grip force and tangential torque, which is in the bottom graph that plots the grip force against tangential torque load for the corresponding data. The shading indicates a similar safety margin against rotational slips irrespective of curvature. (a, b) Adapted from Johansson, R. S. and Westling, G. 1984a. Roles of glabrous skin receptors and sensorimotor memory in automatic control of precision grip when lifting rougher or more slippery objects. Exp. Brain Res. 56, 550–564; Johansson, R. S. and Westling, G. 1988a. Coordinated isometric muscle commands adequately and erroneously programmed for the weight during lifting task with precision grip. Exp. Brain Res. 71, 59–71. (c) Jenmalm, P. and Johansson, R. S. 1997. Visual and somatosensory information about object shape control manipulative finger tip forces. J. Neurosci. 17, 4486–4499. (d) Goodwin, A. W., Jenmalm, P., and Johansson, R. S. 1998. Control of grip force when tilting objects: effect of curvature of grasped surfaces and of applied tangential torque. J. Neurosci. 18, 10724–10734, respectively.

surface friction (Figure 6(d)) and shape (Figures 4 and 7(a)) when a surface is contacted. Thus, the initial contact event represents a critical control point where predicted and actual sensory feedback related to surface properties can be compared. Mismatches between predicted and actual contact responses lead to an updating of the grip-load force coordination about 100 ms after contact. Figure 7(a)

illustrates such updating when repeatedly lifting objects with tapered grasp surfaces without visual cues about object shape. The tapering was changed between trials in a pseudo-random order. In all trials, the tapering (and hence force requirements) in the previous trial determined the initial increase in grip force. This indicates that predictions based on knowledge about the status of the object obtained in previous trials specify the force coordination. After a change in tapering, the grip force output is modified about 100 ms after contact with the object and tuned for the actual object properties (Figure 7(a)). By the second trial after the change, the force coordination is appropriately adapted right from the onset of force application. Thus, when a prediction error occurs, tactile information obtained at initial contact with the object rapidly initiates a corrective action accompanied with an updating of the representation of the object used to control forces in future interactions with the object. Knowledge about object surface properties remains critical for controlling grip forces for grasp stability when transporting held objects and using them as tools to impose forces on other environmental objects. A coupled decrease in the load and grip forces ensuring grasp stability also applies to the unloading phase where grip and load forces decrease in parallel in order to release an object placed on a support surface (Figures 1 and 5). Sensory events, especially in ensamples of FA-I afferents, related to the breaking of contact between the digits and the surface of the object represent the sensory goal of this phase (see release responses in Figure 1(b); see also responses in FA-I afferents to the retraction phase in Figures 3 and 4).

Under favorable conditions, visual geometric cues about object shape can provide state information for predictive parameterization of fingertip forces such that the grip-to-load force coordination is adapted to the prevailing shape right from the beginning of the force application (Figure 7(b)) (Jenmalm, P. and Johansson, R. S., 1997; Jenmalm, P. *et al.*, 2000). Once the object is contacted, tactile signals also provide state information about object shape that can override visual predictions if necessary. With regard to friction between the hand and an object, it appears that vision is unhelpful for feedforward adaptation of

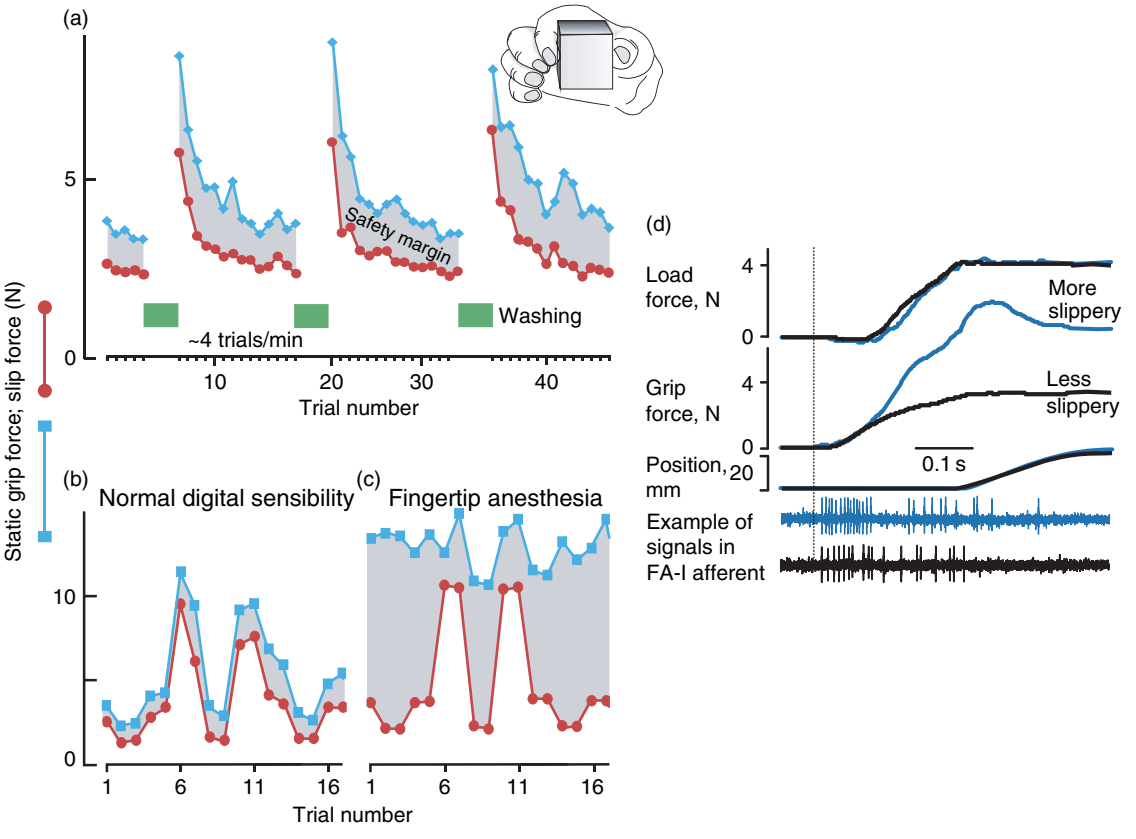

Figure 6 (*Continued*)

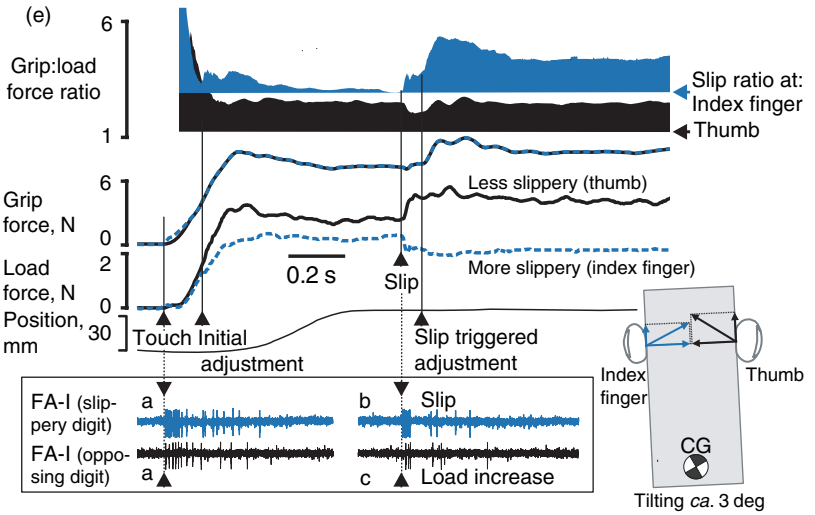

Figure 6 Adjustment of grip force to frictional changes in everyday situations. (a) Static grip force when holding an object in air using a precision grip (diamonds) and the corresponding minimum grip forces to prevent slips (slip force, dots) before and after the subject's hand was washed (soap and water) and dried (towel); 48 consecutive lifts with suede as surface structure (single subject, weight constant at 400 g). (b and c) Corresponding grip force data during frictional changes between lifts caused by changing the grasped surfaces among fine-grain sandpaper, and suede and smooth rayon, during normal digital sensibility (b) and with anesthetized finger tips (c). (d) The influence of friction on force output and initial contact responses in an fast-adapting type I (FA-I) afferent. Two lifting trials are superimposed, one with the grasped surfaces being less slippery (sandpaper; black lines) and a subsequent trial with more slippery surfaces (silk; blue lines). The sandpaper trial was preceded by a trial with sandpaper and therefore the force coordination is initially set for the higher friction. The vertical line indicates initial touch. (e) Digit-specific adjustments of force coordination to the frictional condition. The participant lifted a test object with low center of gravity (CG) from a support surface, and held it still in the air. The index finger contacted a more slippery surface (silk; blue curves) than that contacted by the thumb (sandpaper; black curves). The grip-to-load force ratio and corresponding slip ratios are shown for each digit; the blue and black areas indicate the safety margin to prevent slips at the index finger and at the thumb, respectively. In a previous lifting trial, both the index finger and the thumb had contacted fine-grain sandpaper. An initial adjustment to the new frictional condition occurs during the load phase, ~100 ms after the object is contacted. The index finger generates less load force than the thumb, which results in a higher grip-to-load force ratio at the index finger. A slip event occurring at the index finger later in the trial triggers a secondary adjustment to the frictional condition. The slip event is evident by a rapid decrease of the load force at that digit and a concomitant increase of the load force at the thumb. Less than 100 ms later, a grip force increase raises the grip-to-load force ratio at the index finger and restores the ratio at the thumb. Nevertheless, because of the uneven load force distribution between the digits, the test object tilts a bit when aloft. The inset shows signals in single FA-I afferents reconstructed based on microneurography recordings during similar lifting trials in a study by Johansson R. S. and Westling. G. (1987). Note the influence of the surface material on the impulse rate on the initial contact responses (a), the burst response to the slip in the afferent terminating in the tip of the slipping digit (b), and the response to the increase of the load force at the opposing digit. (a) Adapted from Johansson, R. S. and Westling, G. 1984b. Influences of Cutaneous Sensory Input on the Motor Coordination During Precision Manipulation. In: Somatosensory Mechanisms (*eds.* C. von Euler, O. Franzen, U. Lindblom, and D. Ottoson), pp. 249–260. Macmillan Press; (b and c) from Johansson, R. S. and Westling, G. 1991. Afferent Signals During Manipulative Tasks in Man. In: Somatosensory Mechanisms (*eds.* O. Franzen and J. Westman), pp. 25–48. Macmillan Press; (d) from Johansson, R. S. and Westling, G. 1987. Signals in tactile afferents from the fingers eliciting adaptive motor responses during precision grip. Exp. Brain Res. 66, 141–154; and (e) from Edin, B. B., Westling, G., and Johansson, R. S. 1992. Independent control of fingertip forces at individual digits during precision lifting in humans. J. Physiol. 450, 547–564.

force coordination. Presumably, this is because friction depends not only on the object surface but also on sweating rate and the greasiness and wetness of the skin (and objects) (Figure 6(a)). Thus, predictions of frictional conditions are based on the memory of recent haptic experiences with the same or similar objects. By varying the frictional condition independently at individual digits in two-digit and multidigit object lifting tasks it has been shown that the grip-to-load force ratios employed at each of the digits engaged can be independently controlled (Edin, B. B. *et al.*, 1992; Burstedt, M. K. O. *et al.*, 1999). When gripping and lifting an object using a precision grip, the digit that contacts a more slippery surface can exert less vertical lifting force than the digit in contact with a less slippery surface. Unpredicted

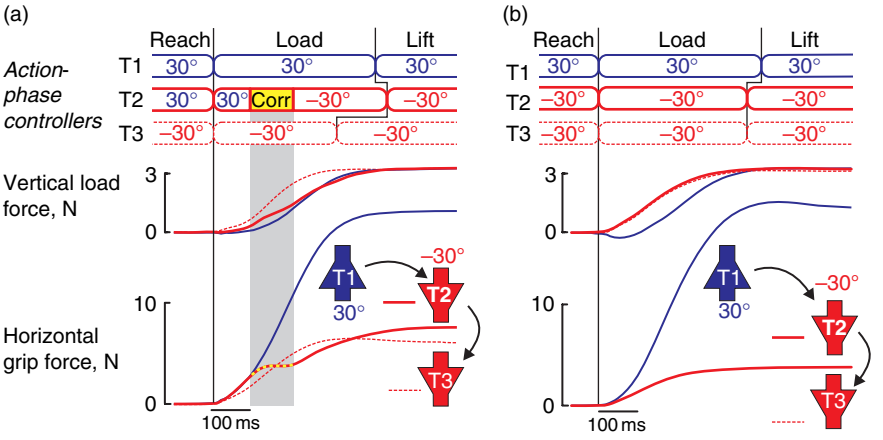

Figure 7 Adaptation of fingertip forces to changes in object shape. Vertical load force and horizontal grip force shown as a function of time for trials (a) without and (b) with vision of the contacted surfaces from a lift series in which surface angle was unpredictably varied between lifts. The blue curves refer to the last trial with the 30° object before the switch (T1; upward tapered grasp surfaces). (This trial was preceded by a trial with a 30° object.) The solid red curves show the next trial (T2) performed with the −30° object (downward tapered grasp surfaces). These curves thus illustrate adjustments to the smaller angle. The dashed yellow segment in the grip force curve in (a) indicates the epoch of the corrective action elicited by the new surface angle. The thin dashed red curves show the following trial, again with the −30° object. The top diagram represents the status of the sequentially implemented action-phase controllers. In T1 they are parameterized for the 30° object throughout. In T2, without vision of the contacted surfaces (a), a corrective action (Corr) is triggered about 100 ms after contact based on a mismatch between predicted and actual tactile information obtained at contact related to object shape. This action is interspersed during the loading phase and involves a change in the ratio between the grip force change and load force change, which, in turn, change the balance between grip and load forces to better suit the −30° object for the remainder of the trial (see also Figure 3(c)). In T3, the controllers remain updated to the −30° object. With vision of the contacted surfaces (b), visual cues about object geometry provide state information for anticipatory parametric adaptation of the motor output after the change in tapering (T2) and no corrective action is triggered. (a and b) Compiled from data presented in Jenmalm, P. and Johansson, R. S. 1997. Visual and somatosensory information about object shape control manipulative finger tip forces. J. Neurosci. 17, 4486–4499.

asymmetries in the frictional conditions at the digits can influence the development of the tangential forces during the load phase some 100 ms after contact (Figure 6(e)). Likewise, the average friction of the grasped surfaces influences the rate of increase of the grip force after this point.

Occasionally, the updating of frictional and shape representations that typically occurs at initial contact is inadequate and may result in an accidental slip later in the task. When an object is held in air after being lifted, such a slip usually results in a transitory and partial unloading at one digit (the slipping digit) and this increases the loads on the other digits engaged (Figure 6(e)). Such transient redistribution of the tangential force triggers a grip force increase. The net outcome is an increased safety margin at the slipping digit for the remainder of the task but a virtually unaffected safety margin at the other digits. This updated force coordination is used as default coordination for subsequent trials with the same object, again indicating that the force coordination is controlled by memory representations related to object properties. While slips during the hold phase lead to an increase in grip force, slips during the load phase in lifting lead to a slowing down of the subsequent increase in load force at the slipping digit (Johansson, R. S. and Westling, G., 1984a; 1987). Hence, different action-phase controllers are associated with different smart reflex mechanisms that support grasp stability and help achieve the current subgoal of the task.

6.05.3.3 Control of Motion of Objects in Hand

Tactile control points can also support planning and control of transport of grasped objects. The goal of many action phases in object manipulation (including tool use) is to move a held object so as to break or form contact between it and another object. The held object transmits various features of these contact events that tactile afferents can signal. Likewise, sensory plans in manipulation tasks integrate and thus predict the occurrence and nature of such signals, which allow

for comparison of predicted and actual sensory events at the level of the appropriate action-phase controllers. This applies, for example, when we lift an object, hold it in air, and then replace it on the support surface (Figure 1). The object breaking contact with the support surface at liftoff represents the sensory goal of the load phase and constitutes a control point for the load-phase controller. Likewise, the contact event that occurs when the object lands on the support surface represents the sensory goals of the controller that replaces the object. Because of their exquisite sensitivity to mechanical transients, ensembles of FA-II afferents most quickly and reliably signal the incidence and the dynamics of both the liftoff and the landing event (Westling, G. and Johansson, R. S., 1987).

Because no sensory information is available about weight until liftoff in object lifting, a natural, smooth, and critically damped lifting motion requires that the load force drive at liftoff, which accelerates the object, be scaled predictively to object weight. People form such predictions based on sensorimotor memory of the object derived from previous interactions with the object (Johansson, R. S. and Westling, G., 1988a). Familiar objects can be identified visually (or by haptic exploration) for retrieval of weight estimates (Gordon, A. M. *et al.*, 1991), and size–weight associations can be used to predict the weights of familiar objects that are organized into families of objects where the items can vary in size (e.g., cups, books, loafs of bread) (Gordon, A. M. *et al.*, 1993). Erroneous weight predictions often result in pronounced performance errors. For example, when we lift an object that is lighter than predicted and the load phase is programmed for a heavier weight, we typically make jerky movements and lift the object higher than intended (Figure 8(a), T2). The sensory events elicited by the liftoff occur before the predicted events that are part of the sensory plan (*cf.* predicted and actual neural events in Figure 8(a)). This mismatch automatically triggers a learned corrective action (smart reflex) that involves termination of the load-phase force followed by corrective motor commands that bring the object back to the intended position. However, due to the substantial delays in sensorimotor control loops, this corrective action pattern kicks in too late to avoid an overshoot in the lifting movement (see position signal in Figure 8(b)). When lifting an object that is heavier than expected, the load phase becomes slow and hesitant because the force drive is targeted for a lighter weight and additional increases in force are required to bring the object aloft (Figure 8(b), T2). In this case, the predicted sensory event related to liftoff does not occur at the predicted time (*cf.* predicted and actual neural events in Figure 8(b)). Hence, again there is a mismatch between actual and predicted sensory events. The corrective action triggered by the mismatch now involves slow, probing increases in fingertip forces until terminated reactively by sensory events signaling liftoff. Thus, the sensorimotor system reacts to both the presence of an unpredicted event and the absence of a predicted sensory event. Importantly, in addition to triggering corrective actions, these sensory mismatches lead to an updating of memory representations related to object weight, which in turn, improves predictive control in subsequent action phases and tasks that engage the same object. In natural situations, this updating generally occurs in a single trial (see Figure 8) while with objects with unusual dynamics (relating applied force to motion) (Flanagan, J. R. and Wing, A. M., 1997; Flanagan, J. R. *et al.*, 2003) or in the presence of misleading cues (Gordon, A. M. *et al.*, 1991; Flanagan, J. R. and Beltzner, M. A., 2000), updating may require repeated lifts or movements of the object.

6.05.4 Predictions and Control Points in Other Modalities

Studies of eye movements in object manipulation indicate that contact events that demarcate action phases can also be predicted and monitored in the visual modality (Land, M. *et al.*, 1999; Johansson, R. S. *et al.*, 2001; Land, M. F., 2006). Accordingly, people use saccades to direct their gaze to successive contact locations as they gain salience in the evolving manipulation task. For example, when people pick up a bar, move the bar in hand to contact a target switch, and then replace the bar, gaze is successively directed to the grasp site on the bar, the target, and the landing surface where the bar is replaced (Johansson, R. S. *et al.*, 2001). Both hand and eye movements are specified based on peripheral vision about the contact location (or on memorized landmark locations), but gaze reaches the contact location well before the hand (or object in hand) because the saccadic eye movements are quick. Gaze typically remains at the contact location until around the time of goal completion (e.g., until the grasp is established, the target switch is released, or the bar is replaced in the target contact task). This indicates that the visual system, like the tactile system, can monitor control points linked to the completion of task subgoals.

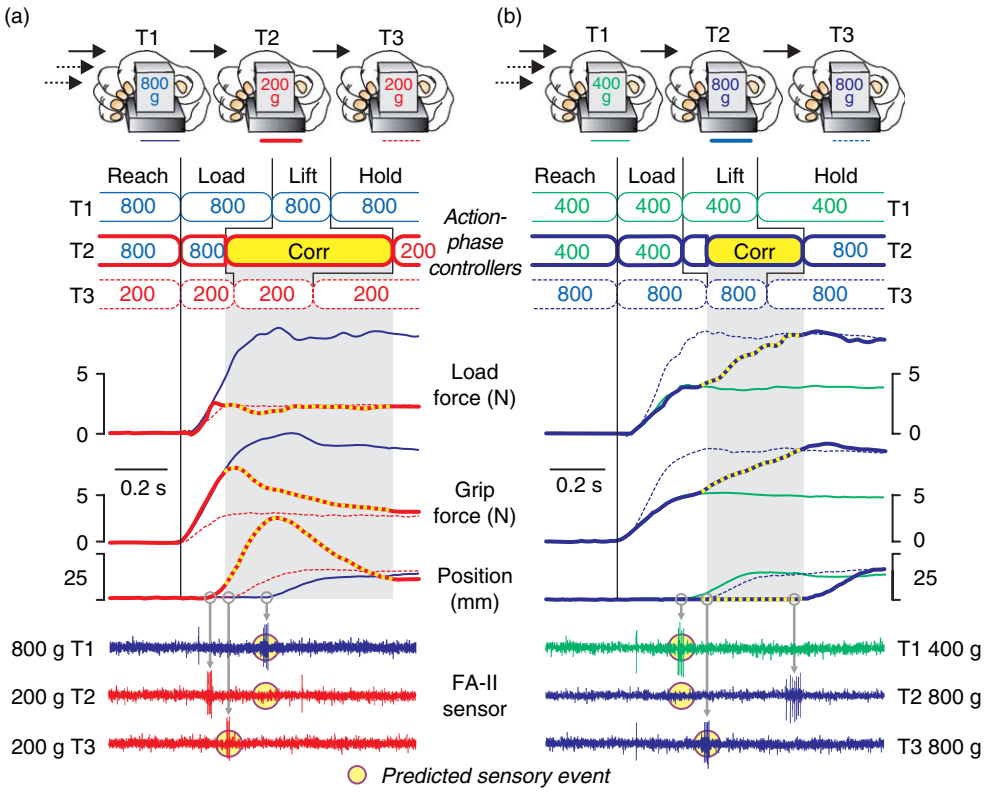

Figure 8 Adaptation of motor output to object weight. Single-unit tactile afferent responses and adjustments in force to unexpected changes in object weight. Data from single lift trials aligned on initial touch (vertical line). Gray circles and vertical lines indicate the moment of liftoff for each trial and the arrowheads point at the actual sensory events generated by the liftoff in a fast-adapting type II (FA-II) afferent. The circles behind the nerve traces indicate the corresponding predicted sensory events. (a) Three successive trials (T1–T3) in which the subject lifted an 800 g object (blue curves), a 200 g object (solid red curves), and then the 200 g object again (dashed red curves). The forces exerted in the first lift are adequately programmed – they had previously lifted the 800 g object. The forces are erroneously programmed in the first 200 g lift (T2), i.e., they are tailored for the heavier 800 g object lifted in the previous trial. The sensory information about the start of movement occurs earlier than expected (*cf.* actual and predicted sensory events), which initiates a corrective action (yellow–dashed red curves). The strong force drive of the ongoing load phase is terminated but still results in overshoots in position due to the reflex delay and a corrective motor command is launched that brings the object back to the intended position. (b) The participant performed an adequately programmed lift with a 400 g weight (T1, green curves), followed by a lift with 800 g, erroneously programmed for the lighter 400 g weight lifted in the previous trial (T2, solid blue curves), and then a lift with the 800 g object again (T3, dashed blue curves). The absence of burst responses in fast-adapting type II (FA-II) afferents at the predicted point for the erroneously programmed 800 g trial (*cf.* actual and predicted sensory event) elicits a corrective action (yellow–dashed blue curves). This involves abortion of the lift-phase command followed by triggering of a second load-phase command that involves a slow, discontinuous, and parallel increase in grip and load forces until terminated by sensory input signaling liftoff. The top diagram in (a) and (b) represents the status of the sequentially implemented action-phase controllers. In T1 they are parameterized for the 800 g (b) and 400 g (b) weight throughout. In T2, a corrective action (Corr) is triggered about 100 ms after the occurrence of the mismatch between predicted and actual sensory information related to object liftoff. This action involves abortion of the operation of the current action-phase controller and the implementation of corrective action patterns that allow the task to continue. The corrective action is linked to an updating of the subsequently implemented controllers for the new weight. In T3, the controllers remain updated to this weight. (a–b) Developed from Johansson, R. S. and Cole, K. J. 1992. Sensory-motor coordination during grasping and manipulative actions. Curr. Opin. Neurobiol. 2, 815–823.

Furthermore, the gaze behavior indicates that goal completion can be predicted in sensorimotor systems. That is, the time of gaze shift to the contact location associated with the next action phase occurs around the time of goal completion and is not delayed until sensory feedback verifying goal completion triggers the gaze shift. The latter strategy would lead to substantial lags in gaze behavior because of the time delays in sensorimotor control loops. That both gaze and hand movement commands are initiated in

anticipation of goal completion reinforces the idea that sensory predictions about the terminal state of each action phase provide initial state information for the controller responsible for executing the subsequent action phase.

Although there is no question that contact points predicted and monitored in the tactile modality are essential for skilled object manipulation, there are contact events that do not give rise to tactile events. For example, when we drop a ball onto a surface, we typically direct our gaze to the predicted contact point between the ball and surface. Here, sensory feedback related to contact is only available through vision (and possibly audition). Thus, vision and the tactile system can play complementary roles in predicting and monitoring contact events. Prediction of contact events in the visual modality without the tactile modality being engaged is evident from studies of eye movements when people observe an actor performing familiar manipulation tasks. In this situation, the gaze of both the actor and observer predicts forthcoming contact sites (e.g., where blocks are grasped and replaced in a predictable block stacking task) and gaze is maintained at each contact site until around the time of goal completion (grasp contact and block landing) (Flanagan, J. R. and Johansson, R. S., 2003). By comparing actual and predicted visual feedback related to contact events, both observers and actors may be able to obtain valuable information about outcomes of actions that can be exploited by the sensorimotor system when learning, planning, and controlling future actions. These findings also support the notion that understanding of observed actions performed by others involves a mechanism that maps observed actions onto sensorimotor representations in the observers' brain implemented in real time (Rizzolatti, G. *et al.*, 2001; Flanagan, J. R. and Johansson, R. S., 2003; Rotman, G. *et al.*, 2006).

6.05.5 Conclusions

Dexterity in object manipulation tasks depends on anticipatory control policies that rely on knowledge about movement–effect relationships when interacting with environmental objects. The tactile modality plays a pivotal role in gaining such knowledge because signals from tactile afferents provide direct information about mechanical interactions between the body and objects in the environment. The usefulness of visual and proprioceptive mechanisms in guiding the hands in object manipulation depends on learned associations between visual and proprioceptive cues and their mechanical meaning derived from tactile mechanisms. Signals in ensembles of tactile afferents of different types convey complementary information related to both the timing and the physical nature of the various kinds of contact events that represent the outcomes of motor commands to the hand. Populations of tactile afferents encode time courses, magnitudes, directions, and spatial distributions of contact forces relative to the hand. They likewise encode information related to surface properties of contacted objects such as shape and texture of contacted surfaces and frictional conditions between these surfaces and the skin. In addition to critically supporting the control of fingertip actions in manipulation, the brain uses tactile afferent information for establishing sensorimotor correlations that underlie haptic object identification as well as representations of object affordances used in planning of object manipulation activities.

Such action plans are composed of sequences of action phases implemented to attain task subgoals specified (and verified) in terms of sensory signals. Thus, manipulatory tasks involve a sensory plan that specifies the sequence of task subgoals and provides a scaffold for the selection and shaping of the action-phase controllers implemented for achieving sensory subgoals. Distinct contact events signaled in the tactile modality generally represent subgoals, but these subgoals can also be represented in the visual and auditory modalities. When the brain successfully predicts the actual sensory signals at a given contact event, no corrective action is required and the task runs in a feedforward fashion based on predictions derived from internal representations of object properties gained in previous interactions with objects. When a prediction error arises, a learned corrective action, the nature of which depends on the task and its action phase, is generated and representations of object properties are updated. Prediction of the terminal sensorimotor state of each action phase prevents stuttering phase transitions that would result if the brain relied on peripheral afferent information to confirm subgoal completion and update state information before launching the next action phase. The fact that contact events give rise to distinct sensory signals in multiple modalities permits the sensorimotor system to simultaneously monitor multiple aspects of task performance and, if prediction errors arise, respond to the pattern of errors observed in different modalities. Finally, contact events often give rise to multimodal sensory events that are linked in time

and space and this provides an opportunity for intermodal alignment helpful for learning and upholding multimodal sensorimotor correlations necessary for prediction of purposeful motor commands.

6.06.1 Introduction

As all medical students know, pain is the most common reason for a person to consult with a physician. Under ordinary circumstances, pain has a useful, protective function. It encourages the individual to avoid activities that aggravate the pain, allowing faster recovery from tissue damage. The physician can

often tell from the nature of the pain what its source may be. In most cases, treatment of the underlying condition resolves the pain. However, some kinds of pain are the result of difficult to treat or untreatable conditions and are persistent.

6.06.2 Second-Order Somatosensory Circuits in the Spinal Cord

In discussing second-order somatosensory neural circuits in the spinal cord gray matter, the projections of particular classes of primary afferent neurons to the spinal cord will first be described, as well as the responses of spinal cord interneurons to inputs from these afferents. Then, the responses of sensory projection neurons to somatosensory stimuli and the effects of descending control systems will be considered.

6.06.2.1 Mechanoreceptive Circuits

Mechanoreceptive afferents from the skin that project to the spinal cord innervate various types of cutaneous sensory receptors. Some of the sensory receptors adapt slowly to a maintained stimulus and are thought to mediate a spectrum of sensations described as touch–pressure; other cutaneous sensory receptors are rapidly adapting and are responsible for flutter–vibration sensations (Johansson, R. S. and Vallbo, A. B., 1979a; 1979b; 1993; see review by Willis, W. D. and Coggeshall, R. E., 2004). Slowly adapting receptors in muscles that supply muscle spindles are not only responsible for the stretch reflex but they also provide proprioceptive information about the position and movements of joints (Matthews, P. B. C., 1972). In addition to triggering the inverse stretch reflex, the activity of Golgi tendon organs reflects the tension developed in tendons, because of stretch of the muscles or muscular contractions (Matthews, P. B. C., 1972). Although the sensation evoked by afferents from some viscera, such as the ureter, may be restricted to pain (Cervero, F. and Sann, A., 1989; Giamberardino, M. A. *et al.*, 1995), afferents from other viscera can convey nonpainful mechanical sensations, such as distention, depending on the type of afferents activated and in some cases the firing rate (Jänig, W. and Kolzenburg, M., 1991) (for reviews of the properties of somatosensory and visceral receptors, see Cervero, F and Morrison, J. F. B., 1986; Gebhart, G. F., 1995; Willis, W. D. and Coggeshall, R. E., 2004).

6.06.2.1.1 Touch–pressure

Touch–pressure sensation refers to the perception of a maintained distortion of the skin, such as an indentation. The sensation increases in a linear fashion as skin indentation increases. The sensory receptors responsible for touch–pressure sensation are slowly adapting cutaneous mechanoreceptors. Both glabrous (nonhairy) and hairy skin contain slowly adapting mechanoreceptors, including SA I or Merkel cell endings and SA II or Ruffini endings (Figure 1; Darian-Smith, I., 1984; Guinard, D. *et al.*, 1998; Rice, F. L. and Rasmusson, D. D., 2000; Paré, M. *et al.*, 2002).

The threshold for activating human SA I receptors can be as low as 0.15 g, which is near the threshold for a sensation of touch in hairy skin (Hensel, H. and Boman, K. K. A., 1960; Järvilehto, T. *et al.*, 1981). Studies using intraneural microneurography have found that the conduction velocities of the axons of SA I receptors in humans average nearly $60\,m\,s^{-1}$, indicating that the axons are large myelinated or Aβ fibers (Knibestöl, M., 1975). SA I receptors have one or a few small, spot-like receptive fields that presumably

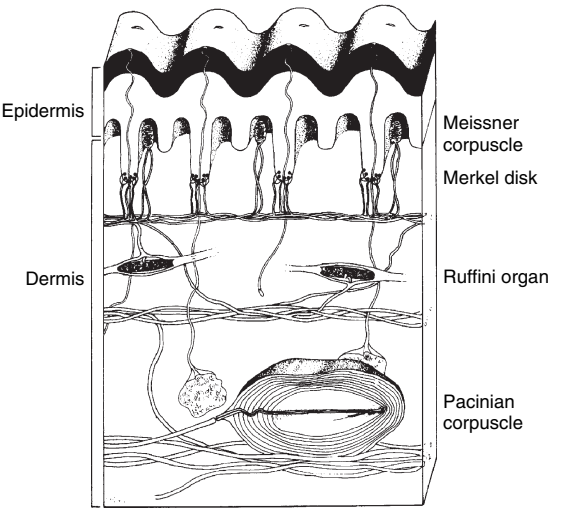

Figure 1 Tactile sensory receptors found in the glabrous skin of a monkey's hand. Meissner corpuscles are shown in several dermal papillae, and Merkel cell endings on ridges of the epidermis that extend into the dermis. Ruffini endings are in the dermis and Pacinian corpuscles in the deep dermis or in subcutaneous tissue. From Darian-Smith, I. 1984. The sense of touch: performance and peripheral neural processes. In: (*eds*. J. M. Brookhart and V .B. Mountcastle), Handbook of Physiology, Section 1: The Nervous System, Vol. III, Sensory Processes, Part 2, pp. 739–788. American Physiological Soc, Bethesda.

reflect the locations of one or more Merkel cell complexes (Johansson, R. S., 1978). These receptors characteristically lack spontaneous activity and do not respond to skin stretch, but they do respond dynamically to stimuli applied directly to the receptive field, and they have a variable firing rate during a maintained stimulus (see Willis, W. D and Coggeshall, R. E., 2004). They are especially responsive to edges. When the axons of human SA I receptors are stimulated repetitively through a microneurography electrode, their activity results in a sensation of continuous pressure (Torebjörk, H. E. *et al.*, 1987). Increasing the frequency of stimulation increases the intensity of the sensation (Ochoa, J. and Torebjörk, E., 1983). SA I receptors are highly likely to contribute to touch–pressure sensation and to the discrimination of form (reviewed in Willis, W. D and Coggeshall, R. E., 2004; see also Werner, G. and Mountcastle, V. B., 1965, and Mountcastle, V. B. *et al.*, 1966).

SA II receptors (or Ruffini organs; Figure 1) also have large myelinated axons. They may or may not display spontaneous activity, and they respond both to indentation and to stretch of the skin. The receptive fields may be near joints or fingernails. Their dynamic sensitivity is low and, when stimulated, they have a regular discharge (see Willis, W. D and Coggeshall, R. E., 2004). Activation of the axon of an SA II receptor through a microneurography electrode usually fails to evoke any sensation (Ochoa. J. and Torebjörk, E., 1983; Schady, W. J. L. and Torebjörk, H. E., 1983), perhaps because spatial summation is required before this type of receptor can elicit a sensory experience. However, stimulation of an occasional SA II unit can result in a sensation of sustained pressure or of joint movement (Macefield, G. *et al.*, 1990), suggesting that SA II receptors can contribute to touch–pressure and proprioception.

The large myelinated primary afferents from slowly adapting mechanoreceptors pass through the medial part of the appropriate dorsal roots to enter the spinal cord. Collaterals of some of these afferents join the dorsal funiculus. However, the axons of most slowly adapting receptors from the hind limb do not ascend all the way to the brainstem, but rather synapse in Clarke's column. By contrast, those from the forelimb often project directly to the main cuneate nucleus and/or the lateral cuneate nucleus (see Willis, W. D. and Coggeshall, R. E., 2004). Other collaterals of these slowly adapting mechanoreceptive afferents terminate in the gray matter of the spinal cord.

Afferents that supply SA I and SA II receptors end in Rexed's laminae III–V (Figure 2; Brown, A. G., 1977; Brown, A. G. *et al.*, 1978; Woolf, C. J., 1987; see Rexed, B., 1952; 1954, for a description of the laminar arrangement of the spinal cord gray matter).

Recordings have been made from a population of neurons in laminae III–VI that respond to input from slowly adapting cutaneous mechanoreceptors, but not to input from proprioceptors (Wall, P. D., 1967; Brown, P. B., 1969; Tapper, D. N. *et al.*, 1973). Rudomin's group has identified interneurons that generate primary afferent depolarization through

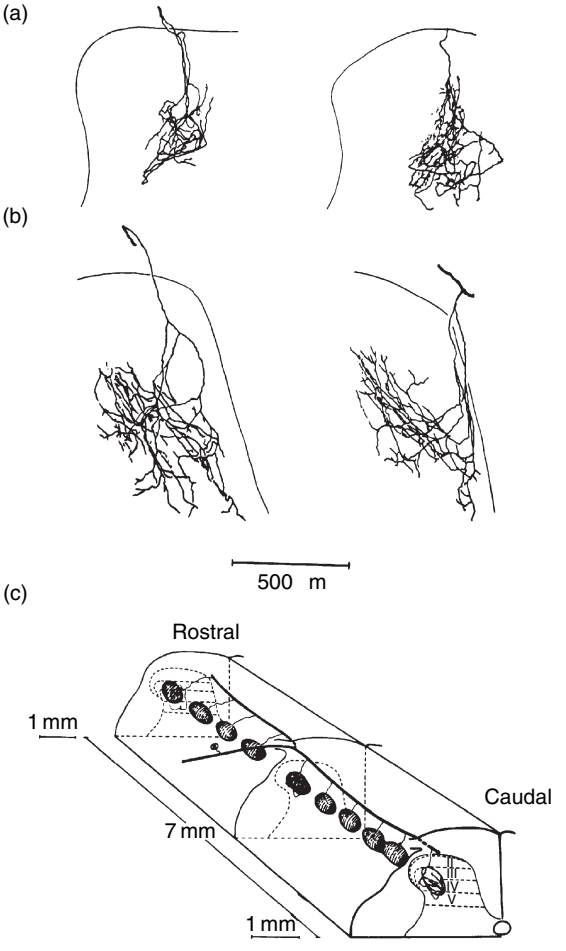

Figure 2 (a) The terminals of the axons of SA I receptors in the dorsal horn of a cat. (b) The terminals of SA II receptors. (c) The longitudinal distribution of the branches of an SA I afferent. (b) From Brown, A. G. 1977. Cutaneous axons and sensory neurons in the spinal cord. Br. Med. Bull. 33: 109–112. (c) From Brown, A. G., Rose, P. K. and Snow, P. J. 1978. Morphology and organization of axon collaterals from afferent fibres of slowly adapting type I units in cat spinal cord. J. Physiol. 277: 15–27.

synaptic actions on afferent terminals, or that excite motor neurons, or both (Rudomin, P. *et al.*, 1987). Spike-triggered averaging has shown that some of the interneurons in laminae V and VI with cutaneous input evoke excitatory or inhibitory postsynaptic potentials in motor neurons and are therefore premotor interneurons in reflex pathways (Hongo, T. *et al.*, 1989a; 1989b). More experiments like these are needed to define more completely the components of the various dorsal horn (and brainstem) circuits.

Information from slowly adapting cutaneous receptors is also transmitted by postsynaptic dorsal column neurons to the dorsal column nuclei through axons that ascend either in the dorsal columns or in the dorsal part of the lateral funiculus (see Willis, W. D. and Coggeshall, R. E., 2004). A sensory experience would then result from transmission of this sensory information from the dorsal column nuclei to the contralateral ventral posterior lateral (VPL) thalamic nucleus and from there to the somatosensory cortex. Recordings from neurons in the gracile nucleus of monkeys and cats that project to the VPL nucleus of the thalamus have demonstrated responses of some low-threshold (LT) gracile neurons to maintained indentation of the skin (Figures 3(a)–3(f)). Other gracile neurons were classified as wide dynamic range (WDR) neurons, as they could be excited by innocuous and noxious stimuli (Figures 3(g)–3(i); Ferrington, D. G. *et al.*, 1988; Cliffer, K. D. *et al.*, 1992; see also Figure 12). These gracile neurons are likely to reflect the activity generated in postsynaptic dorsal column neurons and then transmitted to the gracile neurons. However, more direct evidence is needed in support of this assumption.

6.06.2.1.2 Flutter–vibration

Rapidly adapting receptors in glabrous skin include FA I endings or Meissner's corpuscles and FA II endings or Pacinian corpuscles (see Figure 1; Johannsson, R. S and Vallbo, A. B. 1979a; 1979b;

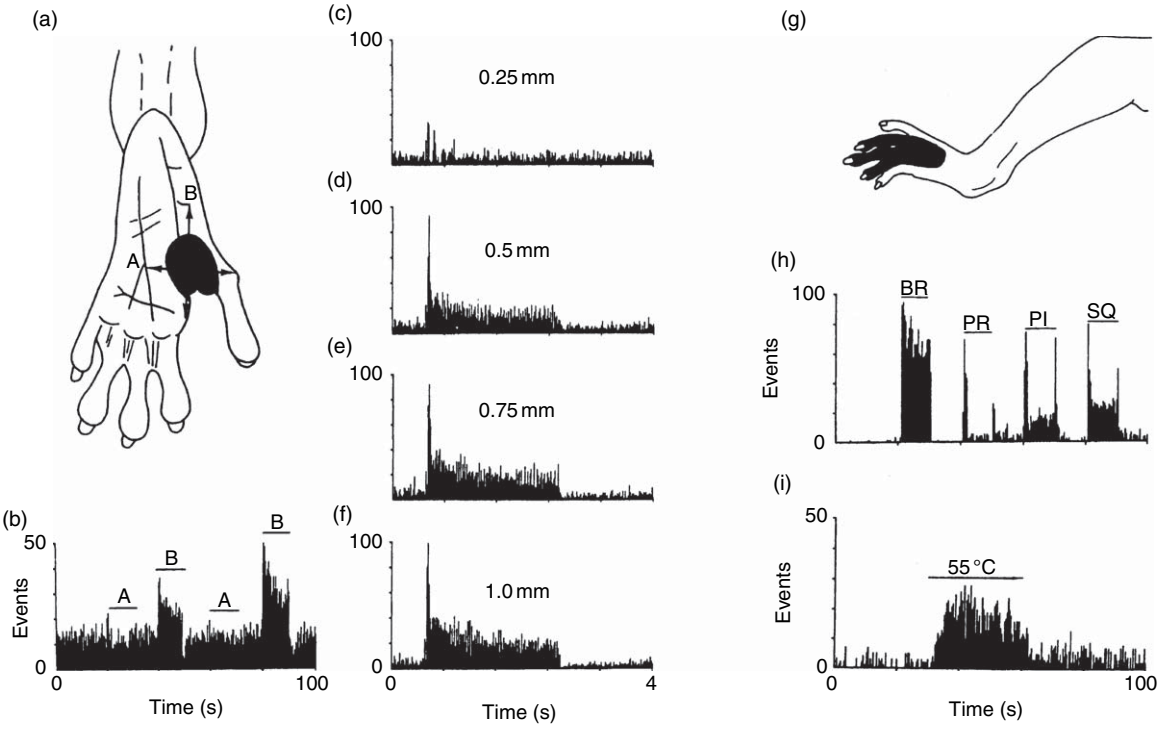

Figure 3 (a–f) Responses of a neuron in the gracile nucleus of a monkey to skin stretch and skin indentation. (a) The area and direction of hind paw skin that was stretched to produce the responses in (b). (h) The responses to brushing (BR), application of pressure using an arterial clip with a weak grip (PR), pinching the skin by an arterial clip with a strong grip (PI), and squeezing the skin with serrated forceps (SQ). (i) The response to a 55 °C heat stimulus that lasted 30 s. From Ferrington, D. G., Downie, J. W. and Willis, W. D. 1988. Primate nucleus gracilis neurons: responses to innocuous and noxious stimuli. J. Neurophysiol. 59: 886–907.

Schady, W. J. L. and Torebjörk, H. E., 1983; Johansson, O., *et al.*, 1999; Paré, M. *et al.*, 2001; 2002). Instead of FA I endings, the hairy skin contains hair follicle receptors (which are rapidly adapting and in effect substitute for FA I receptors) and field receptors, in addition to FA II, SA I, and SA II receptors (Vallbo, A. B. *et al.*, 1979; Halata, Z., 1993). There are several kinds of hair follicle receptors, including G_1, G_2, and T receptors, which are supplied by large myelinated ($A\beta$) afferents, and down hair receptors that are innervated by small myelinated ($A\delta$) afferents (Brown, A. G. and Iggo, A., 1967; Burgess, P. R. *et al.*, 1968; Perl, E. R., 1968). Field receptors respond to tactile stimulation of the skin, but not to movement of hair follicles; the morphology of field receptors is as yet undetermined. In addition, unmyelinated (or C fiber) afferents supply C mechanoreceptors, which are very responsive to mechanical stimuli that move slowly across the skin (sometimes referred to as caress detectors; Iggo, A., 1960; Bessou, P. *et al.*, 1971; Nordin, M., 1990; Vallbo, A. B. *et al.*, 1999).

FA I and hair follicle receptors are responsible for the sensation of flutter and FA II receptors for the sensation of vibration. Flutter sensation reflects the low-frequency components of moving stimuli (best frequency of about 30 Hz), whereas vibration sensation is triggered by the high-frequency components (best frequency of about 250 Hz). These different sensations can be distinguished experimentally by anesthetizing the skin (Talbot, W. H. *et al.*, 1968). When this is done, the threshold for flutter is elevated, whereas that for vibration is not. This shows that the receptors for flutter are located superficially within the skin and those for vibration are deep to the epidermis. The hypothesis that flutter depends on the activity of FA I receptors in glabrous skin and hair follicle and field receptors in hairy skin (Mountcastle, V. B. *et al.*, 1972) is supported by microneurography experiments in which stimulation of the axons of FA I and FA II receptors generally produce sensations related to flutter and vibration, respectively (Ochoa, J. and Torebjörk, E., 1983; Macefield, G. *et al.*, 1990).

The afferents from FA I and FA II receptors project to laminae III–VI of the dorsal horn (Figure 4; Brown, A. G. *et al.*, 1977; see also Wall, P. D., 1967; Brown, P.B., 1969; Tapper, D. N. *et al.*, 1973). The recurrent branches of hair follicle afferents within the dorsal horn have been referred to as flame-shaped arbors (Figures 4(a) and 4(b); Scheibel, M. E and Scheibel, A. B., 1968; Willis, W. D. and Coggeshall, R. E., 2004). Terminals of FA I and FA II afferents have also been traced into the inner part of lamina II (Woolf, C. J., 1987; Shortland, P. and Woolf, C. J., 1993).

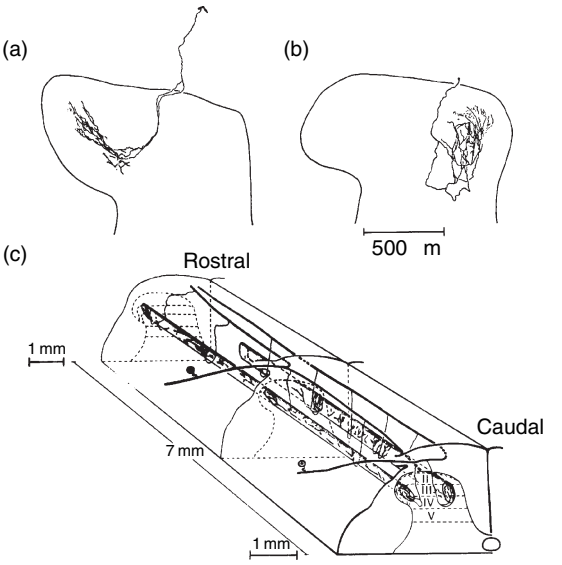

Figure 4 (a) and (b) The terminals of hair follicle afferents in the cat dorsal horn. Such endings have been called flame-shaped arbors. (c) The longitudinal arrangement of the branches of two hair follicle afferents in sagittal sheets within lamina III of the lateral and medial parts of the cat dorsal horn. From Brown, A. G., Rose, P. K., and Snow, P. J. 1977. The morphology of hair follicle afferent fibre collaterals in the spinal cord of the cat. J. Physiol. 272: 779–797.

Collaterals of some FA I, hair follicle afferents and field receptors project directly to the dorsal column nuclei through the dorsal columns. In addition, these afferents can activate postsynaptic dorsal column neurons, spinocervical tract (SCT), and spinothalamic tract (STT) neurons. Thus, there are multiple ascending pathways that share responsibility for signaling flutter sensation (see Willis, W. D. and Coggeshall, R. E., 2004). FA II receptors also have direct projections to the dorsal column nuclei through the dorsal columns and indirect projections by the way of postsynaptic dorsal column neurons; however, neither SCT nor STT neurons respond to FA II afferents.

6.06.2.1.3 Proprioception

Muscle is richly innervated. Proprioceptors in muscle include muscle spindles and Golgi tendon organs. These receptors subserve the position sense and the sensation of limb movement (kinesthesia) at proximal joints (Barker, D., 1962; Goodwin, G. M. *et al.*, 1972a;

1972b; Grigg, P. *et al.*, 1973; McCloskey, D. I., 1973; McCloskey, D. I., *et al.*, 1983; Horch, K. W. *et al.*, 1975; Clark, F. J. *et al.*, 1979). However, proprioception at distal joints, such as those of the digits, also involves SA II and joint receptors (Browne, K. *et al.*, 1954; Provins, K. A., 1958; Goodwin, G. M. *et al.*, 1972a, 1972b; Knibestöl, M., 1975; Gandevia, S. C. *et al.*, 1983; Ferrell, W. R. and Smith, A., 1987).

Recordings have been made from the Group Ia and II afferents that terminate in human muscle spindles as primary and secondary endings and from Group Ib afferents that end in human Golgi tendon organs (Hagbarth, K. E. and Vallbo, A. B., 1968; 1969; Hagbarth, K. E. *et al.*, 1975). The responses resemble those of similar receptors in animals. However, human muscle spindles do not appear to have any background fusimotor drive when the muscle is completely relaxed (Hagbarth, K. E. and Vallbo, A. B., 1968; Hagbarth, K. E. *et al.*, 1970; Burke, D. *et al.*, 1976). Human muscle spindle afferents usually discharge when the muscle contracts, presumably because of the activity of fusimotor neurons (Burke, D. *et al.*, 1978). Electrical stimulation of groups of large muscle afferents can result in illusions of movements (Gandevia, S. C. *et al.*, 1992), as can stimulation of cutaneous or joint afferents at distal joints (Gandavia, S. C., 1985; Macefield, G. *et al.*, 1990).

Group Ia and II muscle spindle afferents project to laminae VI, VII, and IX of the spinal cord gray matter (Figures 5(a)–5(d); Brown, A. G. and Fyffe, R. E. W., 1978; Fyffe, R. E. W., 1979; Brown, A. G., 1981). Group Ib afferents from Golgi tendon organs end in laminae VI and VII (Figures 5(e) and 5(f); Brown, A. G. and Fyffe, R. E. W., 1979; Brown, A. G., 1981). Afferents from these receptors synapse on proprioceptive interneurons (Eccles, J .C., 1965; Lucas, M. E. and Willis, W. D., 1974) and, in the case of muscle spindle afferents, also directly on motor neurons (Eccles, J. C., 1964; Burke, R. E. and Glenn, L. L., 1996). Many of these interneurons are likely to be involved in reflexes, although some may participate in sensory experience. Interneurons in the intermediate region (laminae VI and VII) that respond to volleys in group Ia afferents from muscle spindles or group Ib afferents from Golgi tendon organs include the inhibitory interneurons that produce reciprocal inhibition in the stretch reflex and inverse stretch reflex pathways (Eccles, J. C., 1964).

Like slowly adapting cutaneous receptors, proprioceptors of the lower extremity do not send axonal projections all the way to the dorsal column nuclei, although similar afferents from the upper extremity do project to the main cuneate and lateral cuneate nuclei (see Willis, W. D. and Coggeshall, R. E., 2004). Instead, collaterals of proprioceptive axons ascending in the dorsal column from stretch receptors of the hind limb terminate in Clarke's column, and the axons of some neurons in this nucleus accompany the dorsal spinocerebellar tract but terminate in nucleus z, a small nucleus just rostral to the nucleus gracilis whose neurons respond to proprioceptive inputs from the lower extremity (Figure 6; Pompeiano, O. and Brodal, A., 1957; Magherini, P. C. *et al.*, 1974; McIntyre, A. K. *et al.*, 1985). Nucleus z projects to the contralateral VPL and ventral lateral thalamic nuclei (Grant, G. *et al.*, 1973), and proprioceptive information is relayed from there to the sensorimotor cortex (Landgren, S. *et al.*, 1967; Landgren, S. and Silfvenius, H., 1971). In addition to its presence in several animal species, this spinomedullothalamic pathway is also likely to occur in humans, since a nucleus z has been described in the human brainstem (Sadjapour, K. and Brodal, A., 1968).

6.06.2.1.4 Visceral sensation

Mechanical events that occur in the viscera are often unaccompanied by sensation. Even very strong stimuli may not reach the level of consciousness (Lennander, K. G., 1907). This may be because many visceral nociceptors, like many cutaneous and articular nociceptors, are not normally responsive to mechanical stimuli (or alternatively because Lennander premedicated his patients with analgesics). However, insensitive nociceptors can be sensitized, after which they respond to weak mechanical and other stimuli and contribute to pain sensation (Häbler, H. J. *et al.*, 1993; Michaelis, M. *et al.*, 1996). Other visceral nociceptors can be activated by the distension of a hollow visceral organ, such as the colon, and produce pain (e.g., Ness, T. J. *et al.*, 1990; Sengupta, J. N. and Gebhart, G. F., 1994). Weak mechanical stimuli can be detected in certain viscera. For example, the urethra contains stretch receptors that detect urine flow (Shafik, A. *et al.*, 2003). These urethral stretch receptors are thought to provide feedback as part of a urethrovesical reflex. Many visceral receptors appear not to function in perception but rather provide sensory data for autonomic or other reflex activities.

Visceral afferents project to the dorsal horn of the spinal cord and are widely distributed, synapsing in laminae I, II, IV–V, and X (Figure 7; Sugiura, Y. *et al.*, 1989). Some cross the midline to end in the contralateral spinal cord gray matter. Furthermore, visceral

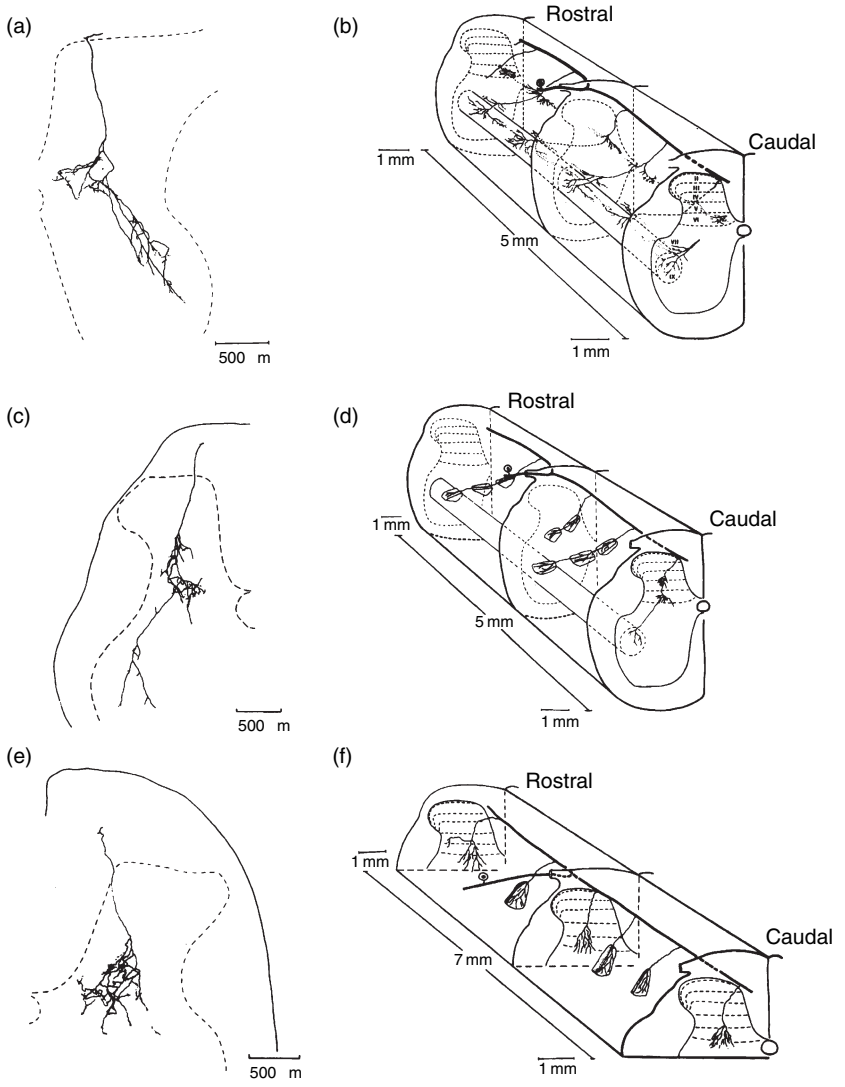

Figure 5 (a) An intrafiber injection of horseradish peroxidase (HRP) allows the visualization of the spinal cord projection of a group Ia afferent belonging to the cat lateral gastrocnemius–soleus (LGS) muscle group. (b) How the collaterals of an LGS group Ia fiber are distributed longitudinally in the lumbosacral spinal cord are shown. (c) and (d) Comparable depictions of the distribution of the terminals of a group II LGS afferent fiber and (e) and (f) of a group Ib fiber. (a, b) From Brown, A .G. and Fyffe, R. E. W. 1978. The morphology of group Ia afferent fibre collaterals in the spinal cord of the cat. J. Physiol. 274: 111–127. (c–f) From Brown, A. G. 1981. Organization in the Spinal Cord: The Anatomy and Physiology of Identified Neurones, Springer-Verlag.

afferents project rostrocaudally in the spinal cord for as many as six segments (Sugiura, Y. *et al.*, 1989), in contrast to cutaneous afferents, which terminate within one to two segments of their level of entry through a dorsal root (Sugiura, Y. *et al.*, 1989). Consistent with this, Fos expression has been demonstrated in spinal cord interneurons located in laminae I, V, and X following intraperitoneal injection of acetic acid in rats (Menétrey, D. *et al.*, 1989). The interneurons in lamina I that show Fos expression extend over many segments. The wide distribution of visceral afferents in the spinal cord may contribute to the common observation that visceral sensations are poorly localized.

Electrophysiological recordings have also demonstrated neurons near the central canal (lamina X) that respond to visceral as well as to somatic stimuli, and some that respond just to visceral stimuli (Honda, C. N., 1985). Ness T. J. and Gebhart G. F. (1987) found that many neurons in the area of lamina X that respond to

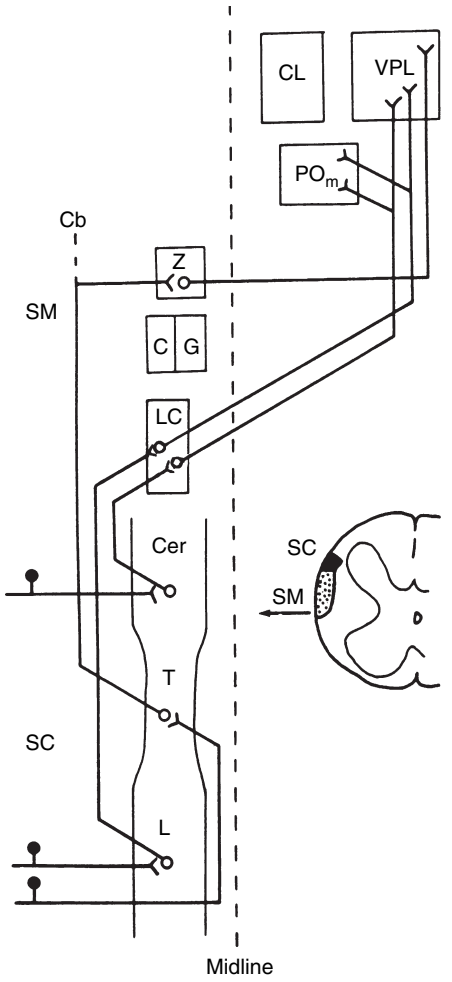

Figure 6 Diagram of the arrangement of the sensory pathways that ascend in the dorsal part of the lateral funiculus of the spinal cord. These pathways include the spinocervical (SC) tract and the spinomedullary (SM) tract. On the left is a schematic view of the connections of these pathways. At the right is a drawing of a cross section of the spinal cord showing the locations of the SC and SM tracts in the lateral funiculus. Primary afferent fibers end in the lumbar (L) and cervical (C) levels of the spinal cord. SC neurons project from these parts of the spinal cord to the lateral cervical nucleus (LC). The LC in turn projects to the contralateral thalamus, with terminations in the ventral posterior lateral (VPL) nucleus and the medial part of the posterior complex (PO$_m$). Branches of proprioceptive afferents are shown to ascend in the posterior funiculus to the thoracic level (T) and to end on neurons of Clarke's column. These neurons then project to the cerebellum (Cb) but also to nucleus z (z). Nucleus z in turn projects to the contralateral VPL thalamic nucleus. From Willis, W. D. and Coggeshall, R. E. 2004. 3rd edn., Sensory Mechanisms of the Spinal Cord, Kluwer Academic/Plenum.

noxious colorectal distention are projection neurons. These cells often have somatic receptive fields in the peroneal region or are activated when the tail is moved.

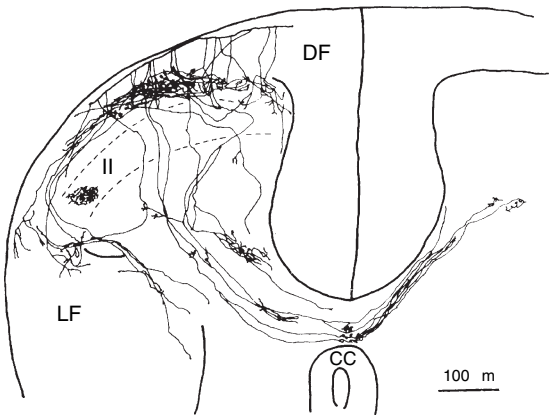

Figure 7 Spinal cord terminations of a visceral C fiber afferent whose cell body was injected with phaseolus vulgaris leucoagglutinin (PHA-L). The projections of the afferent are shown at one transverse level but they actually extended longitudinally over six segments. Note the dense terminations in lamina I and the decussation to the contralateral dorsal horn. From Sugiura, Y., Terui, N. and Hosoya, Y. 1989. Difference in distribution of central terminals between visceral and somatic unmyelinated (C) primary afferent fibers. J. Neurophysiol. 62: 834–840.

6.06.2.2 Thermoreceptive Circuits

Innocuous thermal sensations are signaled by two types of specific thermoreceptors: cold receptors and warm receptors (Hensel, H., 1974). When the skin temperature is in the neutral range, 32–34 °C, there is no experience of a thermal sensation. A slight deviation of the skin temperature from the neutral range results in a sensation of cooling or warmth because of the activation of cold or warm receptors and a reduction in the activity of the other type of thermoreceptor (reviewed in Willis, W. D. and Coggeshall, R. E., 2004). Thermal sensation adapts slowly (Kenshalo, D. R. and Scott, H. A., 1966). Extremes of temperature change lead to cold or heat pain by activating thermal nociceptors (see Section 6.06.2.3).

Cold and warm receptors have spot-like receptive fields (Dallenbach, K. M., 1927). Recordings have been made from afferents that supply each of these types of receptor, not only in animals but also in humans (see Willis, W. D. and Coggeshall, R. E., 2004). Cold receptors are thought generally to be supplied by Aδ fibers and warm receptors by C fibers in humans; however, some cold receptors in both humans and animals appear to be innervated by C fibers.

Thermoreceptors do not respond to mechanical stimuli. However, cold receptors (and cold sensation) can be activated by chemical substances, such as

menthol (Hensel, H. and Zotterman, Y., 1951). Recently, transducer proteins that permit cold and warm receptors to respond to certain ranges of temperature have been identified. These proteins form a family of TRP (transient receptor potential) receptors. For example, specific cold receptors contain TRPM8 that responds to cooling (<28 °C) and to menthol (McKemy, D. D. *et al.*, 2002; Peier, A. M. *et al.*, 2002). On the other hand, warm receptors that contain TRPV3 or TRPV4 respond to temperatures in the ranges of 34–38 °C and 27–34 °C, respectively (Patapoutian, A. *et al.*, 2003). These transducer proteins are found in both sensory neurons and keratinocytes (leading to the proposal that keratinocytes might contribute in some way to thermal sensation; Chung, M. K. *et al.*, 2004). The presence of these transducer molecules should lead to the identification of primary afferent terminals in the skin, dorsal root ganglion cells, and primary afferent terminals in the spinal cord that belong to cold or warm receptors through the use of immunocytochemical staining (just as nociceptors that contain TRPV1 receptors can be identified in this fashion).

Although the axons of individual thermoreceptors have not yet been traced into the spinal cord gray matter by labeling them with an anterograde marker or by identifying them immunocytochemically, as suggested above, electrophysiological recordings from dorsal horn neurons indicate that thermoreceptors project to laminae I–III of the superficial dorsal horn (SDH). Neurons in these laminae have been described that respond to the application of cold or warm stimuli to the skin (Christensen, B. N. and Perl, E. R., 1970; Courtney, K. *et al.*, 1972; Kumazawa, T. *et al.*, 1975; Iggo, A. and Ramsey, R. L., 1976; Kumazawa, T. and Perl, E. R., 1976; Kanui, T. I., 1988). Some of the responsive neurons in lamina I are STT cells (Craig, A. D. and Kniffki, K. D., 1985; Ferrington, D. G. *et al.* 1987; Kanui, T. I., 1988; Dostrovsky, J. O. and Craig, A. D., 1996; Han, Z. S. *et al.*, 1998; Andrew, D. and Craig, A. D., 2001; Craig, A. D. *et al.*, 2001). The axons from thermoreceptive STT neurons cross to the contralateral side and then ascend in the middle of the lateral funiculus, dorsal to the axons of STT neurons originating from deeper laminae (see Figure 12; Zhang, X. *et al.*, 2000a). This observation is consistent with the report by Foerster O. and Gagel O. (1932) that the thermal projections of the STT are posterior to the projections related to pain sensation.

There is a controversy about the destination in the thalamus of the terminations of lamina I STT neurons that signal cold or pain (see next section). Craig and his co-workers claim that essentially all lamina I STT neurons project to a nucleus located medial to VPL and named by them VMpo (Craig, A. D. *et al.*, 1994; Blomqvist, A. *et al.*, 2000; Craig, A. D., 2004). This has been disputed (Willis, W. D. *et al.*, 2002; Graziano, A. and Jones, E. G., 2004). Several lines of evidence indicate that the axons of many of these lamina I STT neurons terminate in the VPL nucleus (Applebaum, A. E. *et al.*, 1979; Zhang, X. *et al.*, 2000b; Willis, W. D. *et al.*, 2001) and lamina I trigeminothalamic neurons have been shown to project largely to the ventral posterior medial (VPM) nucleus (Graziano, A. and Jones, E. G., 2004).

6.06.2.3 Nociceptive Circuits

Pain is generally signaled by nociceptors, although pain can occur in the absence of activity in primary afferent fibers (e.g., pain can be evoked by stimulation of central neurons belonging to nociceptive circuits; see Mayer, D. J. *et al.*, 1975; Lenz, F. A. *et al.*, 1993; 1994). Primary afferent nociceptors are sensory receptors that signal stimuli that threaten damage or that produce overt damage to the body (Sherrington, C. S., 1906). In addition to pain sensation, nociceptors can evoke a variety of pain-related reactions, including nociceptive reflexes, emotional responses, autonomic activity, endocrine responses, and escape behavior.

There are various types of nociceptors. These are generally classified according to the sizes of the afferent axons that supply them and the kinds of noxious stimuli that activate them. For example, cutaneous Aδ mechanical and Aδ mechanoheat nociceptors are supplied by fine myelinated axons and are distinguished by their responses to noxious mechanical stimuli or to noxious mechanical and heat stimuli, respectively. Other nociceptors are supplied by unmyelinated or C fibers and include C mechanoheat, C heat, and C polymodal nociceptors. The latter are activated by noxious mechanical, thermal, and chemical stimuli. There is also a relatively small population of cutaneous nociceptors with axons that conduct in the Aβ range (see Willis, W. D. and Coggeshall, R. E., 2004).

Under normal conditions, nociceptors do not display spontaneous activity, and pain may not occur even if nociceptors are activated at a low level (Van Hees, J. 1976a; b). Their activity must exceed a threshold level before pain is perceived. Different kinds of pain are produced by different types of nociceptors. For example, activation of Aδ nociceptors in human

cutaneous nerves produces pricking pain, whereas excitation of C polymodal nociceptors results in dull or burning pain or sometimes itch (Konietzny, F. *et al.*, 1981; Ochoa, J. and Torebjörk, E., 1989; Torebjörk, H. E., and Ochoa, J. L., 1983; 1990; Schmelz, M. *et al.*, 1997). Stimulation of human muscle nociceptors evokes cramping pain (Marchettini, P. *et al.*, 1996).

As mentioned, many nociceptors are unresponsive to noxious mechanical stimuli under normal conditions (e.g., the sleeping nociceptors of Schaible, H. G. and Schmidt, R. F., 1985; 1988). However, such afferents can be sensitized following damage or inflammation (see Willis, W. D. and Coggeshall, R. E., 2004). The sensitized nociceptors often develop background activity and become responsive to even weak mechanical stimuli, leading to ongoing pain and to primary allodynia and hyperalgesia (Meyer, R. A. and Campbell, J. N., 1981). Secondary allodynia and hyperalgesia may also develop in neighboring undamaged areas because of changes in the responses of central nociceptive neurons, a process known as central sensitization (LaMotte, R. H. *et al.*, 1991; Simone, D. A. *et al.*, 1991; see Willis, W. D. and Coggeshall, R. E., 2004). Peripheral sensitization results from the activation of membrane proteins, such as TRPV1 receptors (Tominaga, M. *et al.*, 1998; Caterina, M. J. and Julius, D., 2001) or tetrodotoxin-resistant sodium channels (Gold, M. S. *et al.*, 1996; 1998). Central sensitization following intradermal injection of capsaicin appears to result (at least in part) from the phosphorylation of glutamate receptors (Zou, X. *et al.*, 2000; Fang. L. *et al.*, 2003).

Cutaneous Aδ nociceptors terminate in the spinal cord chiefly in laminae I and V and sometimes send collaterals to end in the lateral part of the contralateral lamina V (Figure 8(a); Light, A. R. and Perl, E. R., 1979), whereas C polymodal nociceptors end mostly in laminae I and II (Figure 8(b); Sugiura, Y. *et al.*, 1986).

Many interneurons in laminae I, II, and V, as well as in the adjacent laminae, respond to noxious inputs. Some respond to both innocuous and noxious mechanical stimuli, although best to noxious inputs (Figure 9(b)); these are termed WDR neurons (Mendell, L. M., 1966). Others respond solely or primarily to noxious stimuli and can be regarded as narrow dynamic range neurons. These are referred to as high-threshold (HT) or nociceptive-specific (NS) cells (Figure 9(c)). Other narrow dynamic range neurons, termed LT neurons, respond selectively to tactile stimuli (Figure 9(d)). This classification scheme is still in common use (see Willis, W. D. and Coggeshall, R. E., 2004). Although HT neurons are often said to be located principally in lamina I, they are in fact distributed widely in the dorsal horn, as are WDR range neurons. In monkeys, WDR STT neurons in lamina I appear to outnumber HT STT neurons in the same lamina (Owens, C. M. *et al.*, 1992). LT neurons are common in laminae III and IV.

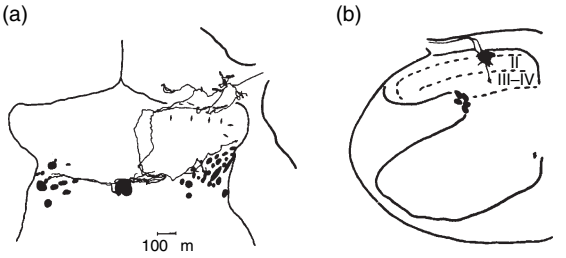

Figure 8 (a) The spinal cord distribution of the terminal branches of an Aδ mechanical nociceptive afferent fiber that had been injected with horseradish peroxidase (HRP) in a monkey. Note the endings in lamina I on one side and near the central canal, and in the deep dorsal horn bilaterally. From Light, A. R. and Perl, E. R. 1979. Spinal termination of functionally identified primary afferent neurons with slowly conducting myelinated fibers. J. Comp. Neurol. 186: 133–150. (b) The terminals of a C polymodal nociceptor in the dorsal horn of a guinea-pig. The cell body of the afferent was injected with phaseolus vulgaris leucoagglutinin (PHA-L). From Sugiura, Y., Lee, C. L. and Perl, E. R. 1986. Central projections of identified, unmyelinated (C) afferent fibers innervating mammalian skin. Science 234: 358–361.

Nociceptive information is transmitted to the brain by way of several different ascending tracts. In addition to the STT (Willis, W. D. *et al.*, 1974; Price, D. D. *et al.*, 1978; Chung, J. M. *et al.*, 1979; Kenshalo, D. R. *et al.*, 1979; Surmeier, D. J. *et al.*, 1988; Owens, C. M. *et al.*, 1992), ascending tracts with a nociceptive component include the SCT, spinoreticular, spinomesencephalic, spinohypothalamic, spinoparabrachial, and spinolimbic pathways (Willis, W. D. and Westlund, K. N., 1997; Willis, W. D. and Coggeshall, R. E., 2004; cf., Noordenbos, W. and Wall, P. D., 1976; Gybels, J. M. and Sweet, W. H., 1989). The postsynaptic dorsal column pathway appears to be particularly important for signaling visceral pain (Hirshberg, R. M. *et al.*, 1996; Al-Chaer, E. D. *et al.*, 1996a; b; Nauta, H. J. W. *et al.*, 2000).

6.06.2.4 Spinal Cord Projection Neurons

6.06.2.4.1 Spinothalamic tract neurons

The STT is generally considered the most important pathway to convey nociceptive information from the spinal cord to the brain. The somas of the cells of

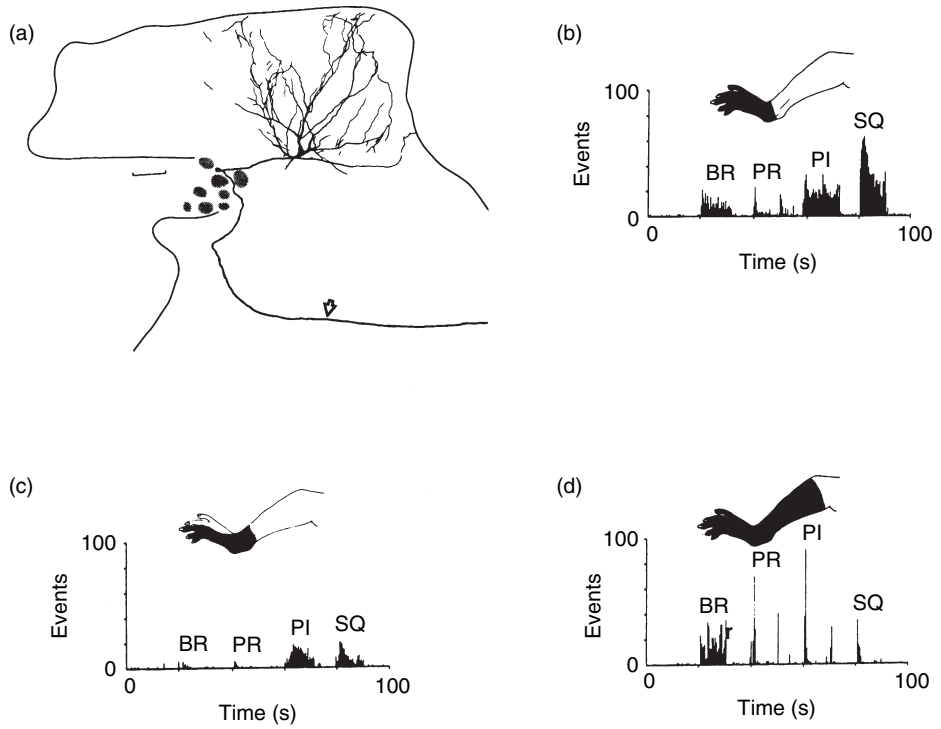

Figure 9 (a) A drawing of a wide dynamic range (WDR) primate spinothalamic tract cell that was injected intracellularly with horseradish peroxidase (HRP). Note that its dendritic tree extends dorsally into lamina I. The axon en route to its decussation in the anterior white commissure is indicated by the open arrow head. (b) The responses of this neuron to brush (BR), pressure (PR), pinch (PI), and squeeze (SQ) stimuli. (c, d) The responses of a high-threshold (HT) and a low-threshold (LT) spinothalamic tract neuron. From Surmeier, D. J., Honda, C. N. and Willis, W. D. 1988. Natural groupings of primate spinothalamic neurons based on cutaneous stimulation: Physiological and anatomical features. J. Neurophysiol. 59: 833–860.

origin of the STT are scattered widely in the spinal cord gray matter of monkeys. Many are concentrated in laminae I and V–VI, but some are located in lamina IV and in the ventral horn (Figure 10; Willis, W. D. *et al.*, 1979; 2001; Apkarian, A. V. and Hodge, C. J., 1989).

Primate STT cells project to several contralateral thalamic nuclei, including the VPL and central lateral nuclei, as well as the posterior complex, as shown by anterograde and retrograde labeling and by antidromic mapping of the terminations of the axons of STT cells (Figure 11; Applebaum, A. E. *et al.*, 1979; Giesler, G. J. *et al.*, 1981; Zhang, X. *et al.*, 2000a; 2000b). Apkarian A. V. and Hodge C. J. (1989) provide evidence that in macaque monkeys about 18 000 STT cells project to one side of the thalamus.

Primate STT cells in lamina I tend to be oriented longitudinally in the spinal cord; their configurations are described as fusiform, pyramidal, or multipolar (Zhang, E. T. and Craig, A. D., 1997). However, intracellularly labeled primate STT cells in laminae IV–VI are oriented transversely and often have long dendrites that can extend dorsally to reach laminae I and II (Figure 9(a); Surmeier, D. J. *et al.*, 1988; see Willis, W. D. and Coggeshall, R. E., 2004). The axons of STT cells in the deep layers of the dorsal horn decussate in the ventral white commissure at a level near the cell body. They then ascend to the thalamus at first in the ventral and then in the lateral funiculus (Willis, W. D. *et al.*, 1979; Apkarian, A. V. and Hodge, C. J., 1989). The axons of lamina I STT cells are concentrated in the middle of the contralateral lateral funiculus (Craig, A. D., 2000), whereas those from STT cells of the deep dorsal horn (DDH) are located more ventrally in the lateral funiculus (Figure 12; Zhang, X. *et al.*, 2000a; 2000b). The STT axons in the lateral funiculus are arranged somatotopically (Applebaum, A. E. *et al.*, 1975; Zhang, X. *et al.*, 2000a; b). The conduction velocities of the axons of primate STT neurons in lamina V average 45.5 m s^{-1} and those in lamina I average 20.3 m s^{-1} (Trevino, D. L. *et al.*, 1973).

The thalamic synaptic terminals of STT cells are enriched in glutamate, suggesting that they release

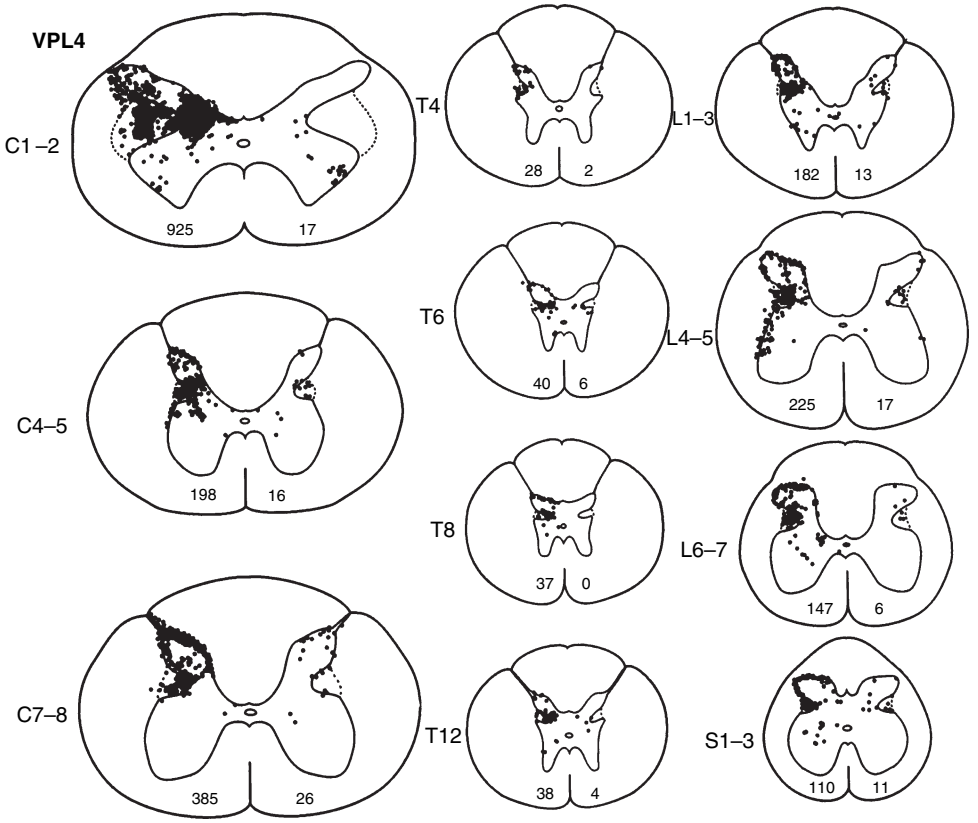

Figure 10 Distribution of the cell bodies of primate spinothalamic tract neurons as shown by retrograde labeling, using a circumscribed injection of the tracer, cholera toxin subunit B, into the ventral posterior lateral (VPL) nucleus of one side. The filled circles indicate the locations of individual neurons at different segmental levels plotted on drawings of transverse sections. The numbers in the ventral funiculi are cell counts. Most of the labeled neurons were contralateral to the injection. From Willis, W. D., Zhang, X., Honda, C. N. and Giesler, G. J. 2001. Projections from the marginal zone and deep dorsal horn to the ventrobasal nuclei of the primate thalamus. Pain 92: 267–276.

glutamate as an excitatory neurotransmitter (Ericson, A. C. *et al.*, 1995; Blomqvist, A. *et al.*, 1996). Some STT cells are thought to contain peptide neurotransmitters, such as substance P (SP) (see review by Willis, W. D. and Coggeshall, R. E., 2004). A variety of substances have been demonstrated immunocytochemically in synaptic endings on STT cells, including glutamate, gamma amino butyric acid (GABA), SP, calcitonin gene-related peptide (CGRP), enkephalin, and serotonin (Ruda, M. A. *et al.*, 1984; Westlund, K. N. *et al.*, 1992; Carlton, S. M. *et al.*, 1990; 1992). Release of these neurotransmitters can excite or inhibit STT cells (see Willis, W. D. and Coggeshall, W. D., 2004).

6.06.2.4.2 Spinocervical neurons

Most SCT neurons are located in lamina IV of the spinal cord dorsal horn, and they project ipsilaterally through the dorsal part of the lateral funiculus to the lateral cervical nucleus, which is in the uppermost cervical spinal cord (Figure 6; reviewed in Willis, W. D. and Coggeshall, R. E., 2004). Axons from neurons in the lateral cervical nucleus decussate immediately and then ascend through the brainstem to the contralateral VPL thalamic nucleus in company with the medial lemniscus. The number of SCT neurons in primates is not known, and it is uncertain if there is a lateral cervical nucleus in the human spinal cord.

Many SCT neurons are activated by hair follicle afferents (Brown, A. G. and Franz, D. N. 1969) and are therefore likely to mediate flutter sensation. However, some are nociceptive and can be classified as WDR or HT neurons Cervero, F. *et al.*, 1977).

6.06.2.4.3 Postsynaptic dorsal column neurons

The postsynaptic dorsal column pathway originates from projection neurons, most of which are located in

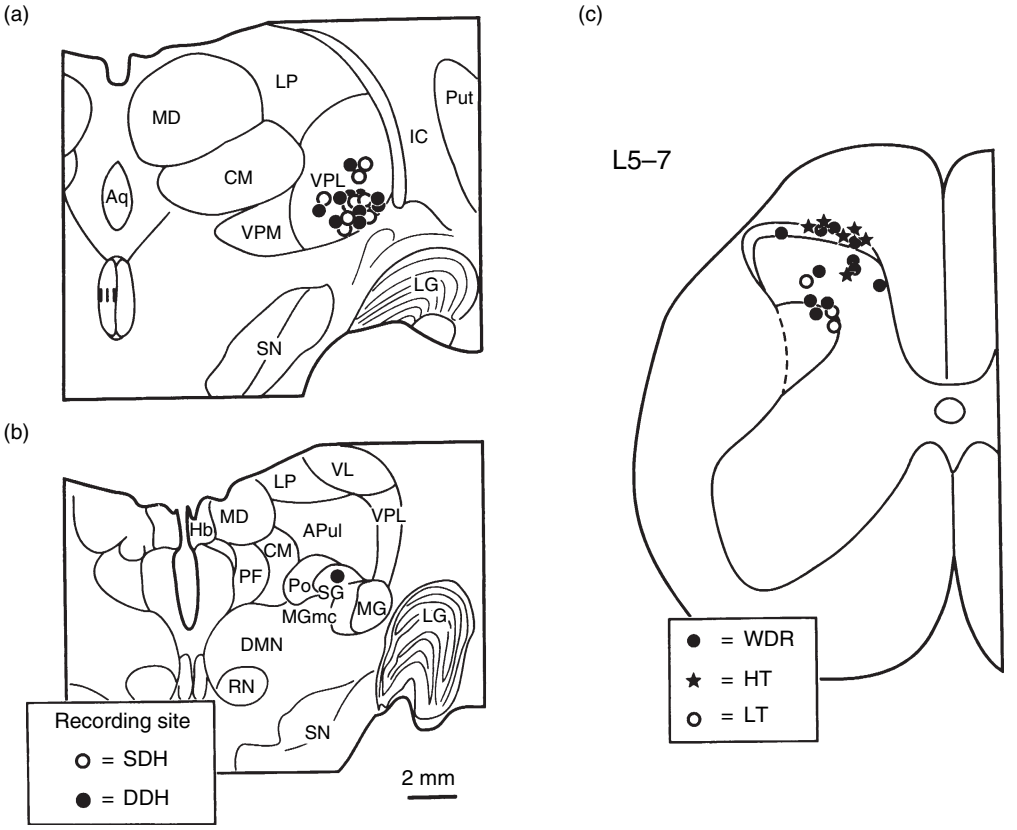

Figure 11 (a, b) The low-threshold (LT) sites determined by antidromic mapping to locate the terminations of primate spinothalamic tract (STT) neurons in the contralateral thalamus are shown. As indicated by the symbols, terminals of STT cells from both the superficial dorsal horn (SDH) and the deep dorsal horn (DDH) were in the VPL nucleus, with the exception of one cell of the DDH that projected to the suprageniculate (SG) nucleus of the posterior complex. (c) The locations of the cell bodies of the STT cells at the L5–7 levels that were antidromically activated in this experiment are shown. Wide dynamic range (WDR) cells are indicated by filled circles, high-threshold (HT) cells by asterisks, and LT cells by open circles. From Zang, X. *et al.*, 2000b.

the dorsal horn (reviewed in Willis, W. D. and Coggeshall, R. E., 2004). In monkeys, the cell bodies of these neurons are concentrated in laminae IV–VI (Rustioni, A. *et al.*, 1979), although some are also found in laminae III, VII, and X (Bennett, G. J. *et al.*, 1983). The dendrites of postsynaptic dorsal column neurons can project dorsally into lamina II and even I (Brown, A. G. and Fyffe, R. E. W. 1981). The axons of these neurons are medium-sized myelinated fibers that ascend to the caudal medulla in the dorsal column (although some of the axons are instead in the dorsal part of the lateral funiculus) to end in the ipsilateral dorsal column nuclei, along with the collaterals of dorsal root ganglion cells that project directly to the dorsal column nuclei (see Willis, W. D. and Coggeshall, R. E., 2004). Sensory information is then conducted from the dorsal column nuclei to the contralateral VPL thalamic nucleus through the medial lemniscus.

The postsynaptic dorsal column pathway was first recognized in recordings from second-order axons in the dorsal columns by Uddenberg N. (1968), who found that neurons in this pathway can respond to noxious mechanical stimuli, as well as to tactile stimuli. For example, in cats, these neurons are activated both by tactile stimuli and by noxious heat, and the responses to mechanical stimuli become sensitized after repeated heat stimuli (Kamogawa, H. and Bennett, G. J., 1986). Recently, it has been found that a population of postsynaptic dorsal column neurons is activated by noxious visceral stimuli, such as colorectal distention (Al-Chaer, E. D. *et al.*, 1996a; 1996b). Interruption of the dorsal columns or pharmacological blockade of the synaptic input from

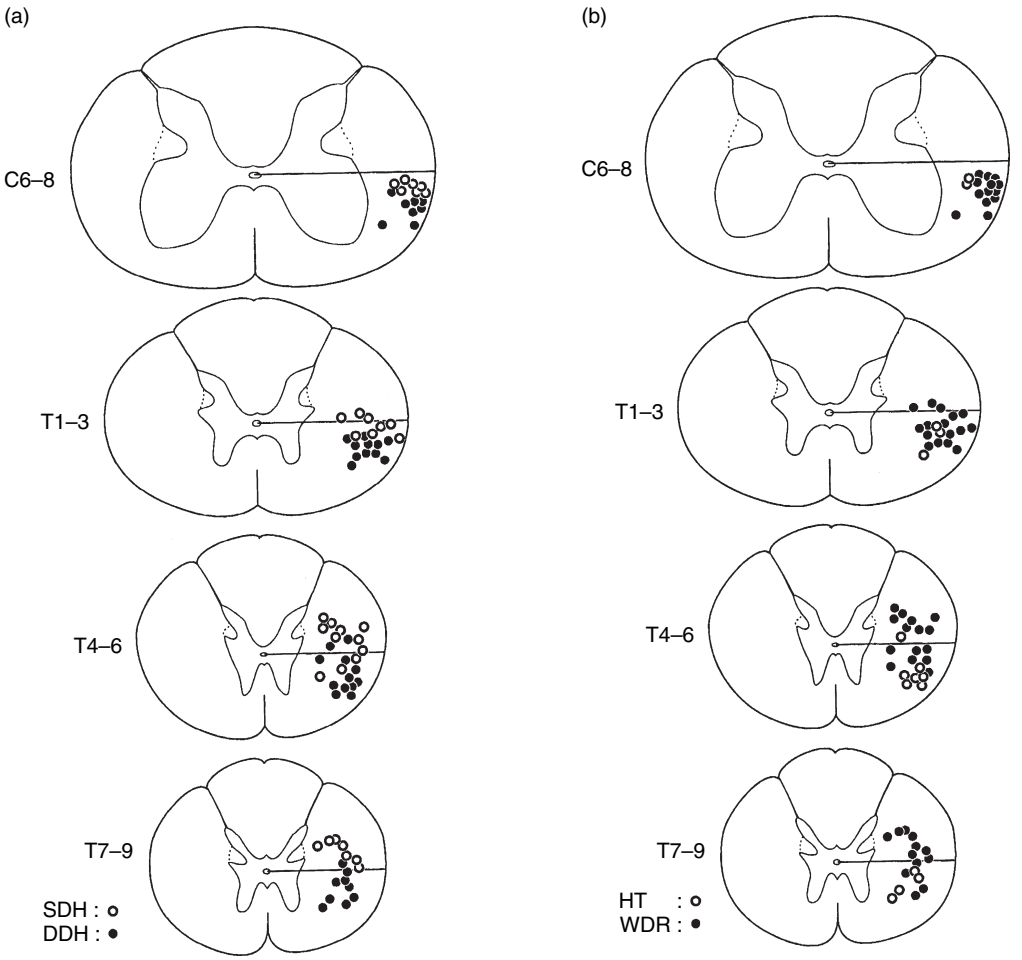

Figure 12 The positions of the axons of monkey spinothalamic tract (STT) cells within the spinal cord white matter and en route to the thalamus are shown at different segmental levels. The axons were activated antidromically by stimulation in the thalamus and the low-threshold points in the spinal cord were marked. (a) The symbols indicate axons from STT cells located in the superficial dorsal horn (SDH; open circles) or the deep dorsal horn (DDH; filled circles). (b) The symbols indicate whether the same axons belonged to high-threshold (HT) (open circles) or wide dynamic range (WDR) (filled circles) STT neurons. From Zhang, X. *et al.*, 2000.

primary afferents that excites these neurons prevents the responses of neurons in the nucleus gracilis (Figure 13) and in the VPL thalamic nucleus to noxious visceral stimuli (Al-Chaer, E. D. *et al.*, 1996b). This observation made in animal experiments helps explain the beneficial effects of midline myelotomy in human patients in relieving the pain of pelvic cancer (Hirshberg, R. M. *et al.*, 1996; Nauta, H. J. W. *et al.*, 2000).

6.06.2.4.4 Spinoreticular neurons

Spinoreticular neurons project to the brainstem reticular formation, including several reticular nuclei in the medulla and pons, such as the nucleus reticularis gigantocellularis (NGc) and the nucleus reticularis pontis caudalis (reviewed in Willis, W. D. and Coggeshall, R. E., 2004). Many of the cells of origin of the spinoreticular tract in monkeys are concentrated in the upper cervical spinal cord. Those found in the spinal cord enlargements are located mostly in lamina VII, although some are in laminae V and VIII (Kevetter, G. A. *et al.*, 1982). The axons of these neurons are myelinated and most cross the midline and ascend in the ventral white matter of the spinal cord. Spinoreticular neurons are often excited by noxious stimuli applied to large cutaneous or deep somatic receptive fields, but inhibitory responses and responses to visceral stimuli are also seen (reviewed by Willis, W. D. and Coggeshall, R. E., 2004).

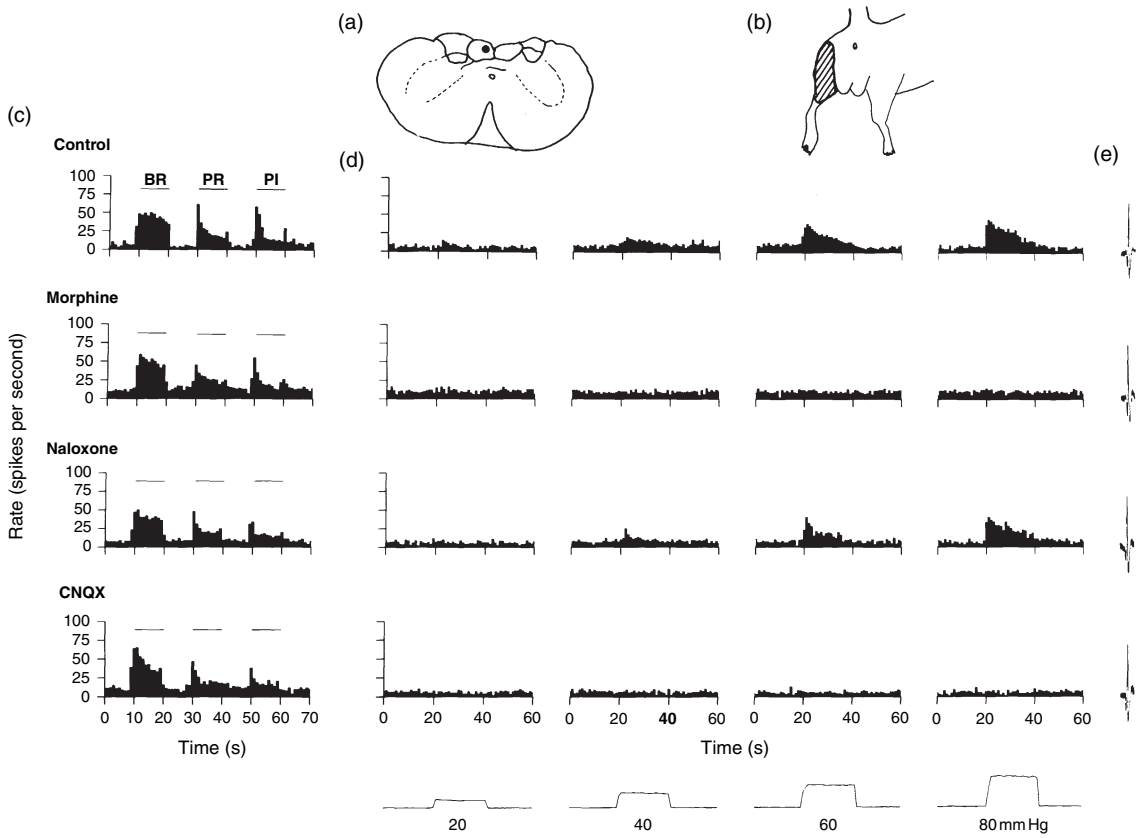

Figure 13 Activation of a neuron in the rat gracile nucleus by visceral input. The input from the colon was limited to that traversing the pelvic nerves by transecting the hypogastric nerves bilaterally. (a) The location of the gracile neuron. (b) Somatic receptive field of the gracile neuron. The peristimulus time histograms in (c) show the responses of the neuron to mechanical stimuli applied to the receptive field. The responses in (d) were to graded colorectal distention (20, 40, 60, and 80 mm Hg, as indicated by the monitor pulses below the histograms). (e) Spikes recorded from the neuron during different phases of the experiment to show that the recording was stable. A microdialysis fiber was placed across the sacral spinal cord to allow the intraspinal administration of drugs. Infusion of morphine blocked the responses to colorectal distention ((d), second row of records), as did the non-NMDA (*N*-methyl-D-aspartate) glutamate receptor antagonist, CNQX ((d), fourth row). Systemic administration of naloxone reversed the action of morphine ((d), third row). The drugs had little effect on the responses to mechanical stimulation (c). The actions of morphine and CNQX were presumably on the synaptic input to postsynaptic dorsal column neurons in the sacral cord; these drugs had a similar effect on the responses of identified postsynaptic dorsal column neurons within the sacral cord. From Al-Chaer, E. D., Lawand, N. B., Westlund, K. N. and Willis, W. D. 1996b. Pelvic visceral input into the nucleus gracilis is largely mediated by the postsynaptic dorsal column pathway. J. Neurophysiol. 76: 2675–2690.

6.06.2.4.5 Spinoparabrachial neurons

The spinoparabrachial tract is a component of the spinomesencephalic projections, which also include the spinotectal tract (to the superior colliculus and intercollicular region) and the spinoannular tract (to the periaqueductal gray (PAG)). Spinoparabrachial neurons are located in lamina I and also in deep layers of the dorsal horn, and their axons terminate in several nuclei in the parabrachial region, including not only the parabrachial nuclei proper but also the locus coeruleus and the Kölliker-Fuse nucleus (Bernard, J. F. *et al.*, 1995; reviewed in Willis, W. D. and Westlund, K. N., 1997). Nociceptive spinoparabrachial neurons activate neurons in the parabrachial region that project to the central nucleus of the amygdala (Bernard, J. F. and Besson, J. M., 1990; Bernard, J. F. *et al.*, 1989; 1992).

6.06.2.4.6 Spinohypothalamic and other spinolimbic neurons

Direct projections have been described from the spinal cord to the hypothalamus of rats, cats, and monkeys (Burstein, R. *et al.*, 1990; Katter, J. T. *et al.*, 1991; Zhang, X. *et al.*, 1999). Branches of the axons of

these neurons have been found to decussate in the hypothalamus and then to descend into the brainstem, where they terminate bilaterally in many nuclei in the diencephalon and brainstem (Zhang, X. *et al.*, 1995). The cells of origin of spinohypothalamic neurons are in the SDH and DDH and in the intermediate region. Most are WDR or HT neurons (Burstein, R. *et al.*, 1991).

Direct spinal cord projections to the amygdala, septal nuclei, nucleus accumbens, and other limbic system structures have also been reported (Burstein, R. *et al.*, 1987; Burstein, R. and Giesler, G. J., 1989; Cliffer, K. D. *et al.*, 1991).

6.06.2.5 Descending Control Systems

Pathways that descend from the brain to the spinal cord (and also to the brainstem) provide a means by which the brain can control its somatosensory input. These descending controls can either inhibit sensory input or facilitate it. The best-known descending controls are those that are capable of inhibiting nociceptive signals. These pathways are generally known collectively as the endogenous analgesia system. However, there are also pronociceptive descending controls, and not only pain but also tactile and other sensory inputs are regulated by such pathways.

6.06.2.5.1 Descending control pathways

6.06.2.5.1.(i) Cortical projections Corticospinal and corticobulbar projections that originate in the sensorimotor areas of the cerebral cortex (Weiberg, J. A. and Rustioni, A., 1977; see reviews by Willis, W. D., 1982; Willis, W. D. and Coggeshall, R. E., 2004) can exert inhibitory or excitatory influences on the activities of sensory neurons in the spinal cord dorsal horn, as well as in the brainstem, such as in the dorsal column nuclei (Jabbur, J. L. and Towe, A. L. 1961; Towe, A. L. and Jabbur, A. L. 1961).

STT neurons in monkeys are generally excited following stimulation in the primary motor cortex or in the medullary pyramid but inhibited by stimulation in the somatosensory cortex (Figure 14; Yezierski, R. P. *et al.*, 1983).

6.06.2.5.1.(ii) Periaqueductal gray and nucleus raphe magnus In addition to direct cortical projections to the spinal cord and brainstem, there are indirect projections to these from cortical and subcortical structures (such as the amygdala and the hypothalamus) by way of the gray matter that surrounds the cerebral aqueduct (PAG). Stimulation in the appropriate part of the PAG in awake, behaving rats results in analgesia so profound that it is possible to perform abdominal surgery without chemical anesthesia (Reynolds, D. V., 1969). In anesthetized monkeys, stimulation in the PAG results in the inhibition of STT cells (Hayes, R. L. *et al.*, 1979; Gerhart, K. D. *et al.*, 1984; see Willis, W. D. and Coggeshall, R. E., 2004). A review of the role of the PAG in defensive behavior and other responses can be found in Depaulis A. and Bandler R. (1991).

Very few neurons in the PAG project directly to the spinal cord. The effects of PAG stimulation at the spinal cord level are mediated by connections of neurons in the PAG with spinally projecting neurons in other parts of the brainstem, including the nucleus raphe magnus (NRM) and adjacent reticular formation (Figure 15), a region often referred to as the rostral ventral medulla (RVM) (Fields, H. L. and Besson, J. M. 1988).

Many of the bulbospinal neurons in the RVM contain serotonin; others may release peptides or other transmitters. Additional projections from the brainstem to the spinal cord arise from the locus coeruleus, subcoeruleus, and Kölliker-Fuse nuclei, which contain noradrenergic neurons. Other inhibitory neurotransmitters released by descending control systems, either from the terminals of descending projections or from spinal cord interneurons include GABA, glycine (Sorkin, L. S. *et al.*, 1993), enkephalin, and the recently discovered endomorphins I and II (Zadina, J. E. *et al.*, 1997; Wu, S. Y. *et al.*, 1999; see review by Willis, W. D. and Coggeshall, R. E., 2004). The actions of several of these neurotransmitters on dorsal horn neurons have been tested by their iontophoretic release in the vicinity of STT cells (Willcockson, W. S. *et al.*, 1984a; 1984b).

Some brainstem projections to the spinal cord have excitatory actions. For example, stimulation in certain parts of the reticular formation can excite primate STT neurons (Figure 16; Haber, L. H. *et al.*, 1980; Giesler, G. J. *et al.*, 1981). Candidate excitatory neurotransmitters released in the spinal cord following brainstem stimulation include the excitatory amino acids, glutamate, and aspartate (Sorkin, L. S. *et al.*, 1993).

6.06.3 Second-Order Somatosensory Circuits in the Brainstem

6.06.3.1 Cranial Nerve Somatosensory Afferents

Most of the somatosensory primary afferent fibers from the head enter the brainstem through the

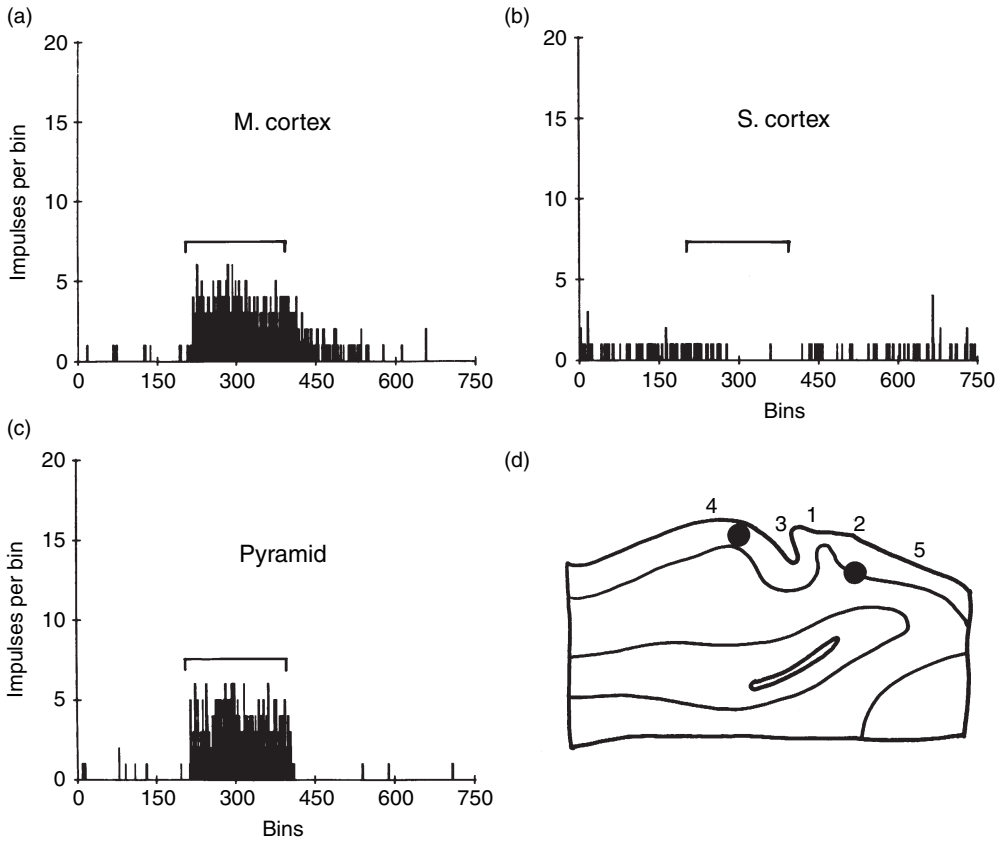

Figure 14 (a) The histogram shows the excitatory response of a primate spinothalamic tract (STT) cell to electrical stimulation in the motor cortex (area 4; 200-ms trains, 100 μA strength pulses). By contrast, (b) shows that stimulation in the somatosensory cortex (area 2; 200-ms trains, 200 μA pulses) inhibited the background activity of the cell. (c) The excitation of the neuron by stimulation in the medullary pyramid. (d) The Two sites in the sensorimotor cortex used for stimulation in (a) and (b). From Yezierski, R. P., Gerhart, K. D., Schrock, B. J. and Willis, W. D. 1983. A further examination of effects of cortical stimulation on primate spinothalamic tract cells. J. Neurophysiol. 49: 424–441.

trigeminal nerve, although some that supply the region of the external ear join other cranial nerves, including the facial, glossopharyngeal and vagus nerves, and somatosensory afferents that innervate the back of the head enter the central nervous system (CNS) through the upper cervical dorsal roots (Arvidsson, J. and Thomander, L., 1984; see a standard neuroanatomy textbook, such as Carpenter, M. B. and Sutin, J., 1983, or Nolte, J., 2002). Many of these somatosensory afferents have their cell bodies in the trigeminal ganglion; others have their cell bodies in the geniculate ganglion of the facial nerve, the superior ganglia of the glossopharyngeal and vagus nerves, or in dorsal root ganglia. Their axons terminate directly in the main sensory nucleus of the trigeminal nerve and/or in the spinal nucleus of the trigeminal nerve after passing caudally through the brainstem in the spinal tract of the trigeminal nerve. The trigeminal nerve, ganglion and nuclei have a somatotopic organization, as shown by tracing the central projections and the synaptic connections of receptors in the distributions of the three peripheral trigeminal branches (ophthalmic, maxillary, and mandibular divisions).

Large myelinated somatosensory afferents that signal touch–pressure and flutter–vibration end in the main sensory nucleus of the trigeminal nerve, whereas small myelinated and unmyelinated somatosensory afferents conveying tactile, pain and temperature information synapse in one or more of the subnuclei of the spinal nucleus of V (subnuclei oralis, interpolaris, and caudalis). The cell bodies of proprioceptive afferents of the trigeminal nerve are located in the CNS in the mesencephalic nucleus. The central processes of these proprioceptive afferent neurons synapse monosynaptically on motor neurons in the motor nucleus of the trigeminal nerve to form the afferent limb of the jaw jerk reflex,

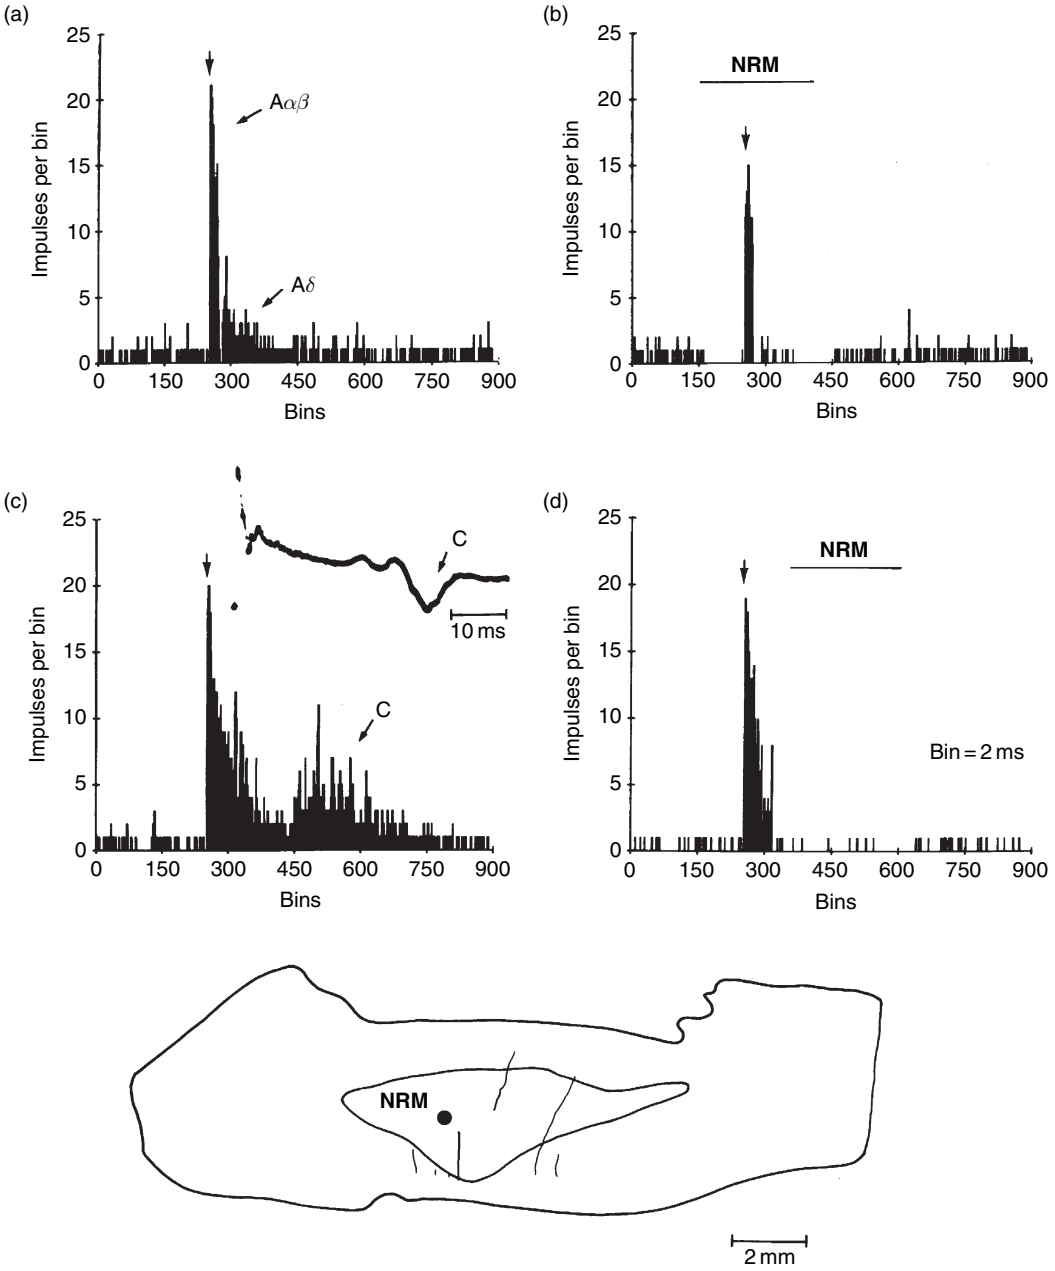

Figure 15 Inhibition of the responses of a wide dynamic range (WDR) primate spinothalamic tract (STT) cell to volleys in the sural nerve following stimulation in the nucleus raphe magnus (NRM). (a) and (b) The STT cell was activated by stimulation of the sural nerve at a strength that activated A$\alpha\beta$ and Aδ afferent fibers. (b) Conditioning stimuli were applied in the NRM during the time indicated by the bar (500 ms trains of 0.1 ms, 150 μA pulses at 333 Hz). Note the reduction in the response. The strength of the stimulus applied to the sural was increased to activate C fibers (1 ms pulses; inset shows compound action potential with the C fiber volley recorded from the sural nerve proximal to the site of stimulation). (d) The NRM was stimulated during the period of the C fiber response of the STT cell. The response was virtually eliminated. The drawing shows the marked position of the tip of the stimulating electrode in the NRM. From Gerhart, K. D. *et al.*, 1981.

a stretch reflex that involves the muscles of mastication. Proprioceptive information is also conveyed from the mesencephalic nucleus to the main sensory nucleus of V. The different nuclei of the trigeminal sensory complex are interconnected in a complicated fashion by ascending and descending projections within the brainstem (Nasution, I. D. and Shigenaga, Y., 1987).

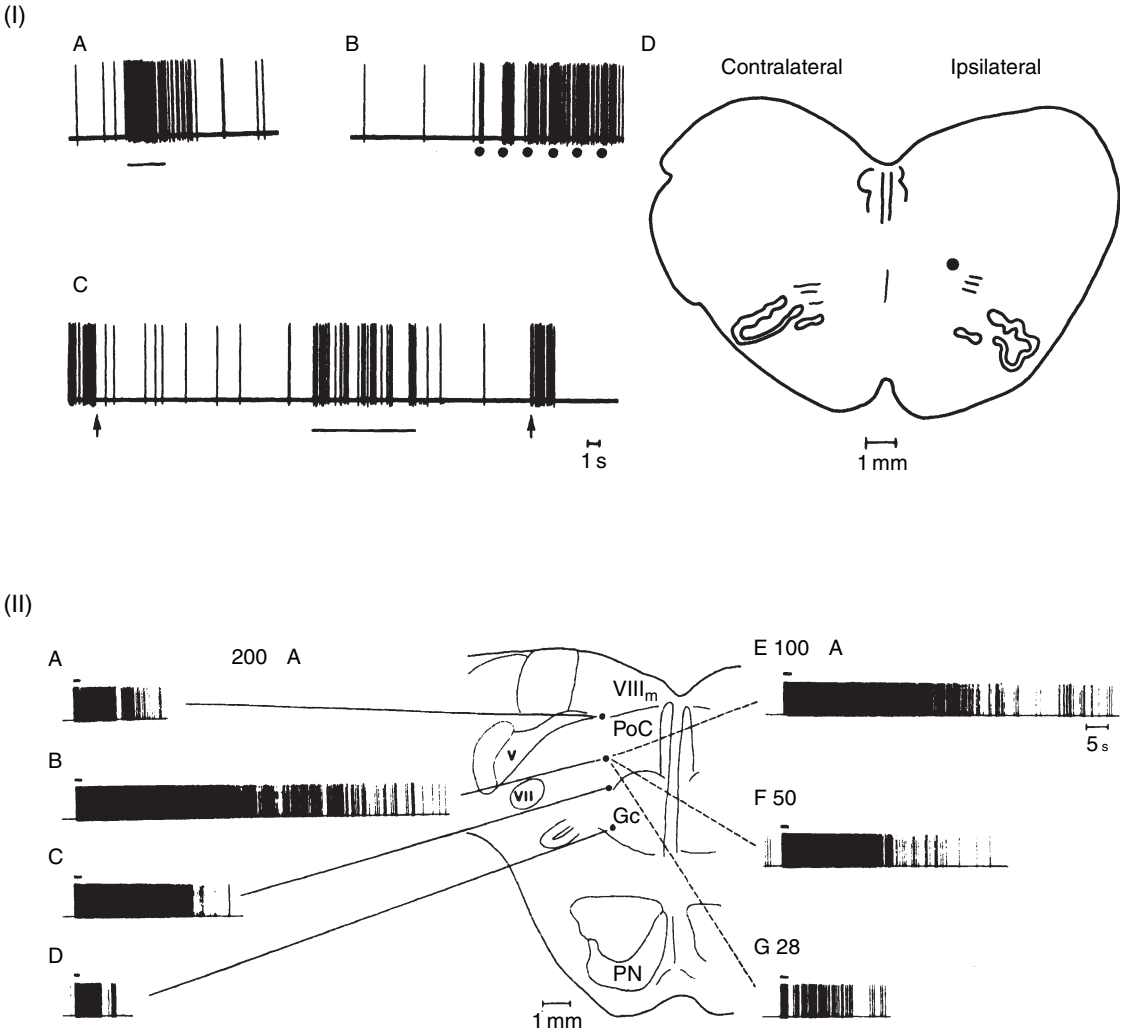

Figure 16 Excitation of primate spinothalamic tract (STT) cells by stimulation in the reticular formation. (I) Excitation and windup of excitation of a primate STT following stimulation in the nucleus reticularis gigantocellularis (NGc). A shows an excitatory burst followed by an after discharge in response to a train of stimuli in the NGc (50 μA, 333 Hz) during the period indicated by the horizontal bar. B shows windup produced by repetitive stimulation in the NGc (repeated 200-ms trains, 100 μA, 333 Hz). C shows that stimulation in the NGc (200 μA, 333 Hz) could interrupt the inhibition of the STT cell produced by squeezing the skin during the time between the two arrows. D is a drawing of a transverse section through the medulla showing the marked stimulus site (filled circle). (II) Long-lasting excitation of a medially projecting STT cell following stimulation in different parts of the pontine reticular formation of a monkey and at different strengths at one location. The drawing of a transverse section of the brainstem shows the locations of the nucleus pontis caudalis (PoC) and the nucleus gigantocellularis (Gc). The responses of STT cells at the left resulted from repetitive stimulation (200 μA, 0.1-ms pulses at 333 Hz) at the locations indicated (filled circles). The responses at the right were recorded from the point in the PoC in response to 100, 50, and 28 μA stimuli. (I) from Haber, L. H, *et al*., 1980. (II) From Giesler, G. J., Yezierski, R. P., Gerhart, K. D. and Willis, W.D. 1981. Spinothalamic tract neurons that project to medial and/or lateral thalamic nuclei: Evidence for a physiological novel population of spinal cord neurons. J. Neurophysiol. 46: 1285–1308.

Somatosensory information related to discriminative touch and proprioception is distributed contralaterally through a part of the trigeminothalamic tract that ascends adjacent to the medial lemniscus to the VPM thalamic nucleus, which then conveys somatosensory information to the face area of the somatosensory cortex. This arrangement for trigeminal sensations is comparable to the dorsal column–medial lemniscus pathway for the body. There is also a projection to the ipsilateral VPM nucleus. Pain and temperature (as well as crude touch) information is transmitted from the spinal

nucleus to the contralateral VPM nucleus through another component of the trigeminothalamic tract that ascends to the thalamus in a position adjacent to the STT. Nociceptive signals are also transmitted to the thalamus indirectly by the way of the reticular formation.

Visceral afferents, including those that supply taste buds, the carotid sinus and carotid body, and other visceral structures innervated by cranial nerves have their cell bodies in the geniculate ganglion of the facial nerve, the inferior ganglion of the glossopharyngeal nerve, or the inferior (nodosal) ganglion of the vagus nerve. They enter the brainstem through the facial (intermediate nerve), glossopharyngeal, and vagus nerves, and pass through the solitary tract to terminate in the nucleus of the solitary tract. Particular types of visceral afferents terminate in the corresponding subdivisions of the nucleus of the solitary tract (Blessing, W. W. *et al.*, 1999). Ascending projections from the solitary nucleus convey visceral information to nuclei that regulate the activity of the autonomic nervous system (Blessing, W. W., 1997; Ruggiero, D. A. *et al.*, 2000) and also to the parvocellular part of the VPM nucleus (VPMpo), which provides information about taste to the cerebral cortex.

6.06.3.2 Mechanoreceptor Circuits

6.06.3.2.1 Main sensory nucleus of V

LT mechanoreceptive afferents have been traced to their terminals in the main sensory nucleus and the subnucleus oralis of the spinal nucleus (Shigenaga, Y. *et al.*, 1990). Both rapidly and slowly adapting receptors that innervated either hairy or glabrous skin were included in the study. Many neurons in the main sensory nucleus have receptive fields on the lips (Arvidsson, J. *et al.*, 1991) or face. Some respond to activation of a single facial whisker or of groups of whiskers (Veinante, P. and Deschenes, M., 1999). Others discharge during mastication (as shown by experiments in which fictive mastication was elicited) and may contribute to the central pattern generator for mastication. Afferent input is from muscle spindles and periodontal receptors (Tsuboi, A. *et al.*, 2003; see also Tabata, T. and Karita, K., 1991).

6.06.3.2.2 Spinal nucleus of V

The axons of sensory neurons that innervate the lips in the rat terminate at several levels of the trigeminal nuclear complex, including not only the main sensory nucleus but also the subnuclei oralis, interpolaris, and caudalis of the spinal nucleus (Shigenaga, Y. *et al.*, 1990; Arvidsson, J. *et al.*, 1992). In addition, sensory axons descend in the spinal tract into the upper cervical spinal cord.

Some neurons in the subnucleus caudalis have been shown to respond in a rapidly adapting manner to hair movement or gentle tactile stimuli; others are activated by light touch and pressure, but the discharges are slowly adapting. These neurons are located in the magnocellular layer of the subnucleus caudalis, and their input is from Aβ afferent fibers (Price, D. D. *et al.*, 1976). Afferents that supply the mystacial vibrissae project to laminae III–V of the subnucleus caudalis and the dorsal horn at C1 (Arvidsson, J. and Rice, F. L., 1991).

6.06.3.2.3 Mesencephalic nucleus of V

Although neurons of the mesencephalic nucleus of V are the cell bodies of primary afferent neurons, they nevertheless receive synaptic input from neighboring nuclei (Verdier, D. *et al.*, 2004). Several different neurotransmitters have been identified in interneurons and in synaptic endings in the nucleus, including GABA and such peptides as galanin, neuropeptide Y, and CGRP (Lazarov, N. E., 2000). Synaptic input has been suggested to modulate the activity of the mesencephalic nucleus neurons, leading to synchronous firing. This may assist with rapid biting movements and with mastication of food. This arrangement of synapses on the cell bodies of primary afferent neurons is unusual, since such synapses do not occur on neuronal cell bodies in dorsal root ganglia or the trigeminal ganglion. Perhaps this unusual synapse formation is related to the fact that the cell bodies of the mesencephalic nucleus of V are in the CNS, rather than in the periphery.

6.06.3.3 Thermoreceptive Circuits

Burton H. *et al.* (1979) reported evidence about the processing of thermal information in the brainstem. They found neurons in the subnucleus caudalis of the trigeminal complex of cats that are thermoreceptive, as shown by their responses to cooling the tongue. These neurons were located in the marginal zone of the medullary dorsal horn, a position comparable to that of second-order thermoreceptive neurons in the spinal cord dorsal horn.

6.06.3.4 Nociceptive Circuits

6.06.3.4.1 Cutaneous pain

Responses of a monkey to noxious stimulation of the face were tested after destruction of the main sensory nucleus and the rostral part of the subnucleus oralis on one side (Lisney, S. J., 1985). Despite the lesion, there were no differences in the nociceptive responses on the two sides of the face, indicating that the rostral parts of the trigeminal sensory nuclear complex are unnecessary for nociception. It was concluded that the main synaptic connections made by facial nociceptive afferents are in the subnucleus caudalis. This is consistent with the presence of SP-containing synaptic terminals in laminae I and II of the subnucleus caudalis (Priestley, J. V. *et al.*, 1982). However, TRPV1 receptors are associated not only with small- and medium-sized neurons in the trigeminal ganglion but also with axons and their terminals in the main sensory nucleus and in the subnuclei oralis, interpolaris, and caudalis of the spinal nucleus. TRPV1 receptors are often colocalized with SP and CGRP (Bae, Y. C., *et al.*, 2004).

The relationship between the speed for detection by a monkey of a noxious heat stimulus applied to the face and the activity of medullary dorsal horn neurons was determined by Dubner R. *et al.* (1989; see also Kenshalo, D. R. *et al.*, 1989 and Maixner, W. *et al.*, 1989). The responses of WDR neurons correlated significantly with detection speed, whereas there was no correlation between the activity of NS neurons and the detection speed.

6.06.3.4.2 Corneal pain

The central terminals of afferent fibers that supply the cornea in monkeys have been traced using horseradish peroxidase (HRP) conjugated to wheatgerm agglutinin (WGA) (Marfurt, C. F. and Echtenkamp, S. F., 1988). Terminals were observed in all of the subdivisions of the trigeminal complex, but the density of the endings of corneal afferents varied. There was a heavy projection to the subnucleus interpolaris and the rostral part of subnucleus caudalis and a lighter projection to the main sensory nucleus, the subnucleus oralis, and the caudal part of the subnucleus caudalis.

The response properties of neurons that have corneal input and are located either in the transition zone between the subnucleus interpolaris and the caudalis or at the transition between the subnucleus caudalis and the cervical spinal cord were compared in experiments by Meng I. D. *et al.* (1997). Nociceptive neurons were classified as WDR, NS, or deep (D). All of the neurons recorded in the caudalis/spinal cord transition zone were WDR or NS, all responded to noxious thermal and mustard oil stimulation, most demonstrated diffuse noxious inhibitory controls (DNIC; see Le Bars, D. *et al.*, 1979a; 1979b), and most could be activated antidromically from the parabrachial area. However, over half of the neurons in the interpolaris/caudalis transition zone had no cutaneous receptive field; most of those that did were LT neurons, although some were WDR or D cells. Many failed to respond to thermal or mustard oil stimulation, few showed DNIC, and none could be activated antidromically from the parabrachial area. It was suggested that neurons in the two transition zones have distinct functions.

Many neurons in the subnuclei interpolaris and caudalis in rats show responses to stimulation of the surface of the cornea by CO_2 pulses. The responses were demonstrated either by increased expression of Fos protein (McEchron, M. D. *et al.*, 1996) or by changes in electrophysiological activity (Hirata, H. *et al.*, 1999). A large proportion of these neurons were also sensitive to mechanical stimulation. Interestingly, some of the neurons in the interpolaris and caudalis subnuclei responded to the CO_2 pulses only after the administration of morphine, whereas neurons in the transition zone between the caudalis nucleus and the C1 dorsal horn were inhibited by morphine (Hirata, H. *et al.*, 1999), and the inhibition could be reversed by naloxone. About one-third of the neurons in the caudalis/C1 transition could be activated antidromically from the contralateral thalamic posterior complex but not from VPM or the nucleus submedius; none of the units in the subnuclei interpolaris and caudalis region with corneal receptive fields could be activated antidromically from these thalamic nuclei. It was concluded that neurons in the caudalis/C1 transition zone that are responsive to corneal stimulation mediate ocular pain due to corneal irritation and that the corneal neurons in the subnuclei interpolaris and caudalis are likely to have some other function.

6.06.3.4.3 Joint pain

Afferents innervating the temporomandibular joint (TMJ) in cats were traced into the brainstem, using WGA–HRP (Capra, N, F., 1987). As in the case of corneal afferents, temporomandibular afferents project to all parts of the trigeminal complex. The greatest density of innervation was in the main sensory nucleus and the subnucleus oralis of the spinal

nucleus. Terminals were also found in laminae I–III of the subnucleus caudalis.

Inflammation induced by injection of complete Freund's adjuvant into TMJ resulted in significantly enhanced responses of WDR neurons in the medullary dorsal horn to mechanical stimuli (Iwata, K. *et al.*, 1999). Inflammation of the perioral skin also resulted in increased responses of these neurons, but was less effective than TMJ inflammation.

6.06.3.4.4 Dental pain

Injection of HRP into tooth pulp results in the labeling of afferent terminals in the main sensory nucleus and in the subnuclei oralis, interpolaris, and caudalis of the spinal trigeminal nucleus (Arvidsson, J. and Gobel, S., 1981; cf., Dong, W. K. *et al.*, 1990). Terminals in the medullary dorsal horn are in laminae I, II_{outer}, and V. HRP injected into the teeth of very young cats yields similar findings (Henry, M. A. and Westrum, L. E., 1990). In addition, cell bodies are also labeled in the mesencephalic nucleus of V. These presumably belong to mechanoreceptors. Electrical stimulation of the tooth pulp in human subjects can produce nonpainful sensations, as well as pain, depending on the stimulus parameters (McGrath, P. A. *et al.*, 1983). Therefore, some of the terminals of tooth pulp afferents in parts of the trigeminal complex may not relate to the processing of pain.

Park S. J. *et al.* (2001) found that application of mustard oil to the tooth pulp of a maxillary molar tooth in rats results in plastic changes in the activity of neurons of the subnucleus oralis similar to those seen in the subnucleus caudalis. There is an increase in spontaneous activity and receptive field size, and an increased sensitivity to mechanical stimuli in WDR, HT, and other nociceptive neurons, but not in LT neurons of the subnucleus oralis. These changes can be prevented by pretreatment with MK-801, an antagonist of *N*-methyl-D-aspartate (NMDA) receptors.

6.06.3.4.5 Meningeal pain

The dura is innervated by nociceptors belonging to the trigeminal nerve. As with nociceptors supplying other types of tissue, recordings from fine, mostly unmyelinated afferents that innervate the superior sagittal sinus and surrounding dura (Bove, G. M. and Moskowitz, M. A., 1997) show that these afferents respond to several modalities of stimulation, including mechanical, thermal, and chemical stimuli (capsaicin, inflammatory mediators, low pH). Application of inflammatory mediators, including lowered pH, to the dura enhances the sensitivity of nociceptive neurons in the subnucleus caudalis to mechanical stimulation of the dura and also to mechanical and thermal stimulation of the skin (Burstein, R. *et al.*, 1998). Ongoing activity develops in WDR and HT but not in LT neurons. Local anesthetic application to the dura blocks the responses to dural stimulation but not to cutaneous stimulation. Strassman A. M. and Levy D. (2006) confirmed that dural nociceptors exhibit chemosensitivity and showed that they can undergo peripheral sensitization.

6.06.3.5 Brainstem Projection Neurons

6.06.3.5.1 Trigeminothalamic neurons

Trigeminothalamic neurons can be identified by antidromic activation from the VPM and/or posterior thalamic nuclei (Price, D. D. *et al.*, 1976). Several classes of trigeminothalamic neurons can be recognized, based on their responses to mechanical stimulation. The classification scheme utilized applies both to trigeminothalamic cells and to presumed interneurons. Class 1 units have rapidly adapting responses to hair movement or light touch and are activated by Aβ afferents. Class 2 units have slowly adapting responses to light touch and pressure and are also activated by Aβ fibers. These two classes correspond to sets of LT neurons. Class 3 units are activated by light touch and pressure but maximally to pinch; these cells are excited by Aβ, Aδ, and C fibers and can also be classified as WDR neurons. Class 4 units respond to pressure and pinch and are excited by Aδ and sometimes C fibers. Class 5 units respond only to pinch and input is only from Aδ fibers. These two sets of neurons can also be classified as NS or HT cells. Receptive fields of the LT and HT neurons tend to be small, whereas the receptive fields of the WDR cells are large. HT neurons are prominent in the marginal zone of the subnucleus caudalis, although some WDR neurons are also found there, but no LT cells are. Instead, the LT cells are in the superficial part of the magnocellular layer. Deeper in this layer are WDR and HT cells.

Bushnell M. C. *et al.* (1984) confirmed that nociceptive trigeminothalamic tract neurons in the medullary dorsal horn include WDR and HT neurons. Both types of neuron respond to noxious heat stimuli. The responses are greater when associated with a thermal discrimination task, suggesting that

these neurons are involved in the discrimination of thermal stimuli.

Trigeminothalamic projections have been demonstrated by De Chazeron I. *et al.* (2004), using anterograde tracing with phaseolus vulgaris leucoagglutinin (PHA-L). The thalamic targets of these projections include the VPM nucleus and the posterior complex; in addition, terminals are found in the parvocellular part of VPM, suggesting that the subnucleus oralis is involved not only in the processing of somatosensory but also of gustatory information. Guy N. *et al.* (2005) confirmed by retrograde tracing in rats that trigeminothalamic neurons that project to the VPM nucleus and to the Po complex are located not only in the subnucleus caudalis but also in the subnucleus oralis.

Consistent with observations concerning the response properties of trigeminothalamic neurons, it has been reported that both WDR and HT neurons, as well as LT neurons, can be recorded in the VPM thalamic nucleus (Yokota, T. *et al.*, 1985; see also Bushnell, M. C. *et al.*, 1993; Tremblay, N. *et al.*, 1993). Furthermore, injections of lidocaine into the VPM nucleus in awake, behaving monkeys have shown that this nucleus is important for the perception of noxious and innocuous thermal stimuli, as well as for the detection of tactile stimuli (Duncan, D. H. *et al.*, 1993).

6.06.3.5.2 Trigeminoreticular neurons

Esser M. J. *et al.* (1998) did an anterograde tracing study in which biotinylated dextran was injected into the subnucleus caudalis. Dense labeling was found in several areas of the reticular formation and light labeling near the dendrites of catecholaminergic neurons in the C1, A1, and A5 regions. Injections into the dorsal medullary reticular formation resulted in dense labeling in the ventral medullary and pontine reticular formation, with numerous terminals near catecholaminergic neurons. It was suggested that reflex cardiovascular responses produced by painful stimulation in the trigeminal distribution involve indirect projections to the dorsal medullary and pontine reticular formation and connections from there to ventral medullary and pontine catecholaminergic neurons.

Krout K. E. *et al.* (2002) used retrograde tracing with cholera toxin subunit B to demonstrate projections from the brainstem reticular formation to intralaminar and midline nuclei of the thalamus in rats. The possible roles of the brainstem–thalamic pathways in arousal, somatosensory processing, and visceral control are discussed.

6.06.3.5.3 Trigeminoparabrachial neurons

Dallel R. *et al.* (2004) performed an anterograde tracing study that demonstrated projections from the subnucleus oralis of the spinal nucleus of the trigeminal nerve to the ipsilateral parabrachial nucleus and also to an area near the Kölliker-Fuse nucleus.

They suggest that these connections contribute to the processing of gustatory and nociceptive information. The dendrites of nociceptive parabrachial neurons have been shown to be located within the anterogradely labeled zones of termination of lamina I neurons of the medullary and spinal cord dorsal horns (Bourgeais, L. *et al.*, 2003).

6.06.3.5.4 Other trigeminal projection neurons

Iwata K. *et al.* (1998) performed an anterograde tracing study using injection of PHA-L into the medullary dorsal horn. Large injections resulted in labeling in the contralateral anterior pretectal area, superior colliculus, and the rostral linear raphe nucleus in the midbrain, as well as in the ipsilateral parabrachial nucleus. There were different labeling patterns when the label was injected into the SDH versus the DDH, indicating the presence of at least two different pathways.

6.06.3.6 Descending Control Systems

As for second-order somatosensory circuits in the spinal cord, brainstem somatosensory circuits are regulated by pathways that descend from higher levels of the brain. Corticobulbar projections influence these circuits, as well as do projections from the PAG and NRM (Sessle, B. J. *et al.*, 1981; Sunada, T. *et al.*, 1990). For example, electrical stimulation of the S II somatosensory cortex in rats was shown by Gojyo F. *et al.* (2002) to reduce the number of Fos-expressing neurons in the contralateral subnucleus caudalis following a bilateral injection of formalin into the lower lip. There are also descending projections from the parabrachial region to both the trigeminal sensory nuclei and the spinal cord dorsal horn. The parabrachial projections originate from the ventrolateral parabrachial area, including the Kölliker-Fuse nucleus and terminate in the main sensory nucleus and in the subnuclei oralis, interpolaris, and caudalis of the spinal nucleus, as well as in the spinal cord dorsal horn.

Glossary

anterior pulvinar A subdivision of the pulvinar complex of the dorsal thalamus that is somatosensory rather than visual in function. The anterior pulvinar receives inputs from areas of the somatosensory cortex and projects back to areas of the somatosensory cortex.

dorsal column–trigeminal complex A group of three main subnuclei in the lower brainstem and upper spinal cord that receives cutaneous receptor afferents from the body, via the dorsal columns of the spinal cord, and from the head, via the trigeminal nerve. The complex projects to the ventroposterior nucleus (VP) of the contralateral thalamus. The subnuclei, often called nuclei, include the gracile nucleus for the lower body, the cuneate nucleus for the upper body and forelimb, and the trigeminal nucleus for the face and mouth.

dorsal root ganglia The structures that contain the cell bodies of afferents that course in peripheral nerves and enter the spinal cord via the dorsal roots of peripheral nerves.

dorsal thalamus A major component of the diencephalon, which also includes the epithalamus, ventral thalamus, hypothalamus, and pretectum. The dorsal thalamus, the division that is largest in mammals, receives ascending sensory pathways and projects to the neocortex.

low-threshold mechanoreceptor afferents Four types of low-threshold mechanoreceptors subserve the glabrous skin. The type I class is a slowly adapting afferent (SA-I) that is activated by receptors called Merkel disks, which respond to light pressure. The type II class (SA-II) is activated by Ruffini corpuscles that respond to skin stretch. The type I rapidly adapting afferent (RA-I) is activated by Meissner corpuscles and signals changes in skin indentation. The rapidly adapting type II (RA-II) or Pacinian afferent stems from Pacinian corpuscles that respond to vibration.

thalamic nucleus A collection of neurons and glia in the thalamus that is united by a common function. A nucleus is typically identified as a group of cells that is distinguished from adjoining groups of cells by differences in the sizes and packing of neurons. Many other histological characteristics are used to distinguish nuclei. Each nucleus should also have a distinct set of connections with the neocortex and other structures, and have neurons that have a distinct set of physiological response characteristics.

ventroposterior nucleus A nucleus in the thalamus that receives somatosensory afferents from the contralateral brainstem, systematically represents the cutaneous receptors of the contralateral body, and projects to the primary somatosensory cortex.

6.07.1 Introduction

This chapter describes structures in the early stages of processing in the somatosensory system. The focus is on the ascending sensory inputs to the somatosensory thalamus, the organization of the somatosensory thalamus, and the relay of somatosensory information from the thalamus to the cortex. Most of this description concentrates on what is known about the somatosensory system of anthropoid primates (monkeys, apes, and humans), as this information is most relevant to understanding how somatosensory information is processed in the human brain. Because the types of studies of somatosensory systems that can be conducted using apes and humans are limited, much of the data discussed here comes from investigations on monkeys. Thus, it is important to remember that many features of even the early stages of processing in somatosensory systems are variable across species. The somatosensory system of humans resembles those of monkeys, while being different in many ways. In addition, there are approximately 4500 species of mammals, now divided into six superorders. This impressive radiation of mammalian species has resulted in a number of distinctly different specializations of somatosensory systems (see Chapters The Evolution of Parietal Areas Involved in Hand Use in Primates and Specialized Somatosensory Systems), of which only a few have been studied in any detail. While an extensive comparative approach is not possible here, observations on the somatosensory systems of some of the more fully studied nonprimate mammals are included.

The parts of the somatosensory system of primates covered in this review are depicted schematically in Figure 1. In brief, peripheral nerve afferents related to receptors in the skin, muscles, and joints of each side of the body enter the spinal cord and lower brainstem where they branch to terminate locally in the dorsal horn of the spinal cord. Other branches of these afferents ascend in the ipsilateral dorsal columns or join the trigeminal pathways to terminate in the dorsal column–trigeminal nucleus complex or proprioceptive nuclei in the upper spinal cord and lower brainstem. Neurons in these nuclei send axons across the midline to form the medial lemniscus, a pathway that terminates in the ventroposterior complex of the contralateral thalamus. In addition, a small proportion of these neurons, largely neurons representing afferents devoted to the teeth and tongue, project into the ipsilateral medial lemniscus to the ipsilateral thalamus. Thus, parts of the oral cavity become represented in both the ipsilateral and the contralateral ventroposterior complex, as well as in the cortex. Another source of somatosensory information to the ventroposterior complex is from the spinothalamic pathway. Afferents that terminate in the dorsal horn of the spinal cord, and the equivalent part of the trigeminal nuclei of the lower brainstem, synapse on neurons that send axons across the midline to form the ventrolateral spinothalamic pathway that terminates in several subdivisions of the contralateral somatosensory thalamus. Thalamic neurons in the ventroposterior complex send axons to subdivisions of the anterior parietal cortex and other somatosensory areas such as the second somatosensory area (S2). In anthropoid primates, the anterior parietal cortex consists of the architectonic fields 3a, 3b, 1, and 2 of Brodmann K. (1909). Each of these fields receives a different pattern of projections from the somatosensory thalamus, and each contains a separate, complete representation of peripheral nerve afferents, mainly those from the contralateral half of the body. Thus, each area represents the contralateral body, from tail (if present) to tongue, in a mediolateral sequence across the cortex. The representations of ipsilateral afferents from the tongue and teeth activate the lateral extremes of these representations. Another thalamic nucleus, the anterior pulvinar of primates, receives inputs from areas of the somatosensory cortex, and contains neurons that project back to areas of the somatosensory cortex.

Descriptions of the somatosensory thalamus and cortex of cats and rats, and other well-studied nonprimate mammals, differ from those of anthropoid primates in that several subdivisions of the somatosensory thalamus and cortex are not recognized, or they have different names. In the thalamus, for example, the anterior pulvinar and the ventroposterior inferior nuclei (VPI) are not generally recognized, and the question that arises is whether these nuclei have emerged only in primates, have been named differently in other mammals, or have not been identified in other mammals. Likewise, in the cortex of anthropoid primates, four parallel representations exist in the anterior parietal cortex (areas 3a, 3b, 1, and 2), but only area 3b appears to correspond to the primary somatosensory area, S1, as commonly defined in other mammals. Are the other areas (3a, 1, and 2) unrecognized, differently named, or a derivation of anthropoid primates? Thus, descriptions and discussions of especially the organization of the

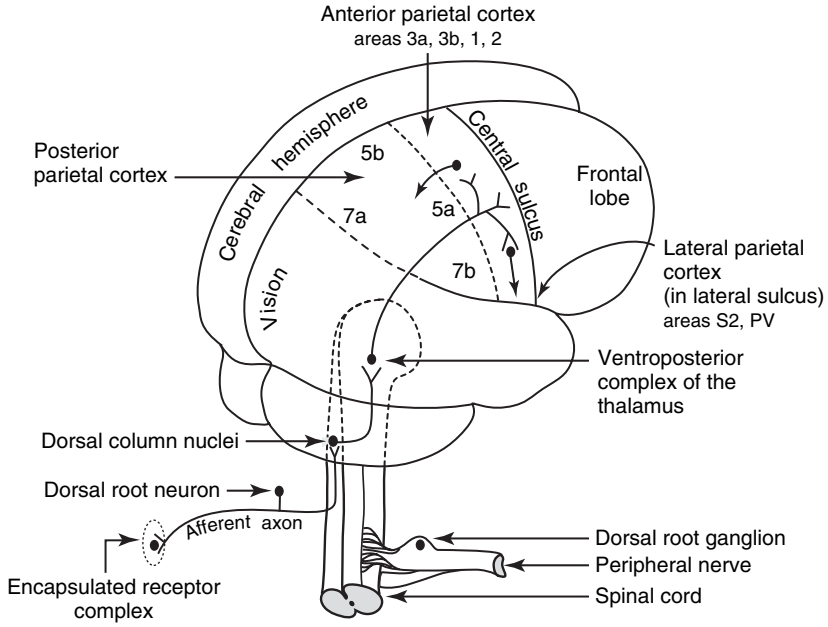

Figure 1 The basic components of the somatosensory system shown on a posterolateral view of a primate brain. Afferents subserving receptors in the skin, muscles, and joints travel in peripheral nerves to enter the spinal cord or brainstem to send axon branches into the dorsal column nuclei or divisions of the trigeminal complex. Neurons in these nuclei send axons to the ventroposterior nucleus (VP) and the ventroposterior superior nucleus (VPS) of the ventroposterior complex of the contralateral thalamus. Neurons in VP and VPS project to areas 3a, 3b, 1, and 2 of the anterior parietal cortex. Information from the anterior parietal cortex is distributed further to areas of the lateral parietal cortex, including the second somatosensory area (S2), the parietal ventral area (PV), the parietal rostral area (PR), and the ventral somatosensory area (VS). Other projections from the anterior and lateral parietal cortex spread somatosensory information to subdivisions of the posterior parietal cortex, shown here as divided into the classical areas of Brodmann K. (1909) numbered 5a, 5b, 7a, and 7b for general locations (this cortex is now known to be more complexly organized). Other afferents (see Figure 2) terminate in the dorsal horn of the spinal cord where neurons contribute to the contralateral spinothalamic tract, which terminates in the ventroposterior inferior nucleus (VPI) where neurons project to areas of the anterior and lateral parietal cortex. From Kaas, J. H. 2004. Somatosensory System. In: The Human Nervous System, 2nd edn. (*eds*. G. Paxinos and J. K. Mai), pp. 1059–1092. Elsevier Academic Press.

thalamus and cortex that go beyond our focus on primates and include other well-studied mammals are complicated by species differences in the appearances and names of brain structures.

6.07.2 Somatosensory Afferents and Afferent Pathways

Because several other chapters in this volume (see Chapters Cutaneous Mechanisms of Tactile Perception: Morphological and Chemical Organization of the Innervation to the Skin, Merkel Cells, Physiological Responses of Sensory Afferents in Glabrous and Hairy Skin of Humans and Monkeys, and Physiological Characteristics of Second-Order Somatosensory Circuits in Spinal Cord and Brainstem) review the functional organization of the peripheral somatosensory system, only a brief overview is necessary here (also see Kaas, J. H., 2004). Our main focus is on the low-threshold mechanoreceptors of the glabrous and hairy skin, as these provide the input that is critical for making fine tactile discriminations and tactile recognition. However, afferents from joint and muscle receptors for proprioception are equally important, as object recognition and localization by touch depend on knowing the articulation of the digits relative to each other, and the relationship between activity from cutaneous and proprioceptors. Low-threshold afferents from the glabrous skin include the slowly adapting type I (SA-I) subserved by Merkel cells, rapidly adapting type I (RA-1) from Meissner corpuscles, slowly adapting type II (SA-II) with Ruffini-like receptors, and rapidly adapting type II, emanating from Pacinian corpuscles. Hairy skin

afferents are similar, except that RA-I and SA-I receptors are also found in hair follicles around shafts of hairs where hair movement disturbs the base. Merkel cell receptors for SA-I afferents may be aggregated in touch domes or spots, and RA-II Pacinian receptors are found in deeper tissues rather than the skin. Other cutaneous afferents include the wide dynamic range (WDR) and other more slowly conducting afferents that respond to touch and more intense stimuli, and contribute to the spinothalamic pathway. In deeper tissues, the muscle spindle receptor afferents are very important for proprioception, perhaps aided by afferents from Ruffini and Golgi types of receptors in and around joints.

Afferents from peripheral receptors combine to form small nerve fascicles that join other fascicles and motor efferent axons to form peripheral nerves that then segregate afferents from efferents as they approach the spinal cord to form the dorsal sensory and ventral motor roots, as sensory afferents enter the spinal cord (and brainstem) and motor neuron axons leave.

Afferents entering the spinal cord terminate locally on neurons in the ipsilateral dorsal horn of the spinal cord to form an elongated representation of the ipsilateral half of the body (e.g., Florence, S. L. *et al.*, 1988; 1989). Terminations of the axon arbors of different classes of afferents distribute differently over the layers of the dorsal horn, maintaining a segregation of types of information. The low-threshold mechanoreceptors and muscle spindle receptor afferents also branch to send a collateral toward the brainstem to terminate either in the dorsal horn at higher levels or in the dorsal column–trigeminal complex of the lower brainstem (Figure 2). These collaterals contribute to the dorsal (posterior) column and dorsolateral column afferent pathways. WDR, nociceptive, and temperature-sensitive afferents terminate locally in the dorsal horn of the spinal cord on neurons that send axons across the midline of the spinal cord to ascend in the ventrolateral white matter to form the spinothalamic pathway, known as a relay of information about pain, temperature, and crude touch (Willis, W. D. and Coggeshall, R. E., 2004).

Primary afferents from oral and facial structures course in the trigeminal (fifth cranial) nerve to branch and terminate in the principal trigeminal nucleus (combining with the dorsal column nuclei to form a complete representation of the tactile receptors of the ipsilateral body surface), the mesencephalic trigeminal nucleus for muscle spindle afferents, and the spinal trigeminal nucleus for WDR and other afferents.

Second-order neurons in the spinal trigeminal nucleus send axons to the opposite ascending spinothalamic pathway. Thus, afferents entering the brainstem sort themselves to terminate with similar types in nuclei with second-order neurons that project contralaterally to form the medial lemniscus or spinothalamic pathways to the somatosensory thalamus.

In addition to neurons in the dorsal horn of the spinal cord that contribute to the spinothalamic tract, a long column of neurons outside the dorsal horn that extends from about the fourth cervical segment to the caudal medulla is known as the lateral cervical nucleus (Kaas, J. H., 2004). In humans, the lateral cervical nucleus is usually only a rudimentary structure, but it may contain up to 8000 neurons in cats where it is well developed. The lateral cervical nucleus receives a wide range of somatosensory inputs, and projects via the spinocervicothalamic pathway to the contralateral somatosensory thalamus to terminate in the septal regions of VP (Broman, J. and Zhang, M., 1996) in conjunction with spinothalamic tract terminations.

6.07.3 Somatosensory Relay Nuclei of the Medulla and Upper Spinal Cord

A collection of nuclei in the lower brainstem and upper spinal cord receive inputs from ipsilateral low-threshold mechanoreceptors and project to the contralateral ventroposterior complex of the thalamus (Figure 2). By tradition, several nuclei have been distinguished and named in this complex, but such subdivisions are best considered subnuclei, that is, parts of a functional system differing mainly in what parts of the body they represent, rather than nuclei that are devoted to distinct functions. Thus, the gracile, cuneate, and principal trigeminal nuclei all receive inputs from the low-threshold mechanoreceptors of the skin, and represent the hindlimb, the trunk and forelimb, and face plus oral cavity in a mediolateral sequence of subnuclei in the lower brainstem and upper spinal cord (e.g., Johnson, J. I. *et al.*, 1968; Xu, J. and Wall, J. T., 1996). Some investigators even distinguish a more medial cell group as Bischoff's nucleus (e.g., Johnson, J. I. *et al.*, 1968), a midline cell group that receives afferent inputs from the tail (Qi, H.-X. and Kaas, J. H., 2006). These subnuclei combine to form a functional unit, the dorsal column–trigeminal complex. However, there are other nuclei or subnuclei associated with the complex, as inputs from muscle spindle and joint

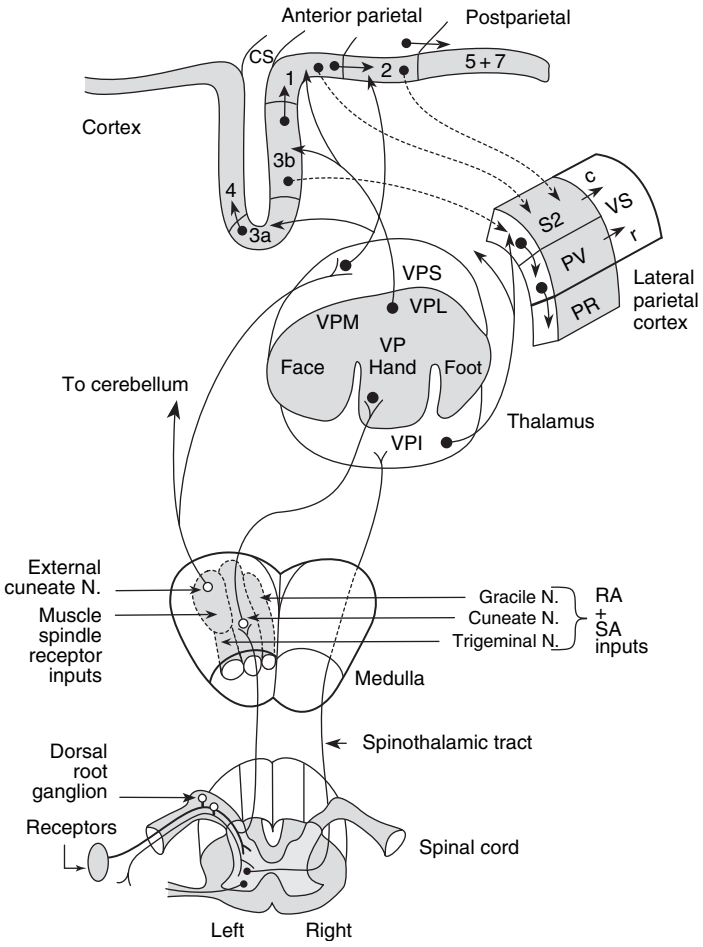

Figure 2 A more detailed schematic of components of the somatosensory system of anthropoid primates. Afferents from low-threshold, rapidly adapting (RA), and slowly adapting (SA) mechanoreceptors in the skin enter the spinal cord and brainstem to send branches that terminate in the gracile and cuneate nuclei (N) of the principal nucleus of the trigeminal nuclear complex, to synapse on neurons that project via the medial lemniscus nucleus (VP), where the ventroposterior lateral division (VPL) represents the foot, trunk, and hand, and the ventroposterior medial division (VPM) represents the face and oral structures. Afferents from muscle spindle receptors enter the spinal cord or brainstem to send branches to the external cuneate nucleus and other nuclei that project via the medial lemniscus to the contralateral ventroposterior superior nucleus (VPS). Other afferents terminate in the dorsal horn of the spinal cord or its equivalent in the trigeminal nuclear complex where neurons project via the contralateral spinothalamic tract to the ventroposterior inferior (VPI) nucleus. Arrows indicate projections of the three thalamic nuclei to the Brodmann K. (1909) areas of the anterior parietal cortex (3a, 3b, 1, and 2), and the lateral parietal cortex (ventral somatosensory area, VS, with caudal and rostral divisions, c and r, second somatosensory area (S2), parietal ventral area (PV), and parietal rostral area (PR)). Arrows also denote cortical connections that further distribute somatosensory information from the anterior parietal cortex, including a projection from area 3a to area 4 of the motor cortex. The bend in the cortical sheet corresponds to the central sulcus (CS). From Kaas, J. H. 2004. Somatosensory System. In: The Human Nervous System, 2nd edn. (*eds*. G. Paxinos and J.K. Mai), 1059–1092. Elsevier Academic Press.

receptor afferents terminate separately in several cell groups that relay to a separate nucleus of the contralateral ventroposterior thalamus, the ventroposterior superior nucleus (VPS) (Figure 2). Thus, two small medullary nuclei, termed X and Z by Pompeiano O. and Brodal A. (1957), receive inputs from muscle spindle afferents of the lower limb, the external cuneate nucleus is activated by muscle spindle afferents from the trunk and upper limb, while the mesencephalic trigeminal nucleus receives muscle spindle afferents from the face. These cell groups form a second functional unit in the lower brainstem that relays proprioceptive information to the contralateral thalamus.

6.07.3.1 The Dorsal Column–Trigeminal Complex

The sensory inputs to the subnuclei of the medullary complex that represent the forelimb, trunk, and hindlimb travel in the dorsal (posterior) columns of the spinal cord, while the inputs from the face and oral cavity course both dorsally and caudally after entering the midpontine brainstem to innervate the principal nucleus and other subnuclei of the trigeminal complex. The two major divisions of the dorsal column pathway are the gracile tract that carries information from the lower limb, lower trunk, and tail (if present) and the cuneate tract subserving the upper limb, upper trunk, and neck. The axons in the dorsal columns include the ascending branches of large, myelinated dorsal root fibers that enter the spinal cord at various levels while subserving adjoining skin regions. As the branches enter the dorsal columns from lower to higher spinal cord levels, the branches at higher levels add to the pathways laterally, resulting in a rough somatotopic pattern from medial to lateral across the dorsal columns (Whitsel, B. L. *et al*., 1972). A further refinement of this pattern occurs as the terminations of these axons sort themselves somatotopically in the dorsal column nuclei. Other axons in the dorsal columns originate from spinal cord neurons in the dorsal horn that either course in the dorsal column for several spinal cord segments to exit or continue to terminate in dorsal column nuclei or associated nuclei. Thus, the dorsal column pathway contains both branches of peripheral nerve axons, and axons that originate in second- or higher-order neurons of the dorsal horn of the spinal cord.

The gracile and cuneate tracts contain mixtures of functional classes of axons (Whitsel, B. L. *et al*., 1972). At lower spinal cord levels, the gracile tract contains a mixture of cutaneous afferents and muscle spindle afferents. The muscle spindle afferents leave at higher levels to innervate proprioceptive nuclei for the lower limb. The remaining afferents appear to be largely of the rapidly adapting RA-I type, but the smaller numbers of RA-II (Pacinian) and SA-I afferents likely course in this pathway as well to terminate in the gracile nucleus. The fate of the SA-II afferents, sensitive to skin stretch and thereby joint movement, is uncertain, but they may enter and then leave the tract to join with muscle spindle afferents to contribute to proprioception (McCloskey, P. I., 1978). The cuneate tract also contains a mixture of axonal branches of cutaneous and muscle spindle afferents, with the muscle spindle afferents separating to terminate in the external (proprioceptive) cuneate nucleus.

Complete lesions of the dorsal column in humans produce major defects in their ability to detect the speed and direction of moving contacts on the skin, but simple contacts can be felt and roughly localized (Nathan, P. W. *et al*., 1986; see Mountcastle, V. B., 2005, for review). The ability to judge the position and movement of the limbs is also greatly impaired, as there can be a major loss of the afferents carrying proprioceptive information. Thus, monkeys and humans with such lesions tend to not use the affected limb, and are impaired in the positioning and control of finger and hand movements (Glendenning, D. S. *et al*., 1992; Cooper, B. Y. *et al*., 1993).

The subnuclei of the dorsal column–trigeminal complex are organized somewhat differently from each other. However, all are elongated in the rostrocaudal dimension (Figure 2), and are largely composed of discrete clusters of cells separated from each other by a matrix of axons and glia. The cell clusters or nests have long been recognized (e.g., Cajal, S. R. Y., 1911). These clusters express higher levels of the inhibitory neurotransmitter, GABA, the calcium-binding proteins calbindin and parvalbumin, the activity-dependent enzyme nitric oxide synthase, and brain-derived neurotropic factor (Strata, F. *et al*., 2003) than the surrounding neuropil. In addition, the cell clusters express higher levels of the metabolic enzyme, cytochrome oxidase (CO), which is commonly used as a histological marker for these nuclei (Figure 3). Thus, the cell clusters are centers of metabolic activity in the nuclei where neurotransmitters are released and high levels of synaptic activity occur. While the majorities of neurons in the clusters are excitatory and project to the contralateral thalamus, roughly 30% of the neurons are inhibitory, and have local connections within the nuclei where they constrain the sizes of receptive fields (Schwark, H. D. *et al*., 1999; Wang, X. and Wall, J. T., 2006). Areas of the somatosensory cortex also project to the cell clusters, and these inputs appear to modulate the response properties of the relay neurons (Willis, W. D. and Coggeshall, R. E., 2004; Wang, X. and Wall, J. T., 2005).

The segregation of neurons into small clusters that are activated by a similar input may be a reflection of developmental mechanisms that isolate particular groups of neurons so that other axons are less likely to inadvertently grow into an inappropriate cluster (Massey, J. M. *et al*., 2006). The cell

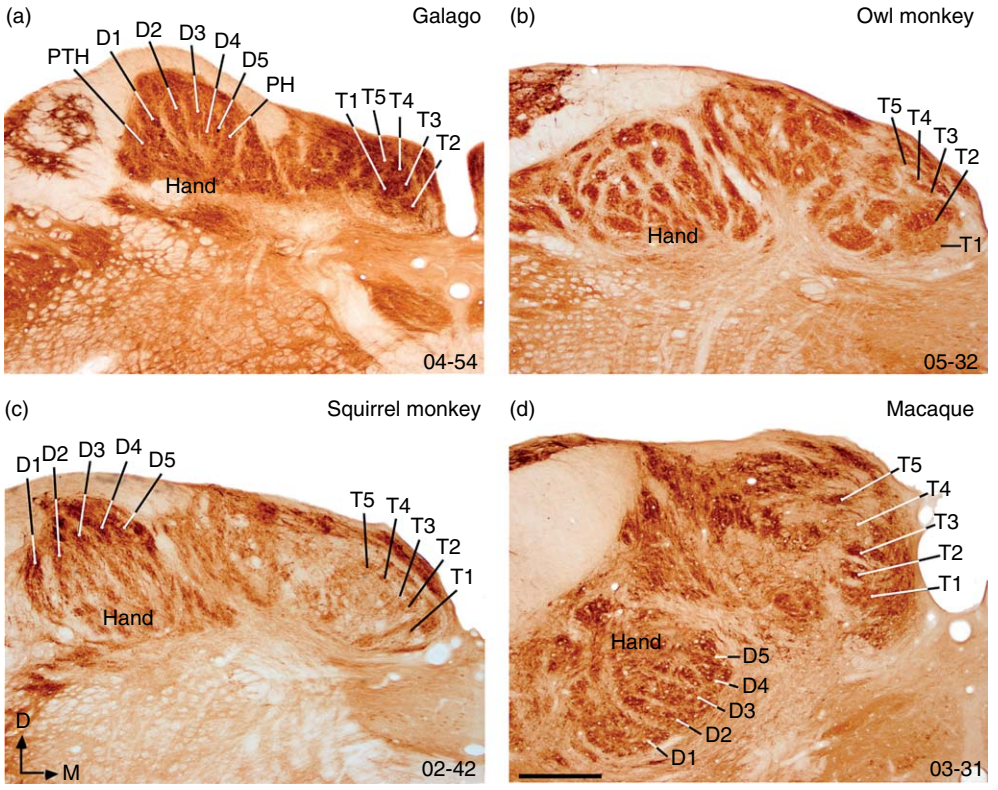

Figure 3 The gracile and cuneate nuclei of (a) a prosimian primate, galago; (b) a New World owl monkey; (c) a New World squirrel monkey; and (d) an Old World macaque monkey. The transverse brainstem sections through the rostral third of the nuclei have been processed for cytochrome oxidase (CO) to reveal CO-dense ovals or islands of tissue that are densely packed with neurons and surrounded by CO-light septa that have few neurons. The CO-dense modules for each primate receive slowly adapting (SA) or rapidly adapting (RA) afferents from different body parts so that collectively they represent the trunk, limbs, and tail, with afferents from the face and oral structures terminating in the principal nucleus of the trigeminal complex (not shown). In each section, dorsal (D) is up and medial (M) is to the right. Note that the toes of the foot (TI–T5) are represented in a mediolateral sequence in the more medial gracile nucleus, while the digits of the hand (D1–D5) are represented in a lateromedial sequence in the more lateral cuneate nucleus. CO-dense cell clusters activated from the thenar pad (Pth) and hyperthenarpad (PH) of the hand are also shown for the galago. The detailed organization of the cuneate nucleus in owl monkeys has not yet been determined. Dorsal (D) and medial (M) are indicated by arrows. Scale bar = 0.5 mm. From Qi, H.-X. and Kaas, J. H. 2006. The organization of primary afferent projections to the gracile nucleus of the dorsal column system of primates. J. Comp. Neurol. 499, 183–217.

clusters are most prominent in the central parts of the nuclei. While these isolated groups of neurons are activated by afferents from the same body part, they may also be receiving a different class of inputs from that body part. In the cuneate nucleus of cats, at least, microelectrode recordings have revealed a mosaic of restricted locations where cell neurons are activated by rapidly adapting type I inputs, Pacinian type II inputs, or slowly adapting inputs, probably type I (Dykes, R. W. *et al.*, 1982). This type of evidence is consistent with the premise that three or four of the major types of cutaneous mechanoreceptor afferents terminate in the nuclei of the dorsal column–trigeminal complex, and that separate groups of cells are activated by each class of input. Nevertheless, the inputs are organized overall into a somatotopic pattern.

The patches of dense expression of CO that correspond to cell clusters are shown for four species of primates in Figure 3. The figure also indicates the clusters that are innervated by afferents from different parts of the hand in the cuneate nucleus, and the foot in the gracile nucleus. These patterns of representation were determined by injecting tracers into restricted portions of the skin, which were then transported by afferents from the skin to terminations in cell clusters (Florence, S. L. *et al.*, 1988; 1989; 1991; Strata, F. *et al.*, 2003; Qi, H.-X. and Kaas, J. H., 2006).

Note that the digits are represented in order from lateral to medial by a series of CO-dense patches in the cuneate nucleus (not shown for the owl monkey, as the relevant experiments have not been done in this primate). Curiously, the glabrous hand is represented ventral to that of the digits in New World monkeys and dorsal to the hand in Old World monkeys (and probably in humans), while parts of the hand are represented both dorsal and ventral to that of the digits in prosimian galagos. In other mammals, the dorsal representation of the digits is often represented with a part of the dorsal and ventral hand (see Florence, S. L. *et al.*, 1991). Because the pattern of organization of the cuneate nucleus in prosimian galagos (Figure 3(a)) resembles patterns seen in other mammals, rather than the patterns seen in monkeys, it is likely that the organization of the cuneate in galagos reflects a primitive pattern of organization for this nucleus. Differences across primate taxa may relate to the increased use of the digits as a sensory surface in macaques, and to a lesser extent squirrel and owl monkeys, over prosimian galagos.

As the dorsal column nuclei are elongated rostrocaudally, a fuller appreciation of the somatotopic organization of these nuclei can be obtained by examining a series of transverse sections. In Figure 4, the gracile nucleus of a prosimian galago is color coded across a series of spinal cord and brainstem sections to show the overall somatotopic organization, and to show that the same body part is represented over most or all of the nucleus. Thus, the representations of the tail, foot, lower leg, and upper leg form a mediolateral sequence, while the representation of each of these skin surfaces is disjunctively focused within separated cell clusters along the rostrocaudal length of the nucleus. Results from other primates are similar, with a certain amount of species-specific variation. The reasons for separate clusters of neurons being activated by inputs from the same body part are not clear, but separate clusters could relate to different classes of afferent inputs, as noted above. The representation of skin receptors in the gracile nucleus seems to be more discontinuous and complex than in the cuneate nucleus.

The trigeminal component of the dorsal column–trigeminal nuclear group is more complex than the gracile and cuneate nuclei, as the trigeminal complex has been traditionally divided into five sensory nuclei: the principal sensory nucleus (Pr5), three spinal nuclei (oralis (Sp5o), interpolaris (SP5i), caudalis (Sp5c)), and

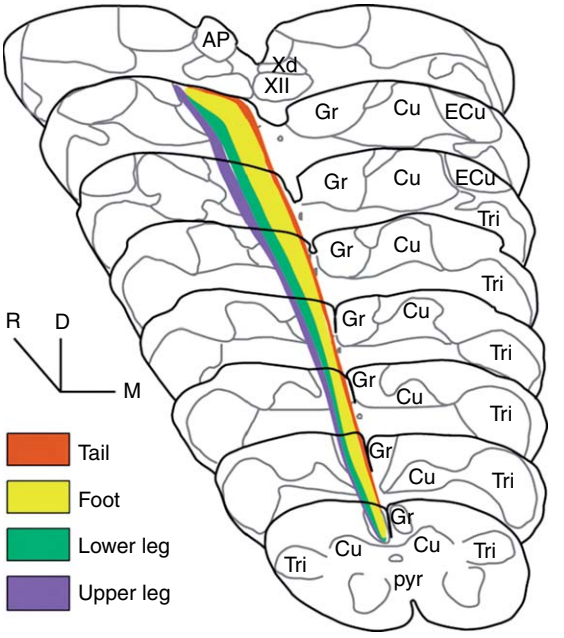

Figure 4 The somatotopic organization of the gracile nucleus in monkeys shown on a rostral (R) to caudal (C) series of brain sections through the dorsal column nuclei. Note that the tail, foot, lower leg, and upper leg are represented in a mediolateral sequence. A more lateral representation of the trunk joins the gracile with the cuneate nucleus for the forelimb. On the individual brain sections, the gracile nucleus (Gr), the cuneate nucleus (Cu), the trigeminal nuclear complex (Tri), and the external cuneate nucleus (ECu) are outlined. The locations of the pyramidal tracts (Pyr), motor nucleus of the twelfth cranial nerve (XII), and dorsal nucleus of the tenth nerve (Xd) and area postrema (AP) are shown for reference. From Qi, H.-X. and Kaas, J. H. 2006. The organization of primary afferent projections to the gracile nucleus of the dorsal column system of primates. J. Comp. Neurol. 499, 183–217.

the mesencephalic nucleus (Me5) for proprioception. Together they form a long column of cells that extends from the rostral pons to the upper segments of the cervical spinal cord (Waite, P. M. E. and Ashwell, K. W. S., 2004). The principal nucleus receives low-threshold mechanoreceptor afferents from the ipsilateral face and mouth, and it is the trigeminal component of the dorsal column–trigeminal complex. Neurons in the principal nucleus project across the midline to join the contralateral medial lemniscus and ascend to terminate in the ventroposterior medial subnucleus of VP. The principal nucleus is somatotopically organized (Kerr, F. W. L. *et al.*, 1968; Florence, S. L. and Lakshman, S., 1995; May, P. J. and Porter, J. D., 1998) and has the CO-dense patches of cells that also characterize the dorsal column nuclei (Noriega, A. L. and Wall, J. T., 1991).

The three spinal trigeminal nuclei all appear to contain separate representations of inputs from the face and oral cavity. CO patches found in the principal nucleus are not evident in the spinal nuclei in primates, but patches representing vibrissae of the face can be found in nucleus interpolaris and nucleus caudalis of rodents and cats (see Noriega, A. L. and Wall, J. T., 1991, for review). These nuclei are analogous to cells located in the dorsal horn of the spinal cord and cells in the proprioceptive nuclei for the lower body. As such, they contribute to the relay of muscle spindle afferent information to the contralateral thalamus, as well as a relay of mechanoreceptor, WDR, and nociceptive afferent information via the trigeminal contribution to the spinothalamic tract.

In addition to the contralateral projections from neurons in the trigeminal complex, both the principal and the spinal nuclei of the complex project ipsilaterally to the ventroposterior thalamus (Ganchrow, D., 1978; Jones, E. G. *et al.*, 1986). This ipsilateral component of a bilateral projection seems to be species variable, being large in sheep and small or absent in rats (Bombardieri, R. A. *et al.*, 1975). Across species, the ipsilateral relay is largely of inputs from the mouth, but ipsilateral inputs from the side of the head and lips are also observed in sheep (Cobral, R. J. and Johnson, J. I., 1971). In monkeys, the ipsilateral projections from the principal nucleus relay information from periodontal receptors that are responsive to light touch on the teeth and from cutaneous receptors on the tongue and inner cheek (Bombardieri, R. A. *et al.*, 1975; Jones, E. G. *et al.*, 1986). Other types of information are relayed from the spinal nuclei.

The mesencephalic trigeminal nucleus is another component of the trigeminal complex. The neurons of this nucleus are unique in that they are the cell bodies of peripheral nerve afferents. Instead of being located in the dorsal root ganglia for peripheral nerves, as for the cell bodies of other peripheral nerve afferents, these cell bodies are located within the central nervous system, mainly in the pons of the upper brainstem (Waite, P. M. E. and Ashwell, K. W. S., 2004). The cell bodies are of several types, mainly the pseudounipolar type that is characteristic of dorsal root ganglion cells, but also bipolar and multipolar neurons (Luo, P. *et al.*, 1991). The afferents of these cell bodies conduct proprioceptive impulses from muscle spindle receptors in the jaw muscles and from periodontal mechanoreceptors (see Luo, P. *et al.*, 1991, for review). The central projections of the cell bodies of the mesencephalic trigeminal nucleus terminate in the principal trigeminal nucleus (Luo, P. *et al.*, 1991; 1995), which in turn, relays proprioceptive information to the contralateral (and possibly ipsilateral) ventroposterior complex (e.g., Williams, M. N. *et al.*, 1994). Thus, most or all of the second-order neurons in the principal trigeminal nucleus that are responsive to proprioceptive inputs are activated by first-order afferent neurons with cell bodies in the mesencephalic trigeminal nucleus.

The trigeminal complex also includes a motor nucleus (Mo5) with cells projecting to muscles of the face and tongue. Some of the inputs to Mo5 are from Me5. The supratrigeminal nucleus and the intertrigeminal nucleus are additional motor nuclei associated with the trigeminal complex (Waite, P. M. E. and Ashwell, K. W. S., 2004).

6.07.4 The Nuclei of the Somatosensory Thalamus, Their Spinal Cord and Brainstem Somatosensory Inputs, and Their Cortical Projections

The somatosensory thalamus of primates includes three major nuclei (Figure 2): VP, VPS, and VPI. VP is the main relay of tactile information to the somatosensory cortex, and is a nucleus that has been identified in all studied mammals. VPS relays information from deep receptors in muscles and joints to the cortex. This nucleus has not been recognized as such in mammals other than primates, but a homologue likely exists in all or most mammals. VPI has spinothalamic inputs and projects broadly to somatosensory cortical areas. As for VPS, VPI is not generally recognized in nonprimate mammals, but has been recognized in squirrels, raccoons, and cats (Herron, P., 1983; Herron, P. and Dykes, R. W., 1986; Krubitzer, L. A. and Kaas, J. H., 1987). In addition to these three nuclei, the anterior pulvinar of primates is associated with somatosensory processing as it has reciprocal connections with the somatosensory cortex. Another subdivision of the pulvinar complex, the medial pulvinar, has connections with posterior parietal cortical fields involved in generating visually directed reaching and grasping and multisensory integration, which suggests that this nucleus is involved in higher-order functions. The lateral posterior nucleus, a less well-defined structure, also has connections with subdivisions of the posterior parietal cortex. However, in cats and a number of other mammals, components of the visual pulvinar have been included in the lateral posterior nucleus or

complex. In most mammals, one or more nuclei have been defined as belonging to the posterior complex (Po), which has somatosensory and multisensory functions. Finally, the ventromedial posterior nucleus, VMpo, has been proposed as a nucleus involved in the sensation of pain and temperature (Craig, A. D. *et al.*, 1994), and the parvocellular ventroposterior medial nucleus (VPMpc) is involved in relaying information about both touch and taste to the cortex (Kaas, J. H. *et al.*, 2006). The focus here is on the three main nuclei of the VP complex: VP, VPS, and VPI.

6.07.5 The Ventroposterior Nucleus

VP is a basic subdivision of the mammalian thalamus (Welker, W. I., 1973; Jones, E. G., 2007) that is easily identified by its densely packed, darkly stained neurons (Figure 5(b)) and its ventral location just posterior to the motor thalamus in coronal brain sections stained for cell bodies (Nissl stain). Neurons in VP express high levels of the metabolic enzyme CO (Figure 5(a)), and the calcium-binding protein parvalbumin (Rausell, E. *et al.*, 1992). In contrast, VP expresses very little of the calcium-binding protein calbindin (Figure 5(c)). These are some of the histochemical features that distinguish VP from the adjacent thalamic nuclei in primates: VPS and VPI. Neurons in VPS and VPI are less densely packed and less darkly stained for Nissl substance, and express less CO and more calbindin. The histological features that distinguish VP are also present in other primary sensory nuclei of the thalamus (the lateral geniculate nucleus and the ventral nucleus of the medial geniculate complex). The distinction between the VP and the VPS is less pronounced in macaque monkeys (see Figure 7) (e.g., Paxinos, G. *et al.*, 2000) and humans (e.g., Morel, A. *et al.*, 1997), where VPS more closely resembles VP in cytoarchitecture than in prosimian galagos (Figure 5) and New World monkeys (Figure 6; Krubitzer, L. A. and Kaas, J. H., 1992). Thus, most early studies of the connections and physiology of VP in macaques did not distinguish between VP and VPS and combined results from both nuclei. The clear architectonic distinctions between VP and VPS in prosimian primates and New World monkeys reflect major differences in the functional properties of neurons in the two structures, and in their patterns of cortical connections. These anatomical and functional differences are also found in macaque monkeys. Thus, there are reasons for distinguishing VP from VPS in all primates.

Another characteristic of VP is that the nucleus is divided into separate masses of cells by narrow cell-poor bands or septa (Figures 5–7). The most conspicuous of these across species is the band that separates the more medial part of VP representing the face from the more lateral part representing the body. These two divisions of VP, the ventroposterior medial division (VPM) and the ventroposterior lateral division (VPL), are typically distinguished as two nuclei separated by a prominent septum called the arcuate lamina, but they are more accurately considered major divisions of VP. Other septa are species variable, but common. In primates, a more lateral septum is present that separates the representations of the forelimb from the hindlimb, and often a narrow, less apparent septum separates a narrow band of cells on the lateral margin of VP, representing the tail from more medial cells representing the hindlimb. In favorable preparations, even septa separating representations of the digits of the hand are apparent in the subnucleus devoted to the hand. In the medial division of VP (VPM), other septa are apparent as they separate groups of cells devoted to different parts of the face and mouth. These septa are also apparent in brain sections processed for CO, myelin, or parvalbumin. Septa are especially numerous in VPM of macaque monkeys (Rausell, E. and Jones, E. G., 1991), although the assignment of specific cell clusters to parts of the face and mouth representations has not been fully determined. Septa separating cell groups that represent distinct body parts, or even individual facial whiskers of some rodents, commonly occur at different levels of the somatosensory system, including the dorsal column–trigeminal complex, the VP of the thalamus, and the primary somatosensory cortex (Welker, W. I., 1973; Killackey, H. and Rhoades, R. W., 1995). These segregating septa may emerge in development as a consequence of perturbations in the balance of target-selection factors by axons based on neural activity patterns and position-dependent attractions (Kaas, J. H. and Catania, K. C., 2002). The septa correspond to discontinuities or disruptions in the distribution of receptors in the skin, and these segregating septa are determined by the body form, including the separation of fingers and the isolation of receptors at the base of each protruding sensory hair from those for other hairs. The sizes of the segregated cell clusters in the thalamus and elsewhere vary according to the number and sizes of the afferents they subserve.

In addition, the cell clusters often have places where they merge with other clusters, as groups of peripheral receptors are usually not completely isolated from each other. Receptor populations for the fingers, for example, are isolated from each other except where the fingers join the palm at their base. These isolated cell clusters in the somatosensory brainstem, thalamus, and cortex are not equivalent to the classical cortical columns (Mountcastle, V. B., 1997), which correspond to alternating patches of cortical neurons that are activated by one class of peripheral afferent or another (e.g., Sur, M. *et al.*, 1984).

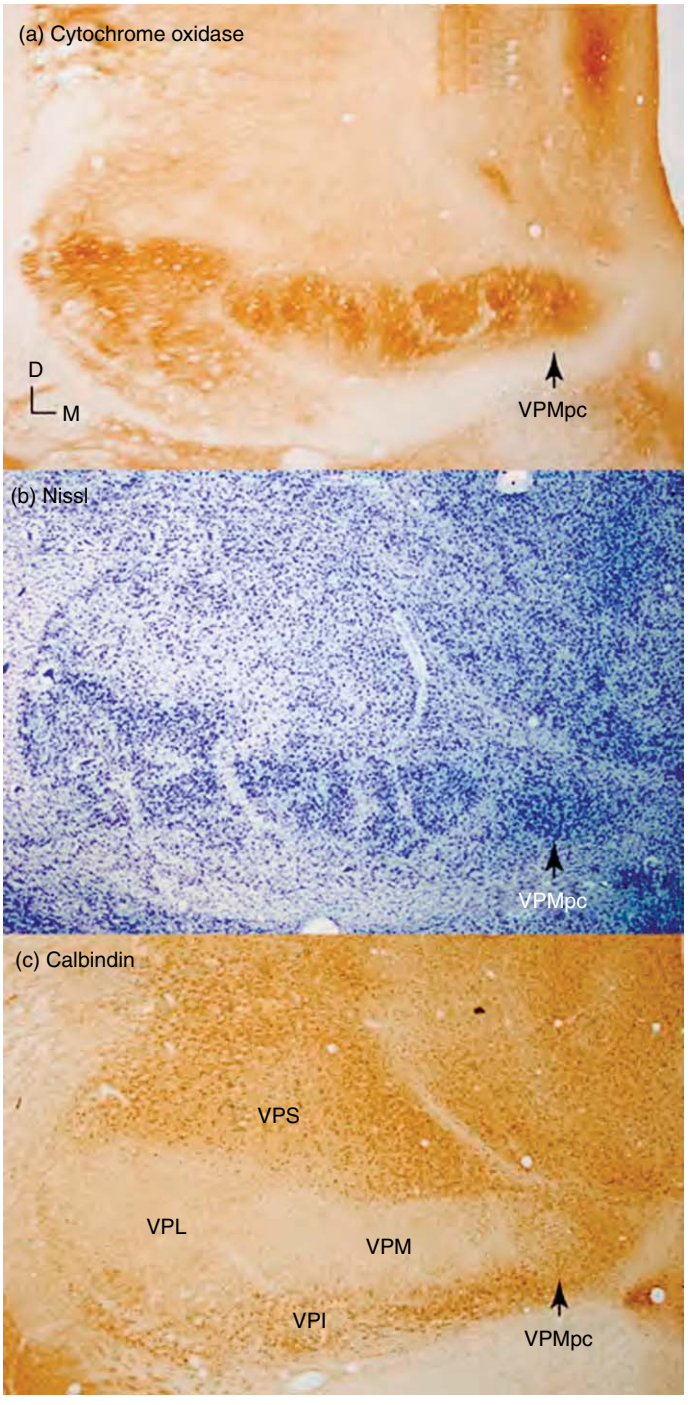
Although there are clear disruptions in the continuity of the somatotopy in VP, the overall pattern is consistent across mammals (Welker, W. I., 1973). From medial to lateral, the representation transitions from mouth to face, forelimb, hindlimb, and tail. When they have been demonstrated, the representations of the ipsilateral tongue and teeth are most medial (Bombardieri, R. A. *et al.*, 1975; Jones, E. G. *et al.*, 1986). The distal limbs are represented ventrally, or ventrorostrally, and the proximal limbs and trunk are represented dorsally. This somatotopy is portrayed in more detail for VP of the squirrel monkey in Figure 8. Note that the digits of the hand and the toes of the foot (1–5) are represented in order from medial to lateral in the subnuclei devoted to the hand and foot. Moreover, the digit and toe tips are represented ventrally, while the bases are represented dorsally. In detail, the representations are complicated by separating septa and by folds in the continuous parts of the representation (Kaas, J. H. *et al.*, 1984). In addition, there is likely to be a segregation of clusters of neurons activated by the SA-I class of peripheral afferents from those activated by the RA-I class (Dykes, R. W. *et al.*, 1981; Zhang, H. Q. *et al.*, 2001). Thus, VP likely contains at least two interdigitated maps of the cutaneous receptors of the contralateral body: one for RA receptors and one for SA receptors (see Sur, M. *et al.*, 1984 for cortex). As in other parts of the somatosensory system, the representations of body parts in VP are proportional to receptor density, so that, for example, the distal phalanges of the digits with high concentrations of afferents have proportionally larger representations than those of the proximal phalanges with fewer afferents. Lee C. C. and Woolsey C. N. (1975) have called this a peripheral scaling factor. In rare instances, the representation of important sensory surfaces can be greater than that predicted by the proportional representation of peripheral afferents. Such an overrepresentation has been called afferent magnification (Catania, K. C. and Kaas, J. H., 1997).

The major activating inputs to VP are from the SA-I and RA-I afferents relayed from the dorsal column–trigeminal complex via the medial lemniscus (Figure 2; Smith, R. L., 1975; Berkley, K., 1980; Kalil, K., 1981; Asanuma, H. *et al.*, 1983). Neurons responding to Pacinian (RA-II) inputs have been detected along the ventral margin of the nucleus (Dykes, R. W. *et al.*, 1981), but their distribution within VP is uncertain. Possibly SA-II afferents also activate VP neurons, but this is unknown. As SA-II afferents may contribute to a sense of digit position (McCloskey, P. I., 1974), they seem functionally more related to VPS, which is involved in proprioception. A few neurons in VP are activated by WDR afferents (e.g., Kenshalo, D. R. J. *et al.*, 1980). These neurons respond to light tactile stimuli, but respond with increasing magnitude as the stimulus intensity increases into the painful range. These neurons in the WDR category likely correspond to the small neurons in the septal regions of VP that have spinothalamic inputs (Rausell, E. *et al.*, 1992). Because some of these septal regions merge ventrally with VPI, which also has spinothalamic inputs and histologically resembles VP septal zones, one interpretation of the VP septa is that they are extensions of VPI (Krubitzer, L. A. and Kaas, J. H., 1992; Wilson, P. *et al.*, 1999). However, VP appears to receive most of its spinothalamic inputs from WDR neurons in layer 5 of the dorsal horn of the spinal cord, while VPI also receives inputs from the nociceptive neurons of layer 1 (Craig, A. D., 2006). A few neurons in VP are responsive to afferents that innervate the bladder, colon, and esophagus, and most of these were WDR or nociceptive, also often responding to afferents from skin (Brüggemann, J. *et al.*, 1994). In addition, spinothalamic axons terminate in a number of small patches along the rostral and caudal borders of VP (Stepniewska, I. *et al.*, 2003). These patches seem to be at least partly outside of VP (Figure 9).

In summary, SA-I and RA-I inputs dominate VP, but other inputs are expressed as well. In humans, electrical stimulation of neurons in VP generally results in a feeling of numbness or tingling in some skin location, rather than touch (e.g., Davis, K. D. *et al.*, 1996; Lenz, F. A. *et al.*, 1998), and localized lesions of VP are followed by persistent numbness in some skin region (e.g., Domino, E. F. *et al.*, 1965).

The inputs to VP of other mammals, judging from the well-studied cats and rats, appear to be similar to those of primates in that the dominating

somatosensory input is from the dorsal column–trigeminal complex. In rats, dorsal column nuclei project densely to VP (Lund, R. D. and Webster, K. E., 1967a), while spinothalamic afferents terminate along the caudal and rostral borders of VP, and more sparsely within VP (Lund, R. D. and Webster, K. E., 1967b; Ma, W. *et al.*, 1986). Spinothalamic afferents from lamina 1 of the dorsal horn of the spinal cord, which carry nociceptive and thermoreceptive information, terminate at the caudal margin of VP (Gauriau, C. and Bernard, J. F., 2004), possibly in a separate nucleus, as in VPMpo of primates (Craig, A. D., 2007). In cats, the dominant inputs to VP are from the dorsal column–trigeminal complex



(Berkley, K., 1980), while the spinothalamic afferents project mainly to the ventral border of VP (Craig, A. D. and Burton, H., 1985) in VPI (Herron, P. and Dykes, R. W., 1986).

As for other thalamic nuclei, VP includes both relay neurons projecting to the cortex and about 30% interneurons with connections within the nucleus (e.g., Spreafico, R. *et al.*, 1983; Chmielowska, J. and Pons, T. P., 1995). The interneurons are inhibitory GABAergic neurons. Curiously, rats and possibly other rodents have very few (1%) GABAergic neurons in VP (Harris, R. M. and Hendrickson, A. E., 1987), and inhibitory functions in the nucleus largely depend on inputs from GABAergic neurons in the thalamic reticular nucleus. These reticular nucleus neurons are activated by collaterals of VP relay neurons projecting to S1, and by cortical neurons in S1, which also provide feedback to VP (Deschênes, M. *et al.*, 1998). Besides inputs to VP from the somatosensory sector of the reticular nucleus (Crabtree, J. W., 1996), VP and other thalamic nuclei receive modulatory inputs from the ascending dorsal tegmental cholinergic system and from other diffusely organized modulatory systems (Sherman, S. M. and Guillery, R. W., 2006; Jones, E. G., 2007).

In all mammals, the major cortical projections of VP are to S1 (see Krubitzer, L. A. and Kaas, J. H., 1987, for review), which corresponds to area 3b of primates (Kaas, J. H., 1982). In most mammals, VP also projects to two adjoining areas, S2 and the parietal ventral somatosensory area, PV (see Krubitzer, L. A. and Kaas, J. H., 1987). This allows S2 and PV to be activated in parallel with S1.

Therefore, S2 and PV can be activated via VP after lesions of S1 (Garraghty, P. E. *et al.*, 1991). However, anthropoid primates (monkeys, apes, and humans), as well as raccoons, appear to have lost most of their VP inputs to S2 (Friedman, D. P. and Murray, E. A., 1986; Krubitzer, L. A. and Kaas, J. H., 1992; Disbrow, E. *et al.*, 2002; see Herron, P., 1983 for raccoons). In macaque monkeys, lesions of the anterior parietal cortex (area 3a, 3b, 1, and 2) result in a loss of 94% of the non-GABA-containing projection neurons, leaving few neurons to project to other areas, including S2 (Chmielowska, J. and Pons, T. P., 1995). Thus, S1 (3b) lesions deactivate S2 and PV in these mammals (Burton, H. *et al.*, 1990; Garraghty, P. E. *et al.*, 1990b; Pons, T. P. *et al.*, 1992). Across species, the major VP inputs to S1 (3b) are to layer 4 (e.g., Jones, E. G., 1975), where they have a powerful activating influence. In addition, the small cells in the septa of VP that are related to spinothalamic input project to the more superficial layers of area 3b (Rausell, E. and Jones, E. G., 1991; Jones, E. G., 1998), and possibly play a modulatory role. Some of these cells also project to other areas including S2 and PV (Stevens, R. T. *et al.*, 1993).

In anthropoid primates, VP has additional projections to two other areas of the anterior parietal cortex: area 1 (the posterior cutaneous field) and area 2 (the deep receptor field of the anterior parietal cortex). While architectonic fields 3a, 3b, 1, and 2 were once all considered to be parts of S1 in primates, there has been long-standing evidence that each of these fields is functionally distinct and contains a separate representation of the contralateral body (see below). In keeping with the functional distinctions between

Figure 5 Architectonic features of the nuclei of the ventroposterior complex of a prosimian primate (galago). In the lower panel (c), showing a coronal brain section, processed for the calcium-binding protein calbindin (Cb), the two major divisions of the ventroposterior nucleus (VP), the ventroposterior lateral (VPL) and the ventroposterior medial (VPM) subnuclei, correspond to the Cb-light central region. Just ventral to VP, the ventroposterior inferior nucleus (VPI) is characterized by neurons and neural processes that express moderate levels of Cb, as does the ventromedially located ventroposterior medial parvocellular nucleus (VPMpc) for taste, touch, and other functions. In the middle panel (b), an adjacent brain section was processed for Nissl substance to reveal the cell bodies of neurons. VP is characterized by densely packed, large neurons that are darkly stained. Groups of neurons within VP are separated from each other by lightly stained, cell-poor septa. The most notable septum separates VPL from VPM, but other septa are visible as well, including a septum in the middle of VPL that separates more lateral neurons representing the foot from more lateral neurons representing the hand. VPMpc has slightly smaller neurons, while VPI and ventroposterior superior nucleus (VPS) both have smaller, more scattered neurons so that the nuclei are less darkly stained. In the upper panel (a), both VP and VPMpc express moderate to dense levels of the metabolic enzyme, cytochrome oxidase (CO). Within VP, a CO-light septum separates VPL from VPM, and several CO-light septa are apparent in VPM. A septum in the middle of VPL is faintly visible. VPI expresses very little CO, while CO is faintly expressed in VPS. These architectonic distinctions, especially evident in some primates such as galagos, provide part of the evidence that VP, VPI, and VPS are separate nuclei within the ventroposterior complex. From Kass, J. H., Qi, H.-X., and Iyengar, S. 2006. Cortical network for representing the teeth and tongue in primates. Anat. Rec. 288A, 182–190.

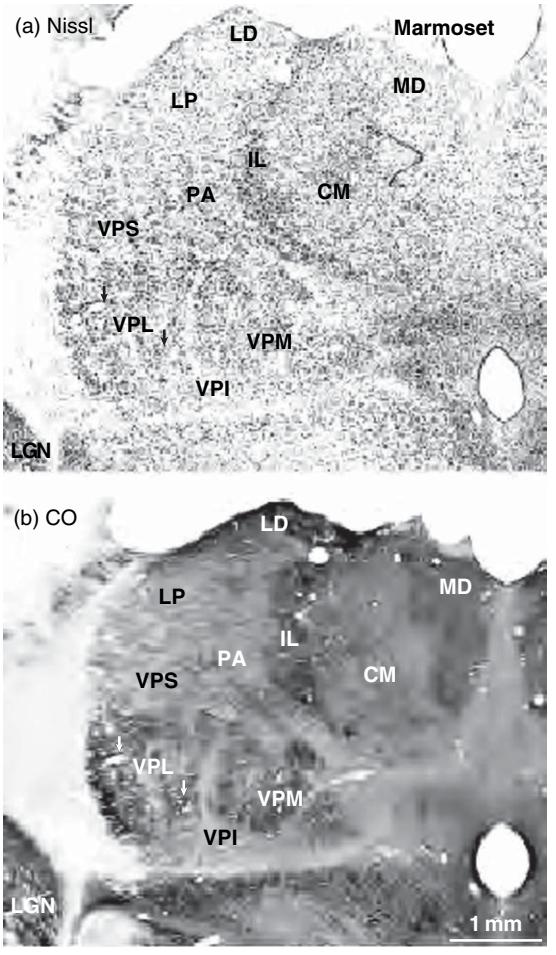


Figure 6 The architectonic subdivisions of the somatosensory thalamus of a marmoset, a small New World monkey. (a) A Nissl-stained section showing cell bodies. (b) An adjacent section processed for cytochrome oxidase (CO). Arrows mark the same two blood vessels for aligning the two sections. Note the darker cells and denser expression of CO in ventroposterior nucleus (VP) (ventroposterior lateral (VPL) and ventroposterior medial (VPM)). A cell-poor, CO-light septum separates VPL from VPM. The Nissl-stained cells in the ventroposterior superior nucleus (VPS) are notably lighter than those in VP, but darker than in the ventroposterior inferior nucleus (VPI) of galagos, making the boundary between VP and VPS less obvious. However, the expression of CO is notably less in VPS than in VP. VPI is less darkly stained than VP in both preparations. The locations of the anterior pulvinar (PA) and the lateral posterior nucleus (LP), both with somatosensory functions, are indicated. The lateral dorsal (LD) nucleus, the intralaminar nucleus (IL), the center median nucleus (CM), the medial dorsal nucleus (MD), and the lateral geniculate nucleus (LGN) are labeled for reference. From Qi, H.-X., Lyon, D. C., and Kaas, J. H. 2002. Cortical and thalamic connections of the parietal ventral somatosensory area in marmoset monkeys (*Callithrix jacchus*). J. Comp. Neurol. 443, 168–182.

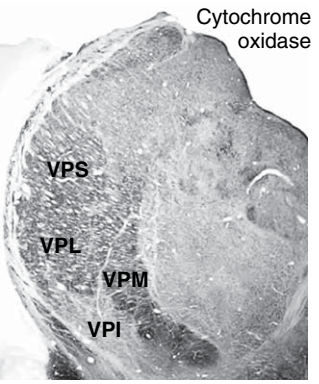

Figure 7 A coronal brain section through the somatosensory thalamus of a two-month-old macaque monkey that has been processed for cytochrome oxidase (CO). Note that the ventroposterior nucleus (VP) (ventroposterior lateral (VPL) and ventroposterior medial (VPM)) densely expresses CO, and a septum separating VPM from VPL is prominent. Ventroposterior superior nucleus (VPS) expresses only slightly less CO than VP. Because VPS is also only slightly less darkly stained in Nissl preparations than VP of macaque monkeys, the two nuclei were considered to be a single nucleus, VP, in early studies. Ventroposterior inferior nucleus (VPI) expresses little CO.

areas 3b, 1, and 2, which can be considered successively higher levels of cortical processing (e.g., Felleman, D. J. and Van Essen, D. C., 1991), VP projects less densely to area 1, and the axons of the neurons projecting to area 1 are thinner, and more slowly conducting than those projecting to area 3b. Further, the terminations of these axons in area 1 are in layer 3 rather than layer 4 (Jones, E. G., 1975). Locations in VP project to somatotopically matched locations in all parts of both the representations in area 3b and in area 1 (Lin, C.-S. *et al.*, 1979; Nelson, R. J. and Kaas, J. H., 1981; Mayner, L. and Kaas, J. H., 1986; Darian-Smith, C. *et al.*, 1990; Krubitzer, L. A. and Kaas, J. H., 1992). More neurons in VP project to area 3b than to area 1 (Nelson, R. J. and Kaas, J. H., 1981), and it is possible that only the RA-I class of VP relay cells projects to area 1. However, perhaps as many as 20% of VP neurons project via collaterals to both areas 3b and 1 (Cusick, C. G. *et al.*, 1985). In addition, parts of area 2 and even area 5 that are most responsive to cutaneous stimuli, those representing the glabrous hand and face, receive sparse inputs from VP, at least in macaque monkeys (Pons, T. P. and Kaas, J. H., 1985). Finally, a few neurons in VP of macaques project to the part of area 5 that is responsive to light tactile stimuli on the forelimb (Pons, T. P. and Kaas, J. H., 1985).

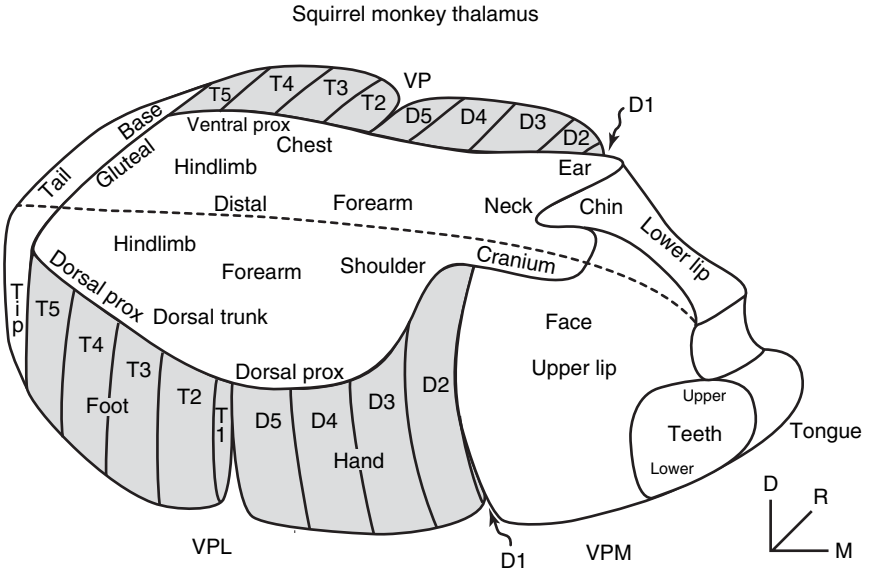

Figure 8 The somatotopic organization of the ventroposterior (VP) nucleus of squirrel monkeys. This 3D rendition is viewed from the back. The medial division of VP, the ventroposterior medial (VPM) subnucleus, devotes large territories to the lips, teeth, and tongue. A most medial portion also represents the ipsilateral teeth and tongue (not shown). A septum separates VPM from the lateral division, ventroposterior lateral nucleus (VPL). A septum within VPL separates the more medial representation of the hand from the more lateral representation of the foot. The tail is represented most laterally. A dorsal cap of VP represents the limbs, trunk, and cranium. Note that digits (D1–D5) and toes (T1–T5) are represented in order. Adapted from Kaas, J. H., Nelson, R. J., Sur, M., Dykes, R. W., and Merzenich, M. M. 1984. The somatotopic organization of the ventroposterior thalamus of the squirrel monkey, *Saimiri sciureus*. J. Comp. Neurol. 226, 111–140.

6.07.6 The Ventroposterior Superior Nucleus

The VPS forms a dorsal cap on the VP of primates. Although the region had long been recognized as having a concentration of inputs from receptors in deep tissues, muscles, and joints, in contrast to VP proper where inputs relayed from cutaneous receptors predominate, traditionally, the VPS region was usually included in VPL (e.g., Poggio, G. F. and Mountcastle, V. B., 1963). VPS was distinguished as a separate nucleus after the results of extensive microelectrode recording experiments were related to thalamic architecture in squirrel monkeys (Kaas, J. H. *et al.*, 1984). The results indicated that VPS is architectonically distinct from VP, and that each nucleus contains a separate representation of the contralateral body with VPS devoted to muscle spindle receptors, while VP is devoted to cutaneous receptors. In general, VPS has neurons that are less darkly stained in Nissl preparations, and less densely packed than neurons in VP. Further, VPS expresses less CO (Krubitzer, L. A. and Kaas, J. H., 1992) and less acetylcholinesterase (Pons, T. P. and Kaas, J. H., 1985) than does VP. VPS also expresses more calbindin and less parvalbumin (Figure 5). Inputs to VPS are from neurons in brainstem and upper spinal cord nuclei, such as the external cuneate nucleus. These inputs are activated by muscle spindle afferents and they send axons into the contralateral medial lemniscus (Berkley, K., 1980; Boivie, J. and Boman, K., 1981). Recordings in VPS, previously recognized as a rostral cap of VP (Maendly, R. *et al.*, 1981) or an anterodorsal shell of VP (Friedman, D. P. and Jones, E. G., 1981), indicate that the vast majority of neurons are activated by muscle spindle receptors (Wiesendanger, M. and Miles, T. S., 1982). VPS projects to areas 3a and 2 (Jones, E. G. *et al.*, 1979; Friedman, D. P. and Jones, E. G., 1980; 1981; Cusick, C. G. *et al.*, 1985; Pons, T. P. and Kaas, J. H., 1985; Darian-Smith, C. *et al.*, 1990; Akbarian, S. *et al.*, 1992; Darian-Smith, C. and Darian-Smith, I., 1993; Huffman, K. J. and Krubitzer, L. A., 2001). Possibly as many as 40% of the relay neurons in VPS project via collaterals to somatotopically matched locations in both area 3b and area 2 (Cusick, C. G. *et al.*, 1985), as both of these fields contain systematic tail-to-tongue representations of deep receptors in mediolateral

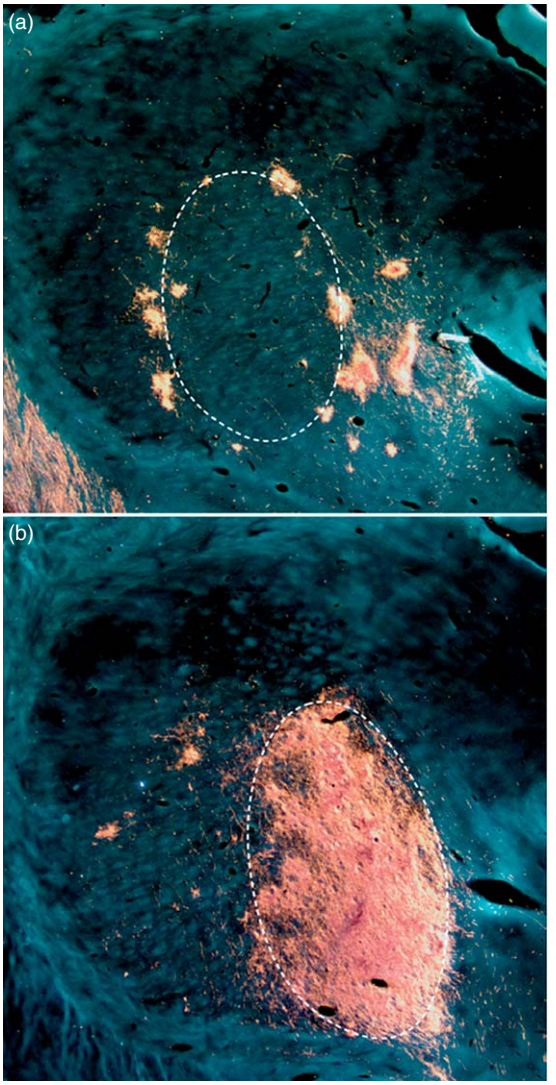

Figure 9 Parasagittal brain sections through the somatosensory thalamus after being processed for axon terminals labeled with wheatgerm agglutinin conjugated to horseradish peroxidase (WGA–HRP). In panel (a), an injection of WGA–HRP into the cervical spinal cord of a macaque monkey labeled patches of terminals along the rostral (left) and caudal borders of the ventroposterior nucleus, VP. Other patches of labeled terminals are in divisions of the posterior nuclei caudal to VP. In panel (b), an injection of WGA–HRP was placed in the contralateral dorsal column nuclei and VP was densely labeled. A few patches of labeled terminals were rostral to VP in the motor thalamus. In both panels, VP is outlined. (a) From Stepniewska, I., Sakai, S. T., Qi, H.-X., and Kaas, J. H. 2003. Distribution of somatosensory pathways in relation to thalamic neurons relaying information to the motor and premotor cortex in the macaque monkey. Soc. Neurosci. Abstr. 29, 60.16.

sequences that parallel those of areas 3b and 1 (e.g., Kaas, J. H. *et al.*, 1979; Pons, T. P. *et al.*, 1985; Huffman, K. J. and Krubitzer, L. A., 2001; Krubitzer, L. A. *et al.*, 2004).

As expected from the more extensive evidence from monkeys, an orderly representation of deep receptors has been described as just rostrodorsal to the representation of cutaneous receptors in VP of humans (Lenz, F. A. *et al.*, 1990; Ohye, C. *et al.*, 1993; Seike, M., 1993).

This human VPS represents receptors activated by movements of the jaw, digits, arm, and leg in a mediolateral sequence. Human VPS is located in a region of thalamus that has been variously identified, but most recently termed anterior VP or anterior VPL (Morel, A. *et al.*, 1997). Rather than an anterior or anterodorsal division of VP, the evidence for distinctly different inputs and outputs, as well as histological differences, justifies distinguishing the region as a separate nucleus in the ventroposterior complex, VPS.

There is also evidence for VPS in nonprimate mammals, although the nucleus may not be well differentiated. However, a problem in identifying VPS in nonprimates is that the cortical targets of VPS in primates, areas 3a and 2, often have not been identified. However, in all mammals, it appears that the primary somatosensory cortex, S1 or area 3b, is bordered rostrally by a narrow zone of the cortex that likely subserves proprioception and is also, based on position and function, a likely homologue of area 3a (Krubitzer, L. A. *et al.*, 2004; Kaas, J. H., 2007b). In rodents, the evidence for area 3a is most clear for squirrels, although there is supporting evidence from rats. In both rodents, S1 is histologically very distinct in preparations of sections cut parallel to the surface of the flattened cortex as a highly granular zone (packed with densely stained, small neurons) that also expresses high levels of CO and myelin (Krubitzer, L. A. and Kaas, J. H., 1987; Jain, N. *et al.*, 2003). The cortex along the rostral border of this S1 has been called dysgranular cortex (Chapin, J. K. and Lin, C. S., 1984), as layer 4 is less pronounced than in S1. In squirrels and rats, part of this dysgranular zone protrudes caudally between the representatives of the face and the forelimb in S1. The larger size of this protrusion of area 3a into S1 of squirrels made it a suitable target for injection of tracers that revealed the connections of the dysgranular cortex (Gould, H. J. *et al.*, 1989). The thalamic inputs to this dysgranular cortex were largely from a thalamic zone along the dorsal border of VP that has been referred to by

various names, but in rodents is called the posterior nucleus with medial (POm) and lateral (POl) divisions (e.g., Jones, E. G., 2007). More recently, Francis J. T. *et al.* (2003) used the results of microelectrode recordings to divide the somatosensory thalamus of rats into a middle zone of VP that responds to cutaneous somatosensory stimuli and a rostral subnucleus of VP that responded mainly to proprioceptive inputs. Furthermore, projections from the external cuneate nucleus in rats (Mantle-St. John, L. A. and Tracey, D. J., 1987), which carry muscle spindle information, terminate in the same rostrodorsal region of the somatosensory thalamus. Thus, rodents have a thalamic nucleus for proprioception that has been variously considered a subnucleus of VP or a rostrodorsal capping nucleus of VP, just as has VPS of primates. The nucleus projects to the dysgranular cortex that appears to be a homologue of area 3a of primates.

Other evidence comes from experiments in carnivores. Most notably, in raccoons, microelectrode recordings from the somatosensory thalamus identified a distinct zone of proprioceptive neurons responsive to receptors in muscles, tendons, and joints that were located rostrodorsal to the zone responsive to cutaneous stimulation (Wiener, S. I. *et al.*, 1987). As the functionally distinct zones were architectonically similar, they were termed cutaneous and kinesthetic divisions of VP (termed Vb for ventrobasal nucleus), although the kinesthetic division of VP was described as having less cell density (Wiener, S. I. *et al.*, 1987). The kinesthetic thalamic zone projects to a 3a-like strip of the dysgranular cortex rostral to S1 (Doetsch, G. S. *et al.*, 1988; Feldman, S. H. and Johnson, J. I., 1988). In cats, the situation is similar, as a rostrodorsal cap on VP has been identified as a proprioceptive nucleus with inputs from muscle spindle receptors (Andersson, S. A. *et al.*, 1966; Maendly, R. *et al.*, 1981; Wiesendanger, M. and Miles, T. S., 1982; Kniffki, K.-D. and Mizumura, K., 1983). This thalamic region, which Dykes R. W. *et al.* (1986) called the ventroposterior oralis nucleus (VPO), appears to correspond to VPS of monkeys. In cats, the cortex between S1 (area 3b) and the primary motor cortex (M1) has long been considered to be area 3a on architectonic grounds (Hassler, R. and Muhs-Clement, K., 1964). This 3a of cats is activated by receptors in muscles and joints (e.g., Dykes, R. W. *et al.*, 1980) and it receives projections from VPO (Dykes, R. W. *et al.*, 1986; Zheng, A.-H. *et al.*, 1986). Thus, at least in carnivores and rodents, there is evidence of a proprioceptive nucleus in the thalamus that is in the relative position of VPS of primates and projects to area 3a or a 3a-like area, as does VPS of primates. A difference is that VPS of moneys also projects to area 2, a subdivision of the somatosensory cortex that may not exist in nonprimate mammals (Kaas, J. H., 2004; 2007a), although the cortex caudal to S1 has been classified as area 1–2 (presumably, a composite of areas 1 and 2) in some instances.

An area 2 is sometimes distinguished in the somatosensory cortex of cats, although this appears to be a misidentification, as some investigators distinguish areas 3b, 1, and 2 within a single area 3b body representation (see for review, Felleman, J. D. *et al.*, 1983). In a detailed reinvestigation of the organization of the somatosensory cortex of cats, Myasinkov A. A. *et al.* (1994) found evidence for two representations of body receptors in the cortex caudal to S1 (they identified S1 as area 3b), with neither corresponding to previously proposed areas 1 and 2, and neither activated by deep receptors. Even in prosimian primates, there is no clear evidence for an area 2, and the cortex caudal to S1 (area 3b) in the position of area 1 is not very responsive to cutaneous stimuli in anesthetized animals, so there are uncertainties even about area 1 (e.g., Wu, C. W.-H. and Kaas, J. H., 2003). Furthermore, the presence of an area 2 has been questioned for some New World monkeys (Padberg, J. *et al.*, 2005), further complicating the use of projections to area 2, as well as those to area 3a, in identifying VPS.

Presently, the evidence suggests that a nucleus responsive to proprioceptive inputs, termed VPS here, is segregated from VP in a wide range of mammals, and this nucleus projects to a proprioceptive zone of the cortex at the rostral border of S1 that is recognized as area 3a in primates and cats, but is variously recognized and named in other mammals. The comparative evidence suggests that area 2, as a secondary target of VPS, emerged with the evolution of anthropoid primates (Kaas, J. H., 2007a), although an area 2 with a mixed representation of deep and cutaneous receptors is not clearly present in all investigated New World anthropoids.

6.07.7 The Ventroposterior Inferior Nucleus

VPI was first distinguished by Crouch R. L. (1934) in macaque monkeys, where it was described as a cell-sparse region ventral to VP. Jones E. G. (2007)

considered VPI to be distinct only in the brains of primates, although the nucleus is obvious in the brains of raccoons (Herron, P. *et al.*, 1997), carnivores with specialized hand use, as in primates. The neurons in VPI are smaller and less densely stained in Nissl preparations than neurons in VP, and VPI expresses less CO and parvalbumin, and more calbindin than VP (Figures 5–7; also see Rausell, E. and Jones, E. G., 1991; Krubitzer, L. A. and Kaas, J. H., 1992). The septal regions that separate the subnuclei of VP are almost identical in histological appearance with VPI proper, and spinothalamic inputs and projections to superficial cortical layers are shared, so it seemed parsimonious to include these septal regions with the main body of VPI as a single nucleus (Krubitzer, L. A. and Kaas, J. H., 1992; also see Wilson, P. *et al.*, 1999). However, there is evidence that the sources of spinothalamic inputs to VPI proper and the septal regions of VP are somewhat different, with the WDR neurons of lamina 5 of the dorsal horn of the spinal cord projecting to septa within VP, and both lamina 5 and nociceptive neurons in lamina 1 projecting to VPI proper (Craig, A. D. and Zhang, E. T., 2006). Thus, there are also arguments for not including septal regions of VP in VPI.

In monkeys, the major source of sensory information to VPI is from the spinothalamic tract, including inputs from the spinal trigeminal nuclei (Mehler, W. R. *et al.*, 1960; Boivie, J., 1980; Burton, H. and Craig, A. D., 1983; Mantyh, P. W., 1983; Apkarian, A. V. and Hodge, C. J., 1989; Ralston, H. J. and Ralston, D. D., 1992). There have been suggestions for a relay of Pacinian afferents, as well (Dykes, R. W. *et al.*, 1981; Herron, P. and Dykes, R. W., 1986), but this seems unlikely as the small cells of VPI and their superficial cortical projections seem incongruent with a low-threshold, rapidly conducting pathway for a Pacinian RA-II subsystem. In addition, Pacinian afferents would relay from dorsal column nuclei rather than from spinothalamic neurons. Some inputs may be from vestibular nuclei, but they are sparse (Deecke, L. *et al.*, 1974; Lang, W. *et al.*, 1979). Recordings indicate that VPI contains a somatotopic representation of afferents from the contralateral body that parallels the representation in VP, and that the major activating input is from WDR peripheral nerve afferents (Craig, A. D., 2007).

In monkeys, the major cortical projections of VPI are to higher-order somatosensory areas, S2 and PV (Friedman, D. P. and Murray, E. A., 1986; Krubitzer, L. A. and Kaas, J. H., 1992; Disbrow, E. *et al.*, 2002; Qi, H.-X. *et al.*, 2002; Coq, J. O. *et al.*, 2004). VPI projects much less densely to other somatosensory areas, such as 3b and 1. Projections to areas 3b and 1 also come from neurons in the embedded septal regions of VP (Penny, G. R. *et al.*, 1982; Rausell, E. and Jones, E. G., 1991). The VPI projections and septal neuron projections are to the superficial layers of the somatosensory cortex, rather than layer 4, and thus are likely to be modulatory instead of driving. This supposition is supported by the observations that S2 and PV, with dense VPI inputs, depend on areas 3a and 3b for activation (Garraghty, P. E. *et al.*, 1990a; Pons, T. P. *et al.*, 1992), and that neurons in S2 and PV respond vigorously to light tactile stimulation (see Coq, J. O. *et al.*, 2004, for review), while VPI neurons do not.

In addition to being recognized in primates, VPI has been described as a distinct nucleus in both cats and raccoons (see Herron, P., 1983; Craig, A. D. and Burton, H., 1985). As in primates, VPI of these carnivores consists of a narrow band of small cells that are lightly stained in Nissl preparations. VPI is just ventral to VP, and the septal regions in VP have lightly stained cells, as in VPI, and are continuous with VPI. Spinothalamic terminations terminate both in VPI proper and in and around VP septal zones (e.g., Berkley, K., 1980; Craig, A. D. and Burton, H., 1985). VPI is larger and more distinct in raccoons, and it appears to receive denser spinothalamic inputs. As in monkeys, there is evidence that Pacinian inputs activate neurons in VPI of cats and raccoons (Herron, P. and Dykes, R. W., 1986), but others place the Pacinian-responsive neurons in ventral VP (Fisher, G. R. *et al.*, 1983). In raccoons, Herron P. (1983) showed for the first time in a convincing manner that VPI projects strongly to S2, although there was some evidence for this from an earlier study in cats (Rinvik, E., 1968). Later studies more conclusively demonstrated VPI projections to S2 in cats (Herron, P. and Dykes, R. W., 1986).

In rats, there is not much of a region ventral to VP that can be identified as VPI (Jones, E. G., 2007), and spinothalamic axons terminate mainly on the rostral and caudal borders of VP (McAllister, J. P. and Wells, J., 1981). However, in squirrels, a small, thin VPI that contains small, lightly stained (Nissl) neurons has been identified (Krubitzer, L. A. and Kaas, J. H., 1987). While no connections were demonstrated between S2 and this VPI, connections with PV were found. A few connections with S1 were also revealed.

In conclusion, most of the evidence for the existence of VPI comes from studies on primates,

although a comparable region of the thalamus has been identified in raccoons, cats, and squirrels. It is not certain from the limited attempts to identify and characterize VPI if the nucleus is a basic component of the mammalian thalamus, although usually not a very distinctive part, or if a nucleus with similar histological characteristics and connections arose independently in primates, carnivores, and some rodents. The main function of VPI seems to be to relay modulating influences based on spinothalamic inputs activated by WDR afferents, to cortical areas S2 and PV, and to a lesser extent S1 and bordering somatosensory fields. The suggestions of Pacinian inputs to VPI deserve further study, but the limited evidence is open to the interpretation that the Pacinian-like thalamic cells are in ventral VP rather than VPI.

6.07.8 Other Nuclei: The Anterior Pulvinar, the Lateral Posterior Nucleus, the Posterior Group, the Ventroposterior Parvocellular Nucleus, and the Ventromedial Posterior Nucleus

A number of other thalamic nuclei contribute to somatosensory function in primates and other mammals. In monkeys, the anterior (oral) pulvinar, which has been identified only in primates, has widespread interconnections with somatosensory areas of anterior, posterior, and lateral subdivisions of the parietal cortex (e.g., Pons, T. P. and Kaas, J. H., 1985; Cusick, C. G. and Gould, H. J. I., 1990; Padberg, J. and Krubitzer, L. A., 2006). As the anterior pulvinar receives inputs from the somatosensory cortex and it projects back to the somatosensory cortex, the anterior pulvinar spreads activity (Sherman, S. M. and Guillery, R. W., 2006) across somatosensory areas, possibly coordinating activities in several areas, rather than providing an additional source of sensory information. Another subdivision of the pulvinar complex, the medial pulvinar, has connections with areas of the posterior parietal cortex that are multisensory or somatosensory, as well as areas of cingulate and the frontal cortex (see Stepniewska, I. *et al.*, 2004, for review). These nuclei of the primate thalamus have no obvious homologues in nonprimates.

The lateral posterior nucleus or region in primates also has interconnections with regions of the posterior and lateral parietal cortex (see Padberg, J. and Krubitzer, L. A., 2006). Comparisons with nonprimates are complicated by the common use of the term lateral posterior complex or nucleus to refer to part of or all of the visual pulvinar. Thus, different parts of the thalamus are called lateral posterior across taxa. Another region, the Po is also defined somewhat differently across species. In rats, the posterior nucleus is divided into medial and lateral nuclei. Both receive a mixture of somatosensory inputs from the brainstem and spinal cord and are interconnected with S1 and S2, and possibly other areas of the somatosensory cortex (see Groenewegen, H. J. and Witter, M. P., 2004). Similar nuclei, POm and POl, have been described in cats, where POl is mainly involved in processing auditory information, while POm has connections with the somatosensory areas of the cortex (Jones, E. G., 2007). A more caudal region of the thalamus is defined as the posterior complex in primates, where connections are with the somatosensory and multisensory cortex of the lateral fissure (Burton, H. and Jones, E. G., 1976).

A nucleus in the medioventral margin of VP, VPMpc (also known as the basal ventral medial nucleus, VMb) is sometimes referred to as the thalamic taste nucleus, although it receives inputs relayed from cutaneous and other somatosensory afferents in addition to those for gustation. In primates, VPMpc projects to the representation of the tongue in S1 (area 3b) and to a gustatory region, area G, in the cortex of the rostral part of the lateral sulcus (Kaas, J. H. *et al.*, 2006; Iyengar, S. *et al.*, 2007). Similar connections are likely in other mammals (Lundy, R. F. and Norgren, R., 2004).

Finally, Craig A. D. *et al.* (1994) have identified a region of the posterolateral thalamus of monkeys as the posterior ventral medial nucleus (VMpo). This nucleus, on the medial margin of VP just caudal to VPMpc, receives trigeminothalamic and spinothalamic inputs from nociceptive second-order neurons (Craig, A. D., 2004; 2007) and projects to the dorsal anterior insular cortex in the lateral sulcus. The nucleus is identified in part by its dense calbindin-positive fiber plexus. Craig A. D. (2004) regarded VMpo as novel to primates, and proposed that this relay in rats and cats involves VPI and VP (also see Zhang, X. *et al.*, 2006). This interpretation of the significance of VMpo has been criticized by Willis W. D. *et al.* (2002) for ignoring the nociceptive inputs to VP of primates that relay to S1 and S2. Jones E. G. (2007) has argued against the concept of VMpo. The proposal of Craig A. D. *et al.* (1994) has

provoked some thought and support, as well as disagreement, and further study is needed.

6.07.9 Cortical Projections to the Somatosensory Thalamus and Dorsal Column Nuclei

Cortical projections to the thalamus are obviously important in the functions of the somatosensory thalamus, as they are many times more numerous than the thalamocortical connections. These connections emerge from pyramidal neurons in layers 5 and 6, with the projections from layer 6 being denser while having smaller terminal endings. The less abundant projections from layer 5 terminate in the thalamus with large endings. The layer 6 projections are postulated to have weak, modulatory effects, while the layer 5 projections are considered to be feedforward, driving connections (Sherman, S. M. and Guillery, R. W., 2006). This laminar pattern of projections exists across cortical areas and mammalian species, with most thalamic nuclei receiving a mixture of layer 5 and layer 6 projections (Rouiller, E. M. and Welker, W. I., 2000). However, in rats, the S1 projection to VP originates entirely from layer 6 neurons (Killackey, H. P. and Sherman, S. M., 2003). The cortical projections to the somatosensory thalamus largely follow the general pattern that areas project back to the same thalamic regions that project to them. But thalamic nuclei also receive projections from somatotopically mismatched parts of a field, or fields without input from that nucleus. The layer 5 and 6 projections to the thalamus are excitatory, and they terminate on both relay neurons and inhibitory interneurons (see Li, L. and Ebner, F. F., 2007). Thalamic neurons may be influenced indirectly via cortical projections to the thalamic reticular nucleus, which has GABAergic inhibitory neurons projecting to the thalamus (Crabtree, J. W., 1996).

The corticothalamic projections to relay nuclei appear to alter the receptive field characteristics of projection neurons, sometimes by increasing the selectivity of these neurons according to behavioral state. For example, Li L. and Ebner F. F. (2007) found that microstimulation of neurons in the S1 cortex of rats rotates the angle of the directional selectivity for whisker movements of VPM neurons toward the direction that cortical neurons prefer. Cortical projections also help constrain the sizes of receptive field for VP neurons. When activity of neurons in S1 (area 3b) of macaque monkeys was suppressed, the receptive fields of neurons in VP increased in size (Ergenzinger, E. R. *et al.*, 1998). Similar results have been obtained in rats (Krupa, D. J. *et al.*, 1999; Chowdhury, S. A. *et al.*, 2004). Other cortical projections, especially those to the intrinsic nuclei such as the anterior pulvinar, may activate relay neurons so that information is transferred from one cortical area to another via the thalamus (Sherman, S. M. and Guillery, R. W., 2006).

The somatosensory cortex also projects to the contralateral dorsal column–trigeminal complex (Rustioni, A. and Sotelo, C., 1974; Wise, S. P. and Jones, E. G., 1977; Weinberg, R. J. *et al.*, 1990; Lue, J.-H. *et al.*, 1997; Martinez-Lorenzana, G., *et al.*, 2001;). One of the suggested functions of these cortical inputs is to activate intrinsic inhibitory neurons to selectively constrain the sizes of receptive fields for neurons in the nuclear complex (Wang, X. and Wall, J. T., 2005).

Glossary

area 1 A somatosensory area that is recognized in anthropoid primates that may exist in other mammals. Area 1 contains a systematic representation of cutaneous receptors of the opposite side of the body and has a less pronounced layer 4 of small neurons than S1 (area 3b), is located immediately caudal to S1, and depends on S1 inputs for activation.

area 2 A somatosensory area that is generally recognized in anthropoid primates but has not been identified with certainty in other mammals. Area 2 is located immediately caudal to area 1, and it contains complex representations or representations of a mixture of cutaneous receptor, information relayed from areas 3b and 1, and muscle spindle information relayed from the ventroposterior superior nucleus of the thalamus. Layer 4 of area 2 is somewhat more distinct than in area 1.

area 3a A subdivision of the somatosensory cortex that is recognized in primates and sometimes other mammals that may be present in most or all mammals. Area 3a is just rostral to S1 (area 3b), is activated by muscle spindle receptors, and has a less pronounced layer 4 of small neurons than S1 (area 3b).

cortical architecture The histological appearance of a cortical area in brain sections stained for cell bodies (cytoarchitecture), myelin (myeloarchitecture), or processed for proteins or other features of cortical tissue. Regional differences in cortical architecture are used to identify cortical areas.

cortical area The classical subdivision of neocortex that is often architectonically distinct, is characterized by a unique pattern of connections with other areas and subcortical structures, and performs a unique set of functions. Somatosensory areas usually contain a complete representation of the opposite side of the body.

cortical modules or columns Subdivisions of cortical areas that differ by being activated by one or another class of peripheral receptor, or by representing segregated inputs from the peripheral, such as receptors for specific whiskers on the face.

parietal ventral area (PV) A somatosensory area that adjoins S2 and represents receptors of the opposite half of the body in a pattern that mirrors the representation in S2. In early studies, PV was not distinguished from S2, but considerable evidence now suggests that PV exists in most and perhaps all mammals.

primary somatosensory cortex (S1) A subdivision of the somatosensory cortex that is present in all mammals. S1 contains a systematic representation of the cutaneous receptors of the opposite side of the body and is directly activated by afferents from the ventroposterior nucleus of the thalamus. Of all somatosensory areas, S1 has the most pronounced architectonic features of the sensory cortex, especially the well-developed layer 4 of small neurons. For historical reasons,

investigators often include other areas in S1 of anthropoid primates, but only area 3b is homologous to S1 of other mammals.

second somatosensory area (S2) A smaller representation of cutaneous and other receptors of the contralateral body that is located just lateral (ventral) to S1. S2 receives inputs from S1 and, in most mammals, from the ventroposterior inferior nucleus of the thalamus. S2 has less pronounced architectonic features than S1, but it is difficult to distinguish architectonically from other adjoining somatosensory areas, such as PV.

6.08.1 Introduction

The somatosensory cortex varies across mammals in how it is divided into areas or fields and how it is divided into modules within areas. Areas are the large functionally distinct subdivisions of cortex that Brodmann K. (1909) called the organs of the brain. For the somatosensory cortex, areas are expected to contain a complete representation of a class or classes of somatosensory afferents from the opposite side of the body (with perhaps some representation of ipsilateral inputs as well), patterns of connections with other parts of the brain that are distinctly different from those of other areas, similar but not necessarily identical types of connections for all parts of the area, and structural specializations within individual areas that reflect the functional specializations of each area. Additionally, the collective response properties of neurons in any area are expected to differ from those of other areas, and the functional consequences of activating or deactivating each area also should differ. Areas are well defined when all or most of these characteristics have been identified, while a correct identification is less certain when an area is incompletely characterized. Most mammals have four or five well-defined areas of the somatosensory cortex while monkeys and other anthropoid primates have more.

Modules are subdivisions of areas that have been defined in various ways, and often the term is used interchangeably with the term cortical column (Kaas, J. H., 1993; Krubitzer, L. A. and Hunt, D. L., 2007). However, cortical column sometimes refers to the vertical organization of cortex, the observations that the succession of neurons in a vertical array through the depth of cortex are highly interconnected and share such features as receptive field location and a number of other response properties. As all cortical areas have this vertical organization, we use the less confusing term module here to refer to two different types of subdivisions within the areas of the somatosensory cortex. One type of module corresponds to Mountcastle's V. B. (1957) original concept of cortical columns as consisting of alternating patches of cortex, from surface to white matter, that are distinguished from each other by being activated by one class of peripheral afferents or another, and have sharp boundaries. As these modules are expected to be small, 500 μm or less in diameter, a large cortical area could have quite a number of modules of at least two types (Towe, A. L., 1975). There is only limited evidence for such modules in the somatosensory cortex, but this evidence is covered briefly. The other type of module is one that is devoted to afferents from some body part, such as from one of the digits of the hand, and is segregated from afferents from adjoining body parts, such as adjacent digits of the hand, by narrow septa that are architectonically distinct. These segregating septa are apparent in the primary somatosensory cortex (S1) of many mammals, but they are rare in other somatosensory areas (for review, see Purves, D. *et al.*, 1992; Catania, K. C. and Kaas, J. H., 1995; Remple, M. S. *et al.*, 2006). The best-known example is the cortical barrel for each sinus hair of the face of rodents in the primary somatosensory cortex (Woolsey, T. A. and Van der Loos, H., 1970). Each barrel focuses inputs related to a single sinus hair, and each barrel is visible as a distinct structure, but they are anatomically and functionally similar. Some of these modules are described here. Their types and occurrences are quite variable across species.

The main focus of this review is the structural or architectonic features of the cortex. Other features are mentioned, but not in detail. The architectonic features of cortical areas that can be described are perhaps limitless. Traditionally, thin slices of cortex that have been stained for Nissl substance to reveal cell bodies (cytoarchitecture) or myelin to reveal myelinated fibers (myeloarchitecture) are examined. Probably the most popular additional procedure has

been to process brain sections for the expression of the metabolic enzyme, cytochrome oxidase (CO) (Wong-Riley, M., 1979). In general, the primary sensory areas are distinguished from adjoining areas by being densely packed in the middle cortical layers with darkly stained, small neurons in Nissl preparations, and by being densely myelinated and expressing high levels of CO. Other cortical areas are lighter in Nissl-stained sections, and harder to distinguish from each other. Fortunately, there are a number of other processing procedures for cortical sections that can be used to help divide cortex into presumptive areas. Antibodies that label proteins that are differentially distributed across the cortex are very useful for architectonic parcellation. For example, the monoclonal antibody SMI-32 labels a neurofilament protein that is expressed in a subset of cortical pyramidal cells (Campbell, M. J. and Morrison, J. H., 1989) in a laminar pattern that varies between cortical areas (e.g., Preuss, T. M. *et al.*, 1997). Another monoclonal antibody that has been useful for defining areas is Cat-301 (McKay, R. D. and Hockfield, S. J., 1982), which recognizes an antigen on the surface of neurons in a pattern that varies across cortical areas and layers (e.g., Jain, N. *et al.*, 1994). Also valuable are antibodies to the calcium-binding proteins, parvalbumin and calbindin, which are distributed differently in primary and secondary areas of the sensory cortex (e.g., Hackett, T. A. *et al.*, 1998). Another useful procedure has been to histochemically process brain sections for the enzyme acetylcholinesterase (AChE), which degrades the neurotransmitter acetylcholine, a neuromodulator associated with neuroplasticity in the developing and mature brain (e.g., Juliano, S. L. *et al.*, 1990). AChE is often expressed at high levels early in the development of primary sensory areas, but it remains at high levels in the primary auditory cortex of adult monkeys (e.g., Morel, A. *et al.*, 1993). Finally, the use of autoradiography for localizing the receptors for the neurotransmitters gamma-amino butyric acid (GABA), glutamate, acetylcholine, noradrenaline, and serotonin has been a powerful tool for demonstrating areal differences in the densities and laminar distributions of receptors (Zilles, K. *et al.*, 2002). These arrays of histological methods allow architectonic borders of cortical areas to be determined with much greater assurance than when Nissl and myelin preparations are examined alone. The results are especially convincing when borders based on the different histological procedures are congruent, and where such histological borders are also compatible with other anatomical and electrophysiological data.

6.08.2 The Somatosensory Cortex of Nonprimate Mammals

In a number of ways, the organization of the somatosensory cortex of mammals is extremely varied across species. Some of this variability is described in other chapters in this volume (see Specialized Somatosensory Systems and The Evolution of Parietal Areas Involved in Hand Use in Primates). Nevertheless, many mammals have a rather limited somatosensory system with perhaps five cortical areas devoted primarily to the processing of information from cutaneous receptors (Kaas, J. H., 2004). For example, marsupial opossums appear to have five somatosensory areas (Beck, P. D. *et al.*, 1996) that are widely shared by other mammals (Kaas, J. H., 2004; 2007). Opossums have a large primary area, S1, that has been identified in all mammals studied to date (Figure 1). S1 is characterized by a systematic representation of the cutaneous receptors of the contralateral body from tail to tongue in a medial-to-lateral cortical sequence, by activating inputs from the ventroposterior nucleus of the thalamus, and by histological features that include dense myelination, high levels of CO, and a layer 4 of densely packed, small

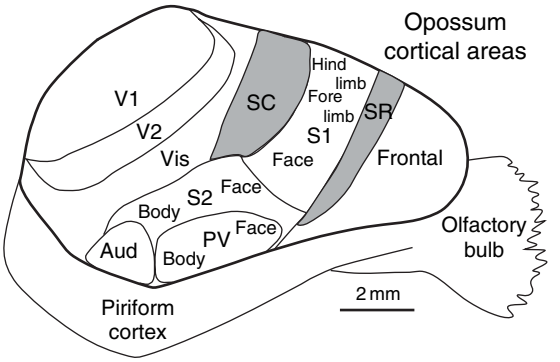

Figure 1 Proposed subdivisions of the somatosensory cortex in North American opossums (*Dedelphis marsupialis*). The areas are shown on a dorsolateral view of the brain. Somatosensory areas include the primary area, S1; the second somatosensory area, S2; the parietal ventral somatosensory area, PV; a caudal somatosensory area, SC; and a rostral somatosensory area, SR. Similar subdivisions of the somatosensory cortex have been identified in a wide range of mammalian species, with SC and SR given various names (see text). Some of the features of somatotopy in S1, PV, and S2 are noted. Cortex also includes the primary visual area (V1), the second visual area (V2), and the more lateral visual (Vis) cortex. Auditory cortex (Aud) may include more than one area. Adapted from Beck, P. D., Pospichal, M. W., and Kaas, J. H. 1996. Topography, architecture, and connections of somatosensory cortex in opossums: evidence for five somatosensory areas. J. Comp. Neurol. 366(1), 109–133.

neurons. Bands of somatosensory cortex rostral (area SR) and caudal (area SC) to S1 are known to have somatosensory functions in that they receive inputs from S1, and they may receive inputs from the ventroposterior complex as well, but they do not respond very well to tactile stimuli, at least in anesthetized animals (see Karlen, S. J. and Krubitzer, L., 2007, for an extensive review of somatosensory cortex organization in marsupials). There is evidence from some mammals, such as rats and cats, that the rostral somatosensory belt, SR, receives a relay of muscle spindle information from the thalamus, as does area 3a on the rostral border of S1 (area 3b) of primates. Thus, SR may be the homolog of area 3a of primates and other mammals where the term 3a is used. SC is in the position of area 1 or areas 1 and 2 of primates, but the relation of SR to areas 1 and 2 is less certain. Both SR and SC have a less prominent layer 4, less myelination, and less CO expression. In rats, the rostral zone has been called the dysgranular cortex (Chapin, J. K. and Lin, C. S., 1984) because the fourth layer of granular cells is poorly developed. Just lateral and ventral to S1, the second area, S2, and the parietal ventral, PV, somatosensory areas are found. The second area, S2, has long been recognized (e.g., Woolsey, C. N. and Fairman, O., 1946) as a distinct representation of the contralateral body surface just ventral to S1 in a wide range of mammals. S2 adjoins S1 where their face representations meet, but S2 represents the forelimb and hindlimb more ventrally, separate from S1. PV has been more recently described, first in squirrels (Krubitzer, L. A. *et al.*, 1986), and then in enough other species of mammals to indicate that PV is likely to be present in the common ancestor of extant mammals (see Disbrow, E. *et al.*, 2000, for humans; Remple, M. S. *et al.*, 2003; Benison, A. M. *et al.*, 2007, for rats). As PV forms a representation of the contralateral body surface in parallel to the one in S2, it may have been confused with S2 in early studies where observations were not made in enough detail to detect two parallel representations. However, in some mammals, a careful search for PV has not provided evidence for the area (e.g., Catania, K. C. *et al.*, 2000). S2 and PV both respond well to cutaneous stimulation and receive inputs from S1 as well as (in most mammals) from the ventroposterior nucleus of the thalamus (see Chapter The Somatosensory Thalamus and Associated Pathways). S2 and PV generally have less CO, myelin, and layer 4 development than S1, but more than SR and SC. In brain sections cut parallel to the surface of the cortex and processed for myelin or CO, S1 usually stands out as a darker region than surrounding areas of the cortex (Figures 2 and 3), as do primary auditory and visual areas. In some mammals, however, areas S2 and PV appear to be fairly similar in histological appearance to S1 (Figure 2; also see Huffman, K. J. *et al.*, 1999).

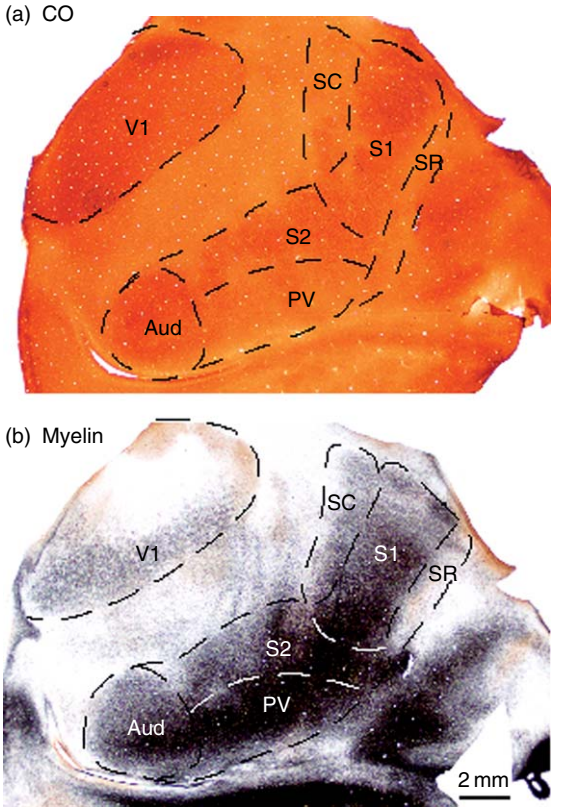

Figure 2 Architectonic characteristics of the somatosensory cortex in opossums. The cortex has been manually flattened and cut parallel to the surface so that it appears as a single sheet in each section. In (a), the section has been processed for cytochrome oxidase (CO). The primary sensory areas, S1, V1, and Aud, express high levels of CO, as does the frontal cortex. However, the CO level in S2 is also quite high. Unlike V1 and Aud, the CO expression in S1 and S2 is somewhat patchy, suggesting an uneven expression related to the somatotopy of the areas (see text). In (b), the brain section has been processed for myelin. Note that S1, S2, PV, and Aud are all densely myelinated. The lighter and uneven level of myelin in V1 is a result of laminar differences in expression, with the level of the section being superficial to the densely myelinated layer 4 of V1. Scale bar = 2 mm. Compare with Figure 1. Reproduced from Beck, P. D., Pospichal, M. W., and Kaas, J. H. 1996. Topography, architecture, and connections of somatosensory cortex in opossums: evidence for five somatosensory areas. J. Comp. Neurol. 366(1), 109–133.

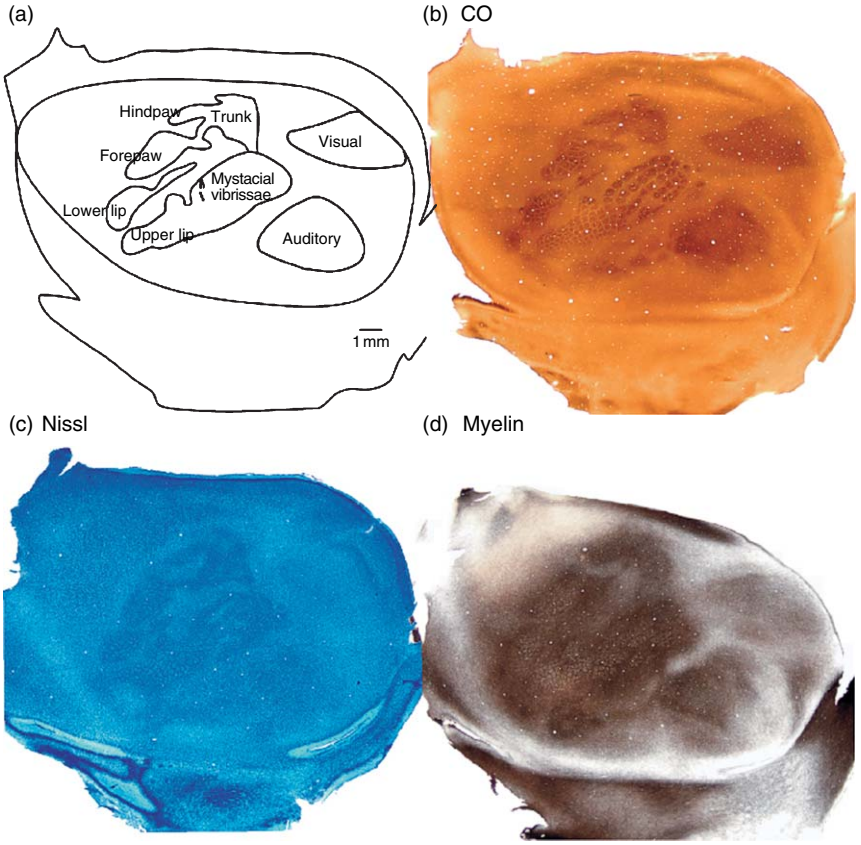

Figure 3 Architectonic characteristics of the somatosensory cortex in rats. As in Figure 2, the cortex has been flattened and cut parallel to the surface so that all of the neocortex can be seen in each brain section. In (a), the brain section is outlined and the portion of neocortex visible in a dorsolateral view is circumscribed. The primary somatosensory cortex is outlined and the portions representing major body parts are labeled. The locations of auditory and primary visual cortex are also indicated. In (c), a brain section has been stained for cell bodies (Nissl-stained). Note that even in this traditional stain, the major parts of S1 can be identified as darker due to the densely stained and packed cells in layer 4 cells of S1. In this section, even barrel-like structures with cell-poor hollows are apparent in parts of S1. In (b), the section has been processed for cytochrome oxidase (CO). Again, the locations of the representations of major body parts in S1 are apparent as CO-dark regions. The larger barrels of the mystacial barrel field stand out as CO-dark ovals, and the smaller barrels of the representation of hairs of the upper lip are also visible. Modular subdivisions of the representations of the forepaw and the lower lip are also apparent. The S2-PV region below S1 has a patchy pattern of CO expression, but the relationship of this pattern to somatotopy has not been established. Primary visual and auditory cortex are CO dense. In (d), the brain section has been stained for myelin. Due to the depth of the section, S1 is less clear, but overall S1 is densely myelinated. Note the less-dense myelination of the hallows of barrels in some locations. The primary visual and the auditory cortex are also more myelinated than the surrounding cortex. Reproduced from Jain, N., Diener, P. S., Coq, J. O., and Kaas, J. H. 2003. Patterned activity via spinal dorsal quadrant inputs is necessary for the formation of organized somatosensory maps. J. Neurosci. 23(32), 10321–10330. Copyright 2003 by the Society for Neuroscience, with permission.

In surface views, S1 typically has a rather mottled appearance, especially in surface views of CO preparations (Figures 2 and 3). This unevenness reflects the modular organization of S1, where small territories of the cortex are activated by inputs from one body part or another (somatotopic modules). The association of CO patches and ovals of cortex in S1 with representation of specific body parts has been demonstrated by correlating the results of mapping the somatotopy of S1 with microelectrodes with the CO pattern in detailed studies in numerous species of mammals (e.g., Krubitzer, L. A. *et al.*, 1986; 1995; Catania, K. C. and Kaas, J. H., 1995; Catania, K. C. and Remple, M. S., 2002; Remple, M. S. *et al.*, 2003). The details of the CO pattern differ with species, according to what types of sensory inputs are prominent, but a visible pattern of CO-dense modules that reflects the somatotopy of S1 in each species is common. Such associations between modular architecture and somatotopy are not usually seen in S2 and PV, as

CO staining is usually not that pronounced as in S1. However, some mammals, such as the star-nosed mole (Catania, K. C. and Kaas, J. H., 1995), do exhibit obvious modules in S2, and a patchy pattern of CO expression is apparent in S2 and PV of opossums (Beck, P. D. *et al*., 1996), rats (Remple, M. S. *et al*., 2003), and tree shrews (Remple, M. S. *et al*., 2007).

Perhaps the best-known example of somatic modularity in S1 is the so-called barrel field of rats and mice. The barrel field was named by Woolsey T. A. and Van der Loos H. (1970) when they discovered that the pattern of patches apparent in Nissl-stained sections through the lateral part of S1 correspond to the pattern of the mystacial vibrissae on the contralateral face, with each whisker activating neurons within a specific barrel. Sections stained for cell bodies (Nissl) cut through layer 4 revealed a pattern of ovals created by cell bodies with thalamic afferents arriving in the cortex of each oval, and cell-poor septa separating the ovals from each other (Figure 3). Subsequent studies revealed that the ovals, including the cell-poor hollows, are CO-dense (e.g., Land, P. W. and Simons, D. J., 1985), and can be revealed by histochemical stains for other mitochondrial enzymes, such as succinate dehydrogenase (Dawson, D. R. and Killackey, H. P., 1987). The barrels were best seen in brain sections cut parallel to the cortical surface. Certain lectins were also found to label the septal regions that separated the barrels (Cooper, N. G. and Steindler, D. A., 1986). In addition, it soon became apparent that the modular organization of S1 extends beyond the barrel field: another region of S1, termed the posteriomedial barrel subfield (PMBSF) that has barrel-like structures that correspond to the sinus hairs on the upper lip and hairy buccal pad, and the hairs of the lower lip, was described (Figure 3, see Jain, N. *et al*., 2003). A more medial group of succinic dehydrogenase and CO-dense ovals corresponded to representation of digits and pads of the forepaw (Dawson, D. R. and Killackey, H. P., 1987; Waters, R. S. *et al*., 1995), while a medial most group of ovals represented the toes and pads of the hindpaw (Dawson, D. R. and Killackey, H. P., 1987). These studies also revealed the protrusion of the SR dysgranular zone well into S1 to separate the representation of the face from the forepaw, the forepaw from the hindpaw, and the lower lip from the upper lip (Figure 3). Thus, histological features of S1 in rats and mice nicely illustrate both the architectonic distinctiveness of S1 and its modular organization, where the modules are devoted to parts of the sensory surface that are distinct by being activated by protruding sensory hairs or semi-segregated body parts such as digits.

Modules based on somatotopy are common in S1 of mammals, as discussed above and below for monkeys. In contrast, functionally distinct modules for different classes of receptors from the same body part have not been described in S1 of most mammals. In rats, however, the CO expression within the barrels of the barrel subfield is not uniformly dense, as CO-dark subbarrels, corresponding to functionally distinct inputs where neurons are differentially responsive to the angle of whisker deflection, are separated by narrow CO-sparse clefts (Bruno, R. M. *et al*., 2003; Andermann, M. L. and Moore, C. I., 2006; Louderback, K. M. *et al*., 2006). A more conspicuous example of such functionally segregating modules is the S1 representation of the receptors of the bill of the duck-billed platypus where separate, alternating islands of cells represent tactile and electrosensory inputs (Krubitzer, L. A. *et al*., 1995). Finally, modules of cells responding to either slowly adapting (SA) or rapidly adapting (RA) afferents have been described in S1 (area 3b) of monkeys (see below).

S1 of most mammals can be distinguished using a number of other histological preparations in additional Nissl and CO staining. In squirrels (Wong and Kaas in preparation), for example, parvalbumin is more densely expressed in layer 4 and inner layer 3 of S1 than in adjoining areas. Parvalbumin is expressed at a lower level in S2 and PV than in S1, but at a level that is higher than in the rostral and caudal somatosensory areas (SC and SR, also known as Pm and 3a). Primary sensory areas, including S1, are also marked by a wide layer 4 that is almost free of synaptic zinc (Figure 4), because the thalamocortical terminations that predominate in layer 4 are zinc poor, whereas the corticocortical terminations prominent in other layers are zinc rich. S1 and other primary areas also express more vesicular glutamate transporter 2, as visualized with immunohistochemical procedures. Other markers revealed by receptor autoradiography have been well studied in rats. Thus, S1 of rats expresses higher levels of the $GABA_A$ and cholinergic muscarinic M2 receptors than adjacent areas, and there are low levels of kainate receptor labeling in the middle layers (Palomero-Gallagher, N. and Zilles, K., 2004).

In summary, S1 is architectonically distinct in all mammals examined. Modules that segregate representations of body parts are often histologically apparent as they are isolated by cell-poor septa. In the rat barrel field, there is evidence of minimodules

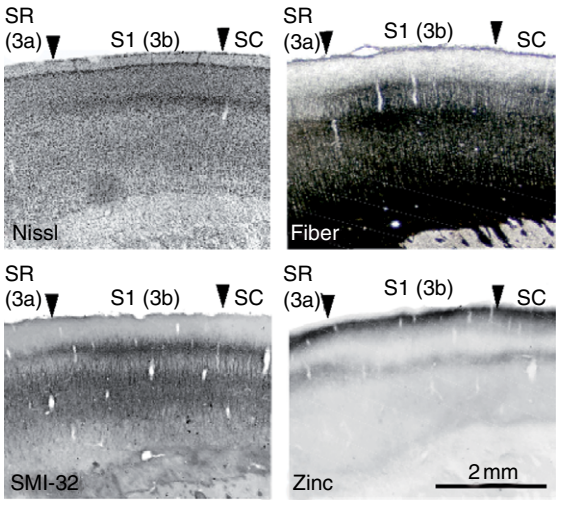

Figure 4 Some architectonic features of the somatosensory cortex of squirrels (*Sciurus carolenenisis*). Brain sections were cut at the parasagittal plane through SR, S1, and SC (rostral in the left). In a Nissl-stained section (upper left), S1 is characterized by a layer 4 that is densely packed with darkly stained neurons. This feature is less pronounced in SC, and much less so in SR such that SR is also called the dysgranular cortex. In sections stained for myelin (fibers; upper right), the middle layers of cortex are more densely myelinated in S1 than in SR or SC. Other layers are also more myelinated in S1, but the difference between S1 and SR or SC is most obvious in layer 4. In sections processed for the neurofilament protein revealed by the antibody SMI-32 (lower left), the staining of neurons and dendrites is more pronounced in layers 3 and 5 of S1 than in SC and PM. In sections processed for synaptic zinc (lower right), which is not expressed in thalamocortical terminations, S1 has a broader zinc-free (white) region in layer 4 and deeper layer 3 than SR or PM. Thus, S1 is distinguished from adjoining areas in all four preparations. Scale bar = 2 mm. Wong and Kaas (unpublished data).

within barrels that relate to groups of neurons with different response properties, and S1 of the duck-billed platypus has histologically visible modules for neurons related to electroreception or tactile sensations. These two examples suggest that the search for additional modules of the functional type would be rewarding. S2 and PV are difficult to distinguish histologically. They have histological characteristics that are similar to those of S1, but less pronounced. These characteristics are also variable, S2 being more or less like S1 in different species. The rostral (SR) and caudal (SC) somatosensory areas bordering S1 have a less well-developed layer 4, especially in SR (area 3a), which has been referred to as dysgranular cortex. A narrow zone of histologically indistinct posterior parietal cortex found in rats (Remple, M. S. *et al.*, 2003) and many other mammals also has somatosensory as well as multisensory functions. In rats, the region identified as the posterior parietal cortex (Reep, R. L. *et al.*, 1994) includes the caudal somatosensory area, SC (or Pm) of this review; so it is uncertain if a separate posterior parietal area exists. In some shrews, which have very small brains, there appears to be no cortex between S1 and the primary visual cortex, V1 (Catania, K. C., *et al.*, 1999). Thus, SC may not exist in all mammals. However, in tree shrews (mammalian order Scandentia), which are close relatives of primates, a posterior parietal region about the width of SC is present just caudal to SC. This posterior parietal region resembles SC histologically (Remple, M. S. *et al.*, 2006), but it has dense connections with the motor cortex, while SC of tree shrew and other mammals has dense connections with S1 (Remple, M. S. *et al.*, 2007).

6.08.3 The Somatosensory Cortex of Prosimian Primates

Prosimians represent one of the three major branches of primate evolution (prosimians, tarsiers, and anthropoids). The prosimians include present-day lemurs, lorises, and galagos. The somatosensory cortex is likely organized in a similar manner in most of the prosimians, but experimental data are largely from the slow lorises (Krishnamurti, A. *et al.*, 1976) and especially galagos (e.g., Wu, C. W. and Kaas, J. H., 2003). As in most mammals, the anterior parietal cortex of galagos consists of three areas (Figure 5): a systematic representation of the contralateral body surface (Sur, M. *et al.*, 1980), corresponding to area S1 or 3b, and rostral and caudal zones that are described as being unresponsive to cutaneous stimulation in anesthetized animals (.Carlson, M. and Welt, C., 1980; Sur, M. *et al.*, 1980; Wu, C. W. and Kaas, J. H., 2003) but have strong connections with S1 (Wu, C. W. and Kaas, J. H., 2003). The S1 representation has a somatotopic organization that is similar to S1 of anthropoid primates (Sur, M. *et al.*, 1980), dense inputs from the ventroposterior nucleus, and architectonic characteristics of the primary sensory cortex (Figure 6; Preuss, T. M. and Goldman-Rakic, P. S., 1991a). Based on its position in the cortical mantle and its architectonic features, the SR somatosensory cortex along the rostral border of S1 appears to be area 3a (e.g., Preuss, T. M. and Goldman-Rakic, P. S., 1991a). Thalamic inputs to SR arise from the ventroposterior superior nucleus, as do inputs to area 3a in anthropoid

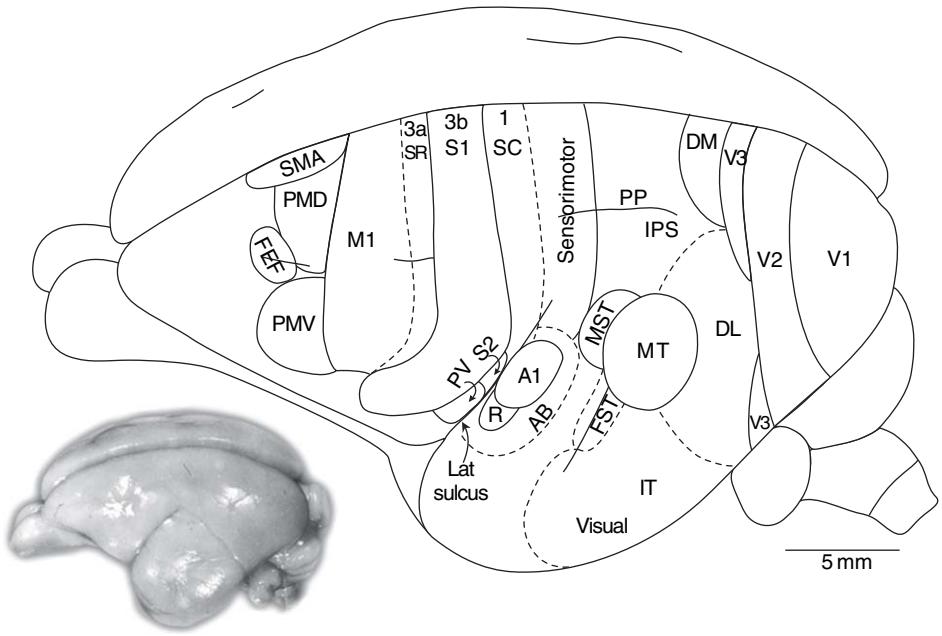

Figure 5 Somatosensory areas on a dorsolateral view of the left cerebral hemisphere of a galago (*Otolemur garnetti*), a prosimian primate. The anterior parietal cortex includes the three areas found in other mammals, S1 or area 3b, SR or area 3a, and area SC, which is in the position of area 1 in anthropoid primates. The second somatosensory area (S2), and the parietal ventral somatosensory area (PV), have been defined just lateral to S1 in the cortex on the upper bank of the lateral sulcus. A rostral strip of the posterior parietal cortex has dense cortical connections with other areas of the somatosensory cortex and with motor and premotor areas (M1, primary cortex; PMD, dorsal premotor cortex area; PMV, ventral premotor area; SMA, supplementary motor area). Other areas shown for reference include visual areas, V1, V2, and V3, dorsomedial (DM) and dorsolateral (DL) visual areas, inferior temporal (IT) cortex, the middle temporal (MT), medial superior temporal (MST), and fundal superior temporal (FST) visual areas. The auditory cortex includes the primary auditory area, A1, and the rostral auditory area, R, as well as an auditory belt (AB) of several areas. Note the lateral (Lat) sulcus and the intraparietal sulcus (IPS). Scale bar = 5 mm. FEF, frontal eye field.

primates (Franca, J. G. *et al.*, 2003). In an earlier architectonic study of another prosimian primate, the slow loris, Sanides F. and Krishnamurti A. (1967) concluded that the cytoarchitecture of S1 (their somatic koniocellular area) identified it as area 3b, while the strip of cortex on the rostral border of 3b was area 3a. The identity of the strip of cortex along the caudal border of 3b is less certain. By position, this cortex should be area 1, but the area has been variously identified as areas 2 + 5 (Preuss, T. M. and Goldman-Rakic, P. S., 1991a) or 1 + 2 (Sanides, F. and Krishnamurti, A., 1967; Wu, C. W. and Kaas, J. H., 2003). The lateral somatosensory cortex, located along the upper bank of the lateral sulcus, contains the second somatosensory area, S2, and the parietal ventral area, PV (Burton, H. and Carlson, M., 1986; Garraghty, P. E. *et al.*, 1991; Wu, C. W. and Kaas, J. H., 2003). S2 and PV of galagos receive dense inputs from the ventroposterior nucleus, as in other mammals with the exception of anthropoid primates, as well as inputs from the ventroposterior inferior nucleus, in common with anthropoid primates. The cortical connections of S2 and PV, together with limited results from microelectrode recordings, suggest the existence of additional areas in the lateral sulcus and insula, which have been designated as the ventral somatosensory area (VS), retroinsular area (Ri) and parietal rostral area (PR) (Wu, C. W. and Kaas, J. H., 2003). Histological distinctions between subdivisions of the lateral parietal cortex have been described in prosimian primates (Sanides, F. and Krishnamurti, A., 1967; Zilles, K. *et al.*, 1979b), but they are not pronounced. The posterior parietal cortex of galagos includes a rostral division having connections with motor and somatosensory areas of cortex, and a caudal division that receives inputs from the visual cortex and is connected with the rostral division (Fang, P. C. *et al.*, 2005; Stepniewska, I. *et al.*, 2005). Both regions have been included in an area 7 (with subdivisions) by Preuss T. M. and Goldman-Rakic P. S. (1991a; 1991b).

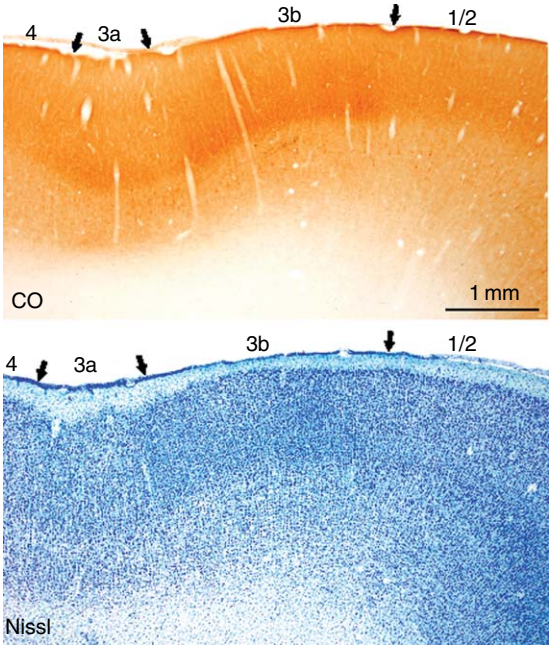

Figure 6 Architectonic characteristics of the somatosensory cortex of prosimian galagos. Brain sections cut in the parasagittal plane were processed for the expression of cytochrome oxidase (CO), above, or Nissl staining of cell bodies, below. CO levels were highest in the metabolically active layer 4 and the inner third of layer 3. This expression of CO was most dense in area 3b (S1), clearly marking the rostral and caudal boundaries of the area. Layer 4 expressed a moderate level of CO in area 3a, which was absent in agranular area 4 (primary motor cortex). The expression of CO in granular (4) and supragranular (3) layers of area 1/2 was much less than in area 3b. In tradition Nissl-stained sections, area 3b was characterized by densely packed, small cells in layers 4 and 3 such that these layers appear to fuse. This fused region of small cells corresponds to the CO-dense region. Layer 4 was less well developed in both area 3a and area 1/2. Scale bar = 1 mm.

Of the proposed architectonic subdivisions of the somatosensory cortex of galagos and other prosimians, such as slow loris (Sanides, F. and Krishnamurti, A., 1967) and microcebus murinus (Zilles, K. *et al.*, 1979a), areas 3b and 3a are most distinct, area 3b because it has the pronounced features of the primary sensory cortex and area 3a because this dysgranular cortex stands out between the highly granular cortex of area 3b and the agranular cortex of area 4 of the primary motor cortex. Nevertheless, the granular appearance of layer 4 in area 3b of prosimians is not as pronounced as in anthropoid primates, and this misled Brodmann K. (1909) into identifying area 3b of prosimian lemurs as area 1. However, layer 4 of area 3b of galagos is thick and densely packed with small neurons, as is area 3b of other primates, and layers 3 and 6 are densely packed with cells as well. The middle layers of area 3b of galagos are more myelinated and express more CO than in adjacent areas, making the field stand out. Area 3b of galagos (Figure 5) corresponds in location and extent to the area 1 of Brodmann K. (1909), area 3 of von Bonin G. (1945), area postcentralis 1 of Zilles K. *et al.* (1979b), and 3b of Preuss T. M. and Goldman-Rakic P. S. (1991a) in galagos and other prosimian primates.

In brain sections cut parallel to the surface of the cortex and processed for myelin, area 3b of galagos has modular subdivisions of the myelin-dense region that are separated by myelin-light septa, (Kaas, J. H. *et al.*, 2006), as in anthropoid primates. One prominent septum separates the forelimb representation from that of the face. Other septa separate representations of parts of the face, the teeth, and the tongue. These modular divisions of area 3b are similar to those found in monkeys, as described further below.

Descriptions of other architectonic areas in prosimians are more variable, reflecting the relative lack of sharp distinctions between areas. The most extensive description of the cytoarchitecture of the parietal cortex of prosimian is that of Preuss T. M. and Goldman-Rakic P. S. (1991a), where a number of subdivisions of their area 7 were identified and homologies with divisions of area 7 in macaque monkeys were proposed. These authors also recognized an S2 region that is extensive enough to include S2 and PV, as well as additional cortex in the lateral sulcus. The cytoarchitecture of a smaller galago (*Galago demidovii*) and of the prosimian mouse lemur (*Microcebus murinus*) has also been studied and S1 (area 3b) was obvious as an area with a pronounced layer 4, but areas SC and SR were not noted (Zilles, K., 1979a; 1979b). In a similar manner, the earlier study of the cytoarchitecture of cortex in galagos by von Bonin G. (1945) only identified S1 (3b).

6.08.4 The Anterior Parietal Cortex of New World Monkeys

The somatosensory cortex of anthropoid primates differs from that of prosimian primates and other mammals in that the anterior parietal cortex usually has four major divisions, areas 3a, 3b, 1, and 2, as an area 2 has been added to the three areas present in prosimians. The lateral parietal cortex is somewhat

expanded, and may have more areas. The posterior parietal cortex is variably expanded, being relatively small, as in galagos, in some New World monkeys, but considerably expanded in others, such as in Old World macaques. The somatosensory areas of New World owl monkeys are shown in Figure 7.

The anterior parietal cortex of New World monkeys is somewhat variable across species in histological appearance and the distinctiveness of subdivisions. At one extreme, these are the small New World marmosets and tamarins in which only area 3b (S1) responds well to cutaneous stimulation (Carlson, M. *et al*., 1986; Krubitzer, L. A. and Kaas, J. H., 1990). As area 1 and, to some extent, area 2 can be identified by having characteristic representations of cutaneous receptors that are separate and distinct from the representation in area 3b, the weakly responsive cortex caudal to area 3b (S1) of marmosets is more like the caudal somatosensory area of galagos and other mammals than area 1 of other anthropoid primates. Area 3b of marmosets (Figure 8) has densely packed granule cells in layer 4, as in other primates. The packing of cells in layers 4 and 3 is less pronounced in the cortex caudal to area 3b in the position of area 1, and a transition more caudally to cortex with somewhat less cell packing in layers 4 and 6 may signify the presence of an area 2. But there is no convincing physiological or connectional evidence for an area 2 in these primates. Cortex rostral to area 3b in marmosets has the typical appearance of area 3a, with a

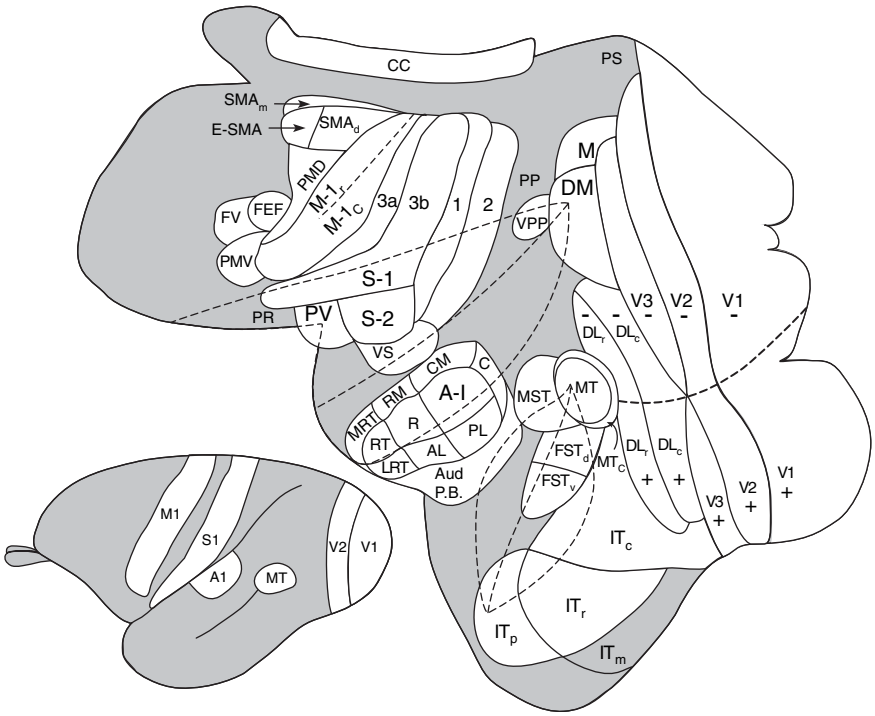

Figure 7 Somatosensory areas of a New World monkey (owl monkey, *Aotus*). On the lower left, a lateral view of the brain shows the locations of primary somatosensory (S1 or area 3b) and primary motor areas (M1), as well as the primary visual cortex (V1) for reference. The second visual area, V2, and the middle temporal area, MT, are also shown. On the upper right, cortical areas are indicated on a larger view of neocortex after it has been separated from the rest of the brain, fissures opened, and the cortex flattened. Somatosensory areas include areas 3a, 3b, 1, and 2 of Brodmann K. (1909), S2, PV, the parietal rostral area (PR), rostral and caudal divisions of the ventral somatosensory area (VSr and VSc), and the retroinsular area (Ri). The posterior parietal cortex (PP) includes a ventral posterior parietal (VPP) area with visual inputs. Other subdivisions are uncertain. Motor areas include rostral and caudal divisions of the primary motor cortex (M1r and M1c), dorsal and ventral premotor areas (PMD and PMV), dorsal and medial supplementary motor areas (SMAd and SMAm), caudal and rostral cingulate motor areas (CMv and CMc), a frontal eye field (FEF), frontal visual area (FV), and a supplementary eye field (E-SMA). Auditory areas include A1, a rostral area (R), and a rostrotemporal area (RT), as well as areas of the auditory belt (Aud B) and parabelt (Aud P.B.). Visual areas include V1, V2, V3, DM, DL with rostral and caudal divisions, MT, MST, FSTd, FSTv, and IT with caudal, rostral, medial and polar divisions (see Figure 5 for abbreviations). The medial visual area (M) and the MT crescent (MTc) are also indicated. CC, corpus callosum.

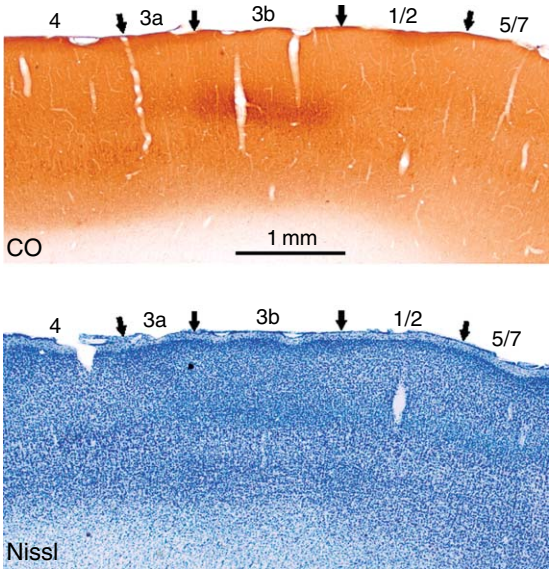

Figure 8 Architectonic characteristics of the anterior parietal somatosensory cortex in marmosets (*Callithrix jacchus*). Brain sections cut in the parasagittal plane have been processed for cytochrome oxidase (CO), above, or stained for cell bodies (Nissl), below. As in galagos (Figure 6), CO was densely expressed in layer 4 and inner layer 3 of area 3b (S1), with more focused and denser CO expression than in area 3b of galagos. The CO expression in layer 4 of area 3a was much less, with even less expression in layer 6 of area 4. Area 1/2 had little layer 4 CO expression, while layer 4 CO expression increased slightly in area 5/7. In area 3b, dense packing of small cells in layer 1 and the adjoining part of layer 3 was the most prominent defining feature, although layer 6 was also densely packed with cells. Layer 4 was less pronounced in area 3a, while the appearance of large pyramidal cells in layer 5 marked the translation to area 4. Layer 4 was moderately well developed in area 1/2, and even more pronounced in area 5/7. The use of the terms 1/2 and 5/7 for areas caudal to area 3b reflects uncertainties over the identities of these fields (see text). Scale bar = 1 mm.

poorly developed layer 4 and a scattering of larger layer 5 pyramidal cells. In addition, the connections of this cortex with the ventroposterior superior nucleus of the thalamus reinforce the identification of this rostral band of cortex as area 3a (Huffman, K. J. and Krubitzer, L., 2001).

In squirrel monkeys (Sanides, F., 1968; Jones, E. G. *et al.*, 1978; Sur, M. *et al.*, 1982; Cusick, C. G. *et al.*, 1985;) and owl monkeys (Merzenich, M. M. *et al.*, 1978), there is architectonic, connectional, and physiological evidence for areas 3a, 3b, 1, and 2. The microelectrode recording evidence for a separate representation of the body in area 2 is limited and has not been published in full. The large cebus monkeys also have architectonic fields corresponding to areas 3a, 3b, 1 and 2, and parallel representation of cutaneous receptor has been described in areas 3b and 1, while limited recordings suggest additional, mainly deep receptor representations in areas 3a and 2 (Felleman, D. J. *et al.*, 1983).

6.08.5 Other Somatosensory Areas of New World Monkeys

Areas of the posterior parietal cortex and the lateral parietal cortex have been difficult to delineate architectonically in primates, and these regions have been less well studied in New World monkeys than in Old World monkeys. In addition, the great range of brain sizes in New World monkeys suggests that subdivisions and architectonic feature vary across taxa, and descriptions developed for one or a few species may not apply to all. Brodmann K. (1909) used a marmoset brain as an example of a New World monkey, and divided all of the posterior parietal cortex into an anterior area 5 and a posterior area 7. Cortex in the positions of areas 1 and 2 of Old World monkeys was included in area 5. Neither area 5 nor area 7 was subdivided. Subdivisions of cortex in the lateral fissure were not identified. Later, Peden, J. K. and von Bonin G. (1947) also concluded that the parietal cortex of marmosets is not well differentiated into areas. These investigators also divided the posterior parietal cortex into an anterior region, PC, and a posterior region, PE, with PC including cortex up to the border of area 3b (their PB, which they stated "hardly deserves to be called koniocortex as in higher primates"). Much of the cortex on the upper bank of the lateral sulcus was included in an area PFD, which has a well-defined granular layer. PFD includes the regions of S2 and PV in marmosets, which have not been distinguished architectonically (Krubitzer, L. A. and Kaas, J. H., 1990).

Other early architectonic studies were those of von Bonin G. (1938) on cebus monkeys and of Lashley K. S. and Clark G. (1946) on spider monkeys, both being New World monkeys with large brains. In cebus monkeys, von Bonin described a narrow intermediate area, corresponding largely to area 2, between granular somatosensory cortex (area 3b) and a large, undivided posterior parietal region. The lengthy paper of Lashley K. S. and Clark G. (1946) on spider monkeys is known for its critical review of the cytoarchitectonic method for dividing cortex into areas, as the two authors independently produced different subdivisions of cortical organization.

Taking a position that now seems extreme, they concluded that only area 3a of the anterior parietal cortex could be reliably identified in spider and cebus monkeys, and that the proposed areas 5 and 7 of the posterior parietal cortex could not be "identified by any consistent characters and certainly do not represent functionally distinct units." Lashley and Clark described a large portion of the insular cortex in the lateral sulcus as the granular cortex.

More recent studies have not led to a clearer understanding of how the posterior parietal cortex is subdivided into areas in New World monkeys. Experimental and architectonic evidence for the array of fields proposed for the cortex of the intraparietal sulcus of macaques has not been obtained for New World monkeys. While an area 2 and an area 5, immediately caudal to area 2, have been described in squirrel monkeys (Rosabal, F., 1967; Jones, E. G. *et al.*, 1978), Padberg J. *et al.* (2005) propose that area 2 is missing in at least some New World monkeys so that area 5 extends to area 1 or even to the area 3b border. For now, a reasonable conclusion is that the origination of the posterior parietal cortex is not well understood in New World monkeys and that further studies combining histological techniques with studies of connections and function are needed.

In the lateral parietal cortex within the lateral fissure of New World monkeys, areas S2, PV, VS, and PR have been defined on the bases of somatotopic patterns and connections (Cusick, C. G. *et al.*, 1989; Krubitzer, L. A. and Kaas, J. H., 1990; Qi, H. X. *et al.*, 2002; Coq, J. O. *et al.*, 2004). All these areas have a moderately well-developed layer 4, and histological distinctions between the areas are not marked. The physiological and connectional data, together with the architectonic results, have not yet resolved the issue of whether areas S2 and PV immediately adjoin area 3b, which presents a clear architectonic border, or whether 3b is separated from S2 and PV by a narrow area 1 (or even an area 2) that cytoarchitectonically resembles S2 and PV. The architectonic border of S2 with VS is more apparent, as layer 4 is broader in S2 in both Nissl and CO preparations (Cusick,C. G. *et al.*, 1989). In squirrel monkeys, Jones E. G. and Burton H. (1976) include most of S2 and PV in the cortex designated as areas S2 and 1–2, while VS is located largely within their granular insular area, Ig. The region of area PR overlaps the cortex identified as gustatory by Sanides F. (1968). The insular cortex was divided from caudal to rostral by Jones E. G. and Burton H. (1976) into granular (Ig), dysgranular (Id), and agranular (Ia) fields. The VS region overlaps most of Ig. Just caudal to the granular insular cortex, a retroinsular region was distinguished as having more clearly separated layers. Thus, there are clear subdivisions of the lateral parietal cortex, but architectonic distinctions between the proposed somatosensory areas (S2, PV, VS, PR) of this region are not pronounced.

6.08.6 Modules in Area 3b of Old World and New World Monkeys

In brain sections cut parallel to the surface and stained for myelin, area 3b of marmosets stands out as a densely myelinated band of cortex that extends mediolaterally from the medial wall to near the lateral sulcus, at which point area 3b curves rostrally into the frontal lobe (.Krubitzer, L. A. and Kaas, J. H., 1990; Qi, H. X. *et al.*, 2002). This strip of densely myelinated cortex has a conspicuous septum crossing its width near the lateral end where it curves rostrally. This septum separates the mediolateral portion, which represents the foot, trunk, and forelimb in a mediolateral sequence, from the caudorostral segment representing the face, tongue, and teeth. Other septa divide the caudorostral segment into a series of ovals that represent different parts of the face, the contralateral teeth, the contralateral tongue, the ipsilateral teeth, and the ipsilateral tongue in a caudal-to-rostral sequence. These isolated ovals of cortex are visibly apparent modules in area 3b that relate to the functional isolation of body parts in the representation, rather than to differing functional classes of inputs. These modular features of area 3b are even more apparent in other New World monkeys (Figure 9; Jain, N. *et al.*, 2001; Iyengar, S. *et al.*, 2007), where septa can be seen dividing the representations of individual digits as well (Jain, N. *et al.*, 1998; 2001). Similar modular subdivisions of area 3b that represent digits, parts of the face, and the oral cavity have been described in area 3b of Old World macaque monkeys (Figure 10, Qi, H. X. and Kaas, J. H., 2004). Some of the modules can be seen, although less clearly, in area 3b of prosimian galagos (Kaas, J. H. *et al.*, 2006). They are likely to be visible in appropriately cut and stained brain sections of area 3b of apes and humans as well, but this has not yet been shown. The septa in area 3b of macaque are apparent soon after birth (Qi, H. X. and Kaas, J. H. 2004), so they are unlikely to depend on postnatal sensory experience. These septa, which separate parts of area 3b with few intrinsic

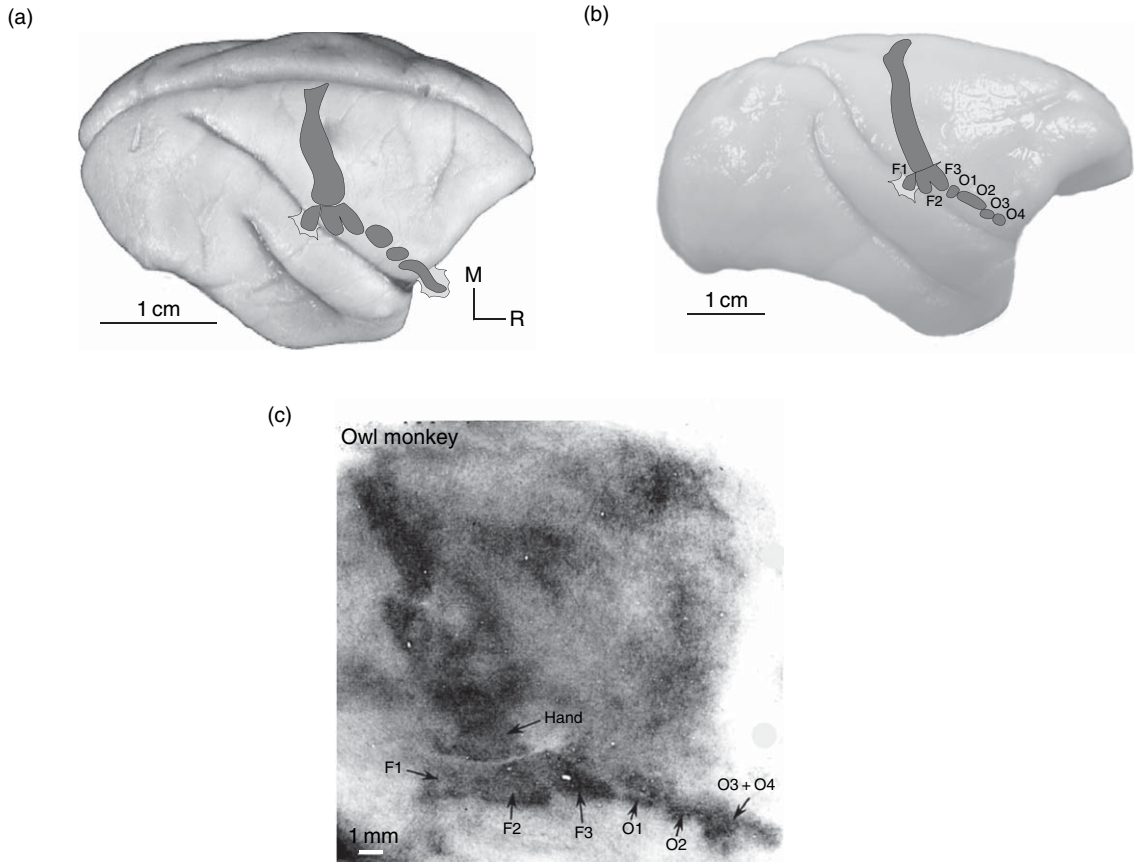

Figure 9 Modular subdivisions of the myeloarchitecture of area 3b (shaded) on lateral views of the right cerebral hemisphere of an owl monkey (a) and a squirrel monkey (b). The long mediolateral extent of area 3b represents the hand and other parts of the lower body, while the subdivided lower part represents the face and oral cavity. In the lower part, the modular subdivisions or ovals, F1–F3, represent the upper face, upper lip, and lower lip in a caudorostral sequence, while oral ovals, O1–O4, successively represent the contralateral teeth, the contralateral tongue, the ipsilateral teeth, and the ipsilateral tongue. The lateral sulcus (LS) and the superior temporal sulcus (STS) are indicated, and the marker bars = 1 cm. Ovals O3 + O4 fold onto the ventral surface of the frontal lobe in owl monkeys and F1 extends onto the upper bank of the lateral sulcus. In (c), a brain section cut parallel to the surface of unfolded and flattened cortex is stained for myelin. The myelin-dark region is area 3b. Lateral (ventral) to the hand representation, a myelin-light septum separates the hand representation from that of the face. Other septa that separate the F1–F3 and the O1–O4 ovals are variably apparent in this section. Other, less apparent, septa that separate the representations of the digits in the hand region need to be viewed at a higher magnification (see Jain, N. *et al.*, 1998). Scale bar = 1 mm. Adapted from Jain, N., Qi, H. X., Catania, K. C., and Kaas, J. H. 2001. Anatomic correlates of the face and oral cavity representations in the somatosensory cortical area 3b of monkeys. J. Comp. Neurol. 429(3), 455–468 and Kaas, J. H., Qi, H. X., and Iyengar, S. 2006. Cortical network for representing the teeth and tongue in primates. Anat. Rec. A Discov. Mol. Cell Evol. Biol. 288(2), 182–190.

interconnections, serve as useful anatomical guides to the somatotopy of area 3b.

The other type of module that appears to exist in area 3b of anthropoid primates is a functional one that divides the area into alternating patches of cortex that are activated by either SA or RA low-threshold cutaneous mechanoreceptors. These modules are not histologically distinct, and they have been demonstrated so far only in the territory of the hand representations of owl monkeys and macaque monkeys (Sur, M. *et al.*, 1981; 1984). The portions of area 3b that were devoted to each digit were divided into regions with inputs from RA receptors and regions devoted to SA receptors. The segregation of these two types of input was most apparent in arrays of microelectrode recordings from layer 4, where the thalamocortical projections from the ventroposterior nucleus terminate. The SA and RA domains revealed by these recordings were about 0.5 mm wide in macaques, and somewhat smaller in owl monkeys. Similar

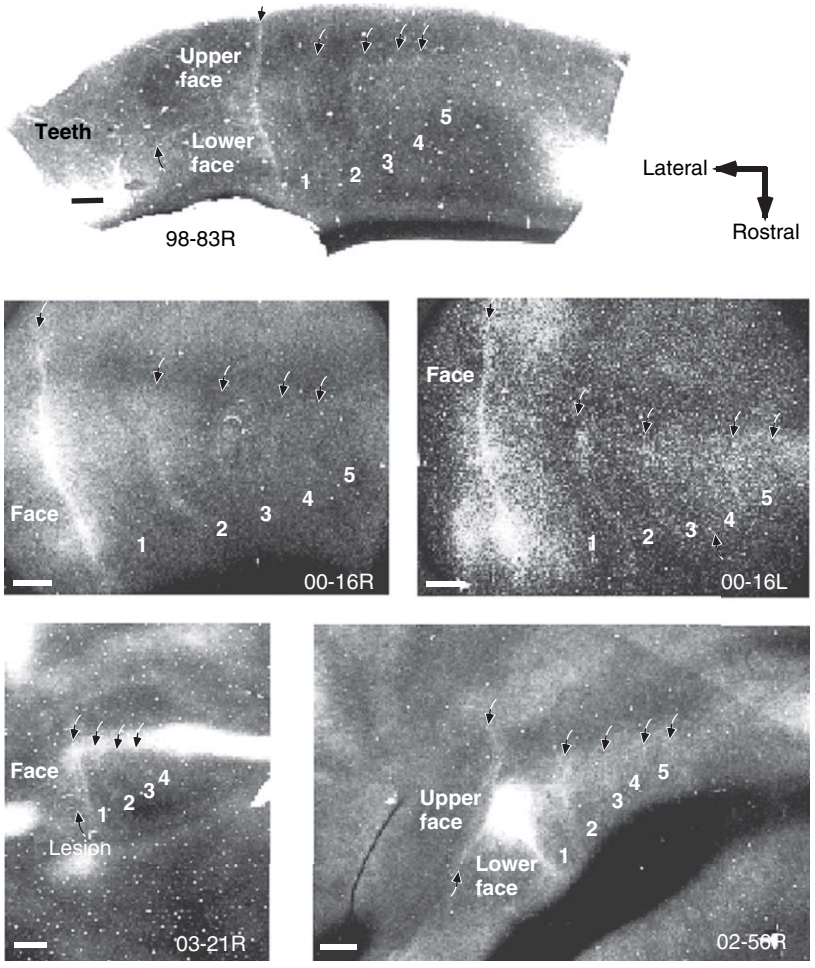

Figure 10 Modular subdivisions of area 3b representing individual digits in area 3b of macaque monkeys. Myelin-stained brain sections have been cut parallel to the surface of area 3b of macaque monkeys. The cortex corresponds to the caudal bank of the central sulcus with the fundus of the sulcus below (rostral). Narrow myelin-poor septa divide this cortex. The conspicuous lateralmost septa separates the representation of the face from that of the hand, while the progressively more medial and less apparent septa separate the representation of the digits, 1–5. A narrow septum separating the upper and lower face representation is apparent in the upper main section. Sections are numbered by case and cerebral hemisphere (R and L). Scale bars = 1 mm. Reproduced from Qi, H. X. and Kaas, J. H. 2004. Myelin stains reveal an anatomical framework for the representation of the digits in somatosensory area 3b of macaque monkeys. J. Comp. Neurol. 477(2), 172–187.

results have more recently been obtained in optical imaging studies of area 3b of squirrel monkeys (Chen, L. M. *et al.*, 2001). Presumably, all parts of area 3b have these modules, which correspond to the functionally distinct type of modules postulated by Mountcastle V. B. (1957). As further evidence for SA and RA modules in area 3b, microstimulation of regions of RA activation in area 3b of macaque monkeys appears to be interpreted by the monkeys as a sensation of flutter matching the frequency of the stimulation (Romo, R., *et al.*, 2000). This result suggests that the RA but not the SA modules participate in the somatosensory sensation of flutter.

Less is known about the existence of functional modules in other areas of the somatosensory cortex, but Friedman R. M. *et al.* (2004) have used optical imaging to determine what parts of the hand representation in area 1 are activated by frequencies of skin indentation that would preferentially activate SA (1–5 Hz, pressure), RA (30 Hz, flutter), or Pacinian RA-II (200 Hz, vibration) afferents. These results suggest that area 1 is divided into small domains-activated SA, RA, or PC afferents, with domains being roughly 200–300 μm in width. Other somatosensory areas may also be subdivided into interdigitating arrays of functionally distinct modules, but in higher-order areas

would be expected to have more complex functional types than the functional types that are closely tied to receptor type as in areas 3b and 1.

6.08.7 The Anterior Parietal Cortex of Old World Monkeys, Apes, and Humans

In Old World monkeys, apes, and humans, motor areas of the frontal lobe are separated from somatosensory areas of the parietal lobe by a deep central sulcus (Figure 11). The anterior parietal cortex includes the cortex in the depths of the central sulcus, and extends to the postcentral sulcus. In humans and Old World monkeys, the four major architecture fields of Brodmann K. (1909) divide the anterior parietal cortex into areas 3, 1, and 2 as a sequence of mediolateral strips of cortex extending from deep in the central fissure, anteriorly, to rostral bank of the postcentral gyrus. While Brodmann K. (1909) described the portion of area 3 lining the fundus of the central fissure as transitional, having architectonic features intermediate between the area 3 proper and the motor cortex (area 4), Vogt C. and Vogt O. (1919) distinguished the fundal cortex, with its narrow layer 4 and prominent layer 5 pyramidal cells, as area 3a, distinct from the hypergranular cortex located on the caudal bank of the central suclus, which they designated as area 3b. The four areas of the anterior parietal cortex distinguished by the Vogts (3a, 3b, 1, and 2) were combined in a single primary somatosensory field, S1, in early physiological studies on macaque monkeys (Marshall, W. H. *et al.*, 1937). As recording electrodes were placed only on the cortical surface in these experiments, recordings were made mainly from areas 1 and 2, and the separate representations of body parts in each of the architectonic fields were not apparent. Areas 3a, 3b, 1, and 2 are now widely recognized as

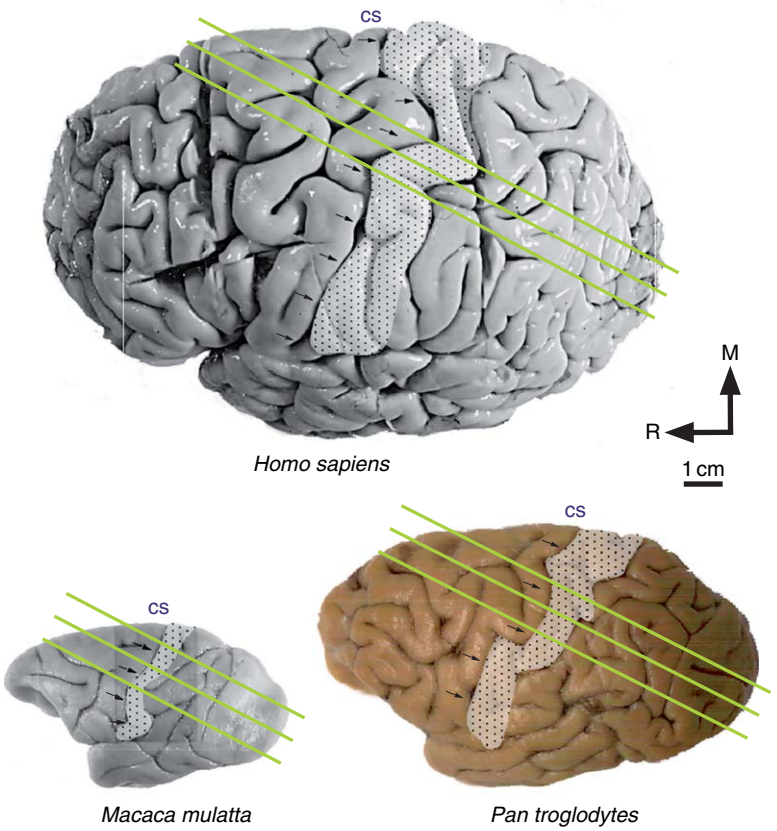

Figure 11 Dorsolateral views of the left cerebral hemisphere of macaque, chimpanzee, and human brains showing the locations of the central sulcus (CS) and the anterior parietal cortex. In these primates, most of area 3b is on the caudal bank of the central sulcus, and the postcentral gyrus is largely occupied by areas 1 and 2. Parallel lines indicate the planes of section for sections illustrated in Figure 13.

separate somatosensory areas, each containing a different representation of the body (Kaas, J. H. *et al.*, 1979). As in New World monkeys, the representations parallel each other while forming mirror reversals of somatotopy at their common borders. In contrast to New World marmosets, area 1 is highly responsive to cutaneous stimuli in Old World monkeys. Unlike New World monkeys such as owl and squirrel monkeys, much of area 2 in Old World monkeys is also responsive to cutaneous stimuli.

A summary of the somatotopic organizations of areas 3a, 3b, 1, and 2 of macaque monkeys, based on the reports of Nelson R. J. *et al.* (1980) and Pons T. P. *et al.* (1985), is shown in Figure 12. As area 3a is located in the depth of the central sulcus, it is the area that was least thoroughly examined in those

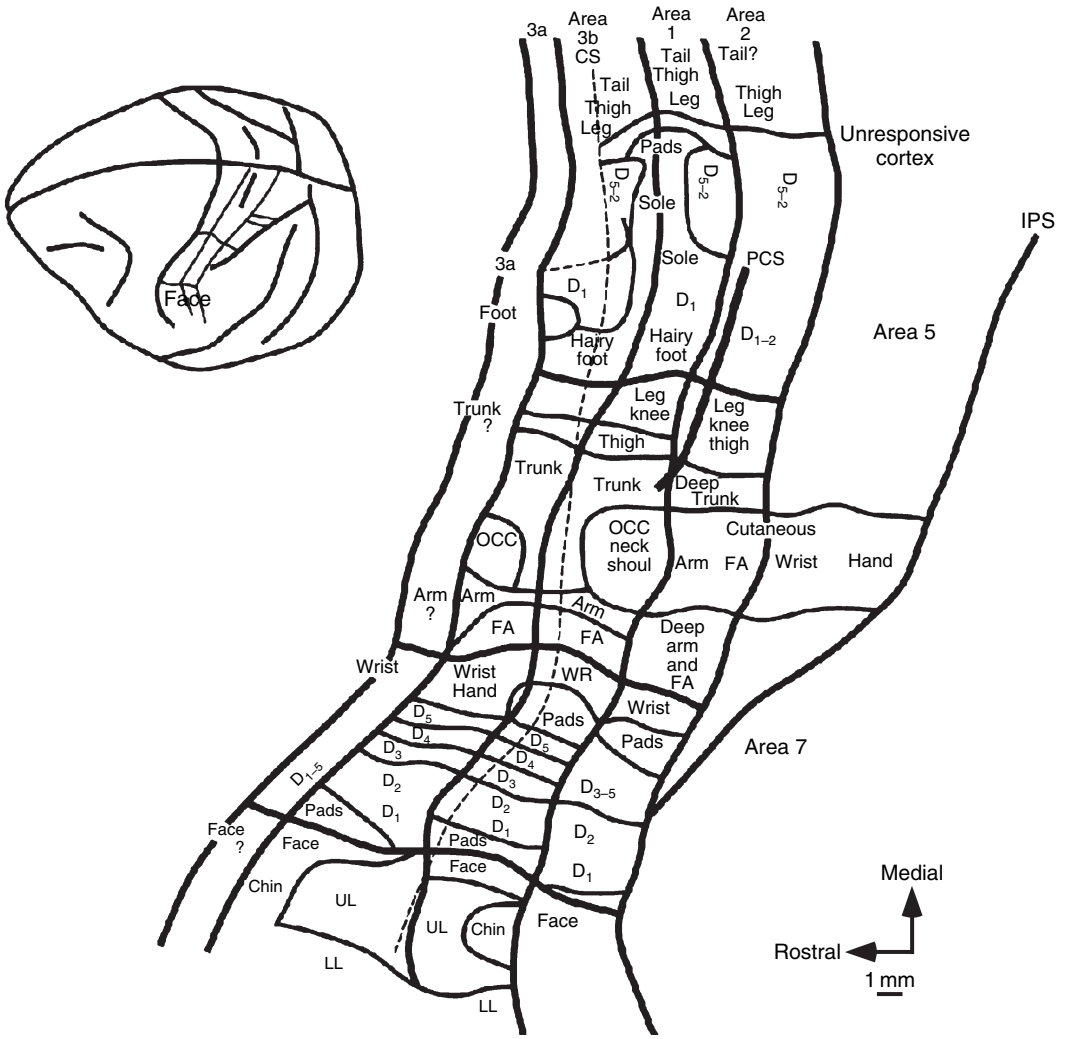

Figure 12 A summary of the somatotopic organization of the anterior parietal cortex of macaque monkeys based on the results of microelectrode recordings through this cortex by Nelson R. J. *et al.* (1980) and Pons T. P. *et al*. (1985). The explored region of the postcentral cortex is indicated on a dorsolateral view of the left cerebral hemisphere on the left. The diagram on the right is of the unfolded cortex of the central sulcus together with the postcentral gyrus, including some of area 5. The upper part of the diagram includes cortex unfolded from the medial wall of the cerebral hemisphere, while the most lateral extents of areas 3a, 3b, 1, and 2 were not explored (however, see Manger, P. R. *et al.*, 1996). Question marks indicate uncertainties about area 3a, which was not fully explored (however, see Krubitzer, L. *et al.*, 2004). A dashed line marks the crown of the central sulcus (CS). Note the location of the intraparietal sulcus (IPS). D1–D5, digits of the hand or foot, UL, upper lip; LL, lower lip; FA, forearm; Should, shoulder; OCC, occiput; Wr, wrist. Reproduced from Pons, T. P., Garraghty, P. E., Cusick, C. G., and Kaas, J. H. 1985. The somatotopic organization of area 2 in macaque monkeys. J. Comp. Neurol. 241(4), 445–466.

studies. A more complete portrayal of area 3a somatotopy in macaques has been presented by Krubitzer L. *et al.* (2004). The most lateral portion of these areas represents the face and receptors of the oral cavity. These parts of the representations have been more extensively described by Manger P. R. *et al.* (1996).

The somatosensory organization of the anterior parietal cortex in chimpanzee is largely unknown. However, some limited mapping of the anterior somatosensory cortex occurred in early studies in chimpanzees, with most of the recordings along the junction of area 1 with area 2 (Woolsey, C. N. *et al.*, 1943). The few recordings from surface sites in this study revealed a mediolateral somatotopic pattern that resembles that of macaque monkeys and humans (see Bailey, P. *et al.*, 1950, for maps of the motor cortex in chimpanzees).

In humans, the mediolateral somatotopy of the anterior parietal cortex, at least at a crude level, is well established (e.g., Penfield, W. and Boldrey, E., 1937; see Kaas, J. H., 2004, for review). However, the recording and stimulating sites in most studies were from the parts of the anterior parietal cortex exposed on the postcentral gyrus. Additional information has come from functional magnetic resonance imaging (MRI) studies. The overall somatotopic pattern is much like that reported for macaque monkeys and other primates. More recently, it has been possible to demonstrate separate representations of the glabrous hands in areas 3b and 1 of humans, with mirror image organizations as in monkeys. Thus, the digit tips are represented at the border of areas 3b and 3a, and again at the caudal border of area 1 with area 2 (Sato, K. *et al.*, 2002; Blankenburg, F. *et al.*, 2003). In addition, it is clear that area 2 contains another representation of the hand in humans (Krause, T. *et al.*, 2001). More laterally in the anterior parietal somatosensory cortex, the lower lip, teeth, and tongue are represented in a sequence that is similar to that of monkeys (Miyamoto, J. J. *et al.*, 2006). Thus, from the limited data available, the areas of the anterior parietal cortex of humans seem to be somatotopically organized in a manner that is similar to that described in monkeys.

Recently, we have started to compare the architectonic features of areas 3a, 3b, 1, and 2 of the anterior parietal cortex of macaque monkeys with those of areas in chimpanzees and humans. One reason to make these comparisons is to determine the extent to which the architectonic features of areas of the anterior parietal cortex vary across these primates, as structural differences may suggest functional differences. A second reason is to help resolve uncertainties about the boundaries of these areas in humans and chimpanzees. In macaques, the proposed boundaries of areas of the anterior parietal cortex are based on the results of studies of the anatomical connections, neuronal response properties, and somatotopic patterns of representation of the anterior parietal cortex. These results have been compatible with previously proposed boundaries of areas 3a and 3b, but, in our opinion, some depictions place the caudal boundary of area 1 too far caudally, and this is even more of a problem with area 2, which has often been shown extending caudally well onto the rostral bank of the intraparietal sulcus. These uncertainties reflect the fact that the architectonic borders of areas 1 and 2 are less obvious than those of area 3b and area 3a. However, the physiological data on somatotopy and neuron response properties and the data on area-specific connection patterns converge to clearly indicate where the caudal border of area 2, as a functional division of cortex, should be in macaques, and an architectonic change does take place at this location. The architectonic border between area 2 and area 5 (Pons, T. P. *et al.*, 1985; Pons, T. P. and Kaas, J. H., 1985) has recently been verified as conforming to a change in the response properties of neurons and somatotopy by Lewis J. W. *et al.* (1999).

As there are almost no data on connection patterns or somatotopy that would establish the significance of architectonic studies in chimpanzees, and very little in humans, consistent features of architectonic areas in macaques, chimpanzees, and humans allow architectonic criteria that have been validated in macaques to be applied to chimpanzees and humans (Figure 13).

Because of the supporting experimental data, the proposed architectonic subdivisions of the anterior parietal cortex of macaque monkeys serve as a standard for interpreting the architecture of the anterior parietal cortex in humans and chimpanzees. In all these primates, most of the anterior parietal cortex is buried in the central fissure, which is roughly 7 mm deep and 30 mm long in macaques, up to 10 mm deep and 65 mm long in chimps, and as much as 20 mm deep and 90 mm long in humans. Area 3b, which occupies much of the caudal bank of the central sulcus, is the most easily recognized subdivision of the anterior parietal cortex in all three primates. In Nissl-stained sections, area 3b of macaques is clearly distinguished from adjoining area 3a in the fundus of the central sulcus and area 1 near the top of the sulcus by a thick layer 4 that is densely packed with darkly

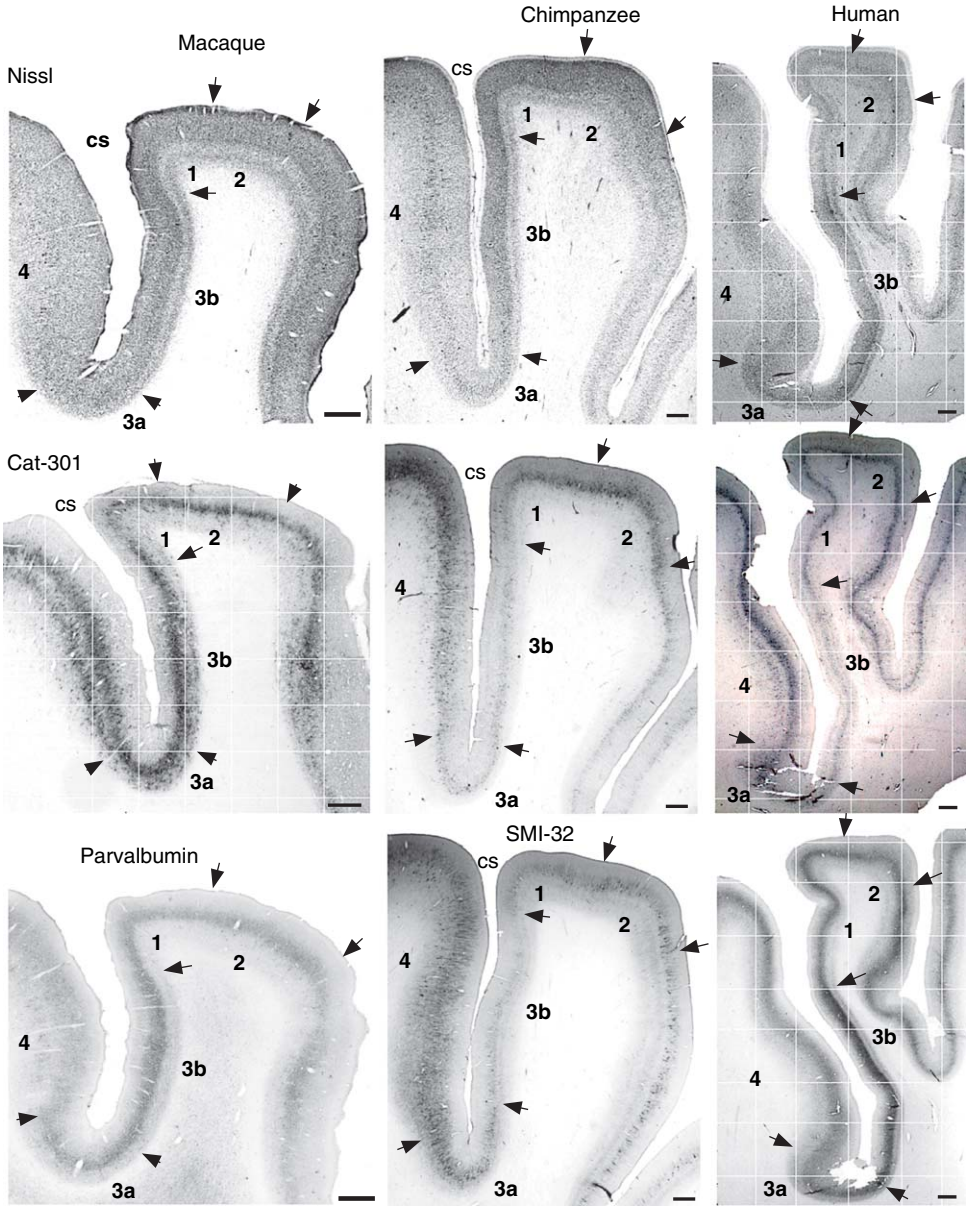

Figure 13 Some of the architectonic features of areas of the anterior parietal cortex of macaques, chimpanzees, and humans. In each column, a series of brain sections (see Figure 11) have been processed for cell bodies with a Nissl stain (top), the antigen for the Cat-301 antibody (middle), or the calcium-binding protein, parvalbumin (bottom, except for chimpanzee, where a section processed for SMI-32 has been substituted). The deep central sulcus (CS) is indicated, while the more caudal sulcus is the intraparietal sulcus. Arrows marking the boundaries of areas 4, 3a, 3b, 1, and 2 are indicated in a rostrocaudal sequence. Rostral is to the left. Scale bar = 1 mm. Unpublished illustration from Qi H-X. *et al.* (1997; 1998).

stained neurons. Layer 6 is also more darkly stained in area 3b than in adjoining areas. These same features mark area 3b of chimps and humans. These cytoarchitectonic features of area 3b are shown at higher magnifications in Figure 14, where the well-developed layer 4 is obvious. Lower-magnification photomicrographs are more useful in showing the pattern of change at the borders of areas. The monoclonal antibody, Cat-301, which is recognized by a proteoglycan antigen that is differentially expressed by different types of neurons (McKay, R. D. and Hockfield, S. J., 1982), has been useful in distinguishing some cortical areas, although not necessarily to the same extent or in the same way across species

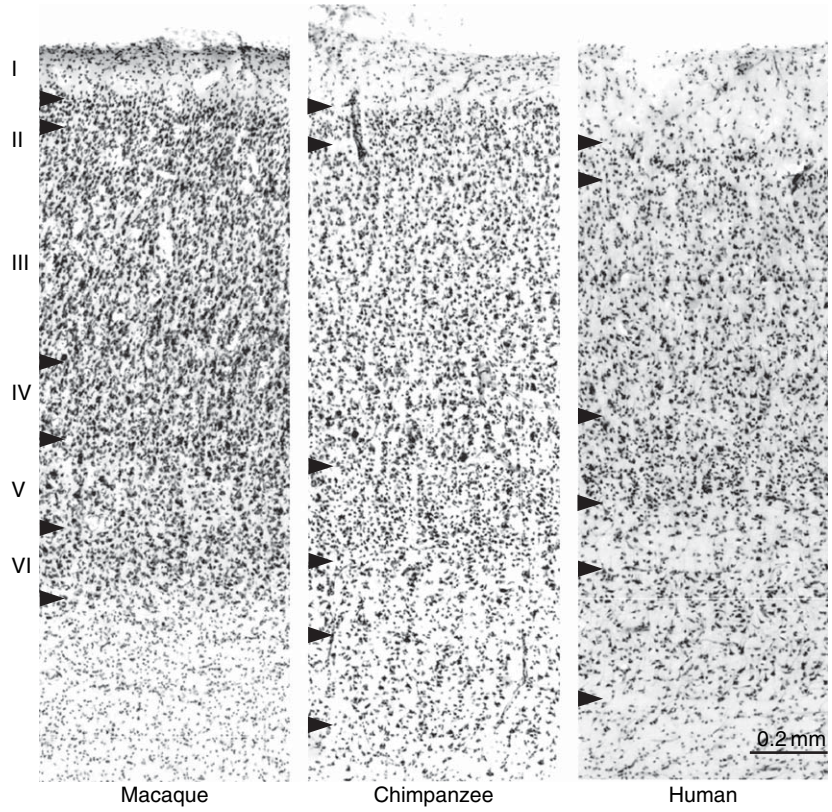

Figure 14 The cytoarchitecture of area 3b of a macaque, chimpanzee, and human at a higher magnification than that shown in Figure 13. Layers 1–6 (I–VI) are indicated. In each primate, a dense packing of small, darkly stained neurons in layer 4 is apparent.

(e.g., Jain, N. *et al.*, 1994). In our preparations, Cat-301 densely labeled layer 3 of area 3b of macaques, while layer 3 of area 1 was much less densely labeled (Figure 13). Layer 3 was also densely labeled in area 3a, thereby failing to clearly mark a 3a–3b border. In contrast, area 3b was not densely labeled by Cat-301 in chimps or humans, while area 1 expressed more of the antigen for Cat-301.

Immunostaining for the calcium-binding protein parvalbumin has also been used to reveal patterns of differential staining in the cortex of primates and has been very successful in demarcating primary sensory areas (e.g., Hackett, T. A. *et al.*, 1998). In area 3b of macaque monkeys, parvalbumin is densely expressed in layer 4 and inner layer 3 (Figure 13). Less parvalbumin is present in areas 1 and 3a. In chimps, the same pattern was present (Figure 15), but overall staining was not always as pronounced as in macaques. In humans the expression of parvalbumin in layer 4 and lower layer 3 was very dense in area 3b, and less dense in areas 1 and 3a. In sections processed for SMI-32 (only shown for chimpanzees; Figure 13; middle bottom; Figure 15, lower left), areas 3a and 3b can be clearly demarcated from area 4, and both the rostral and caudal borders of area 2 were apparent in all three primate species. Overall, area 3b is a very distinct area, and boundaries can be identified in several preparations, although the effectiveness of particular preparations can vary with the species, and with the state of the brain when processed.

Area 3a is also very distinct. In Nissl preparations, area 3a is characterized by a layer 4 that is less pronounced than in area 3b, but more developed than in the adjoining agranular motor cortex, area 4. Area 3a is not completely homogenous in appearance in Nissl preparations, but the significance of these variations is unknown (Jones, E. G. and Porter, R., 1980). Yet, the boundaries of area 3a are clear in macaques, chimps, and humans. In our Cat-301 preparations, the rostral border of area 3a with area 4 is very sharply marked in macaque monkeys, as neurons and neuropil are stained in a bilaminar pattern in area 4 that is not apparent in area 3a. In humans, the bilaminar pattern was weaker in area 4, but the border with area 3a was revealed by the

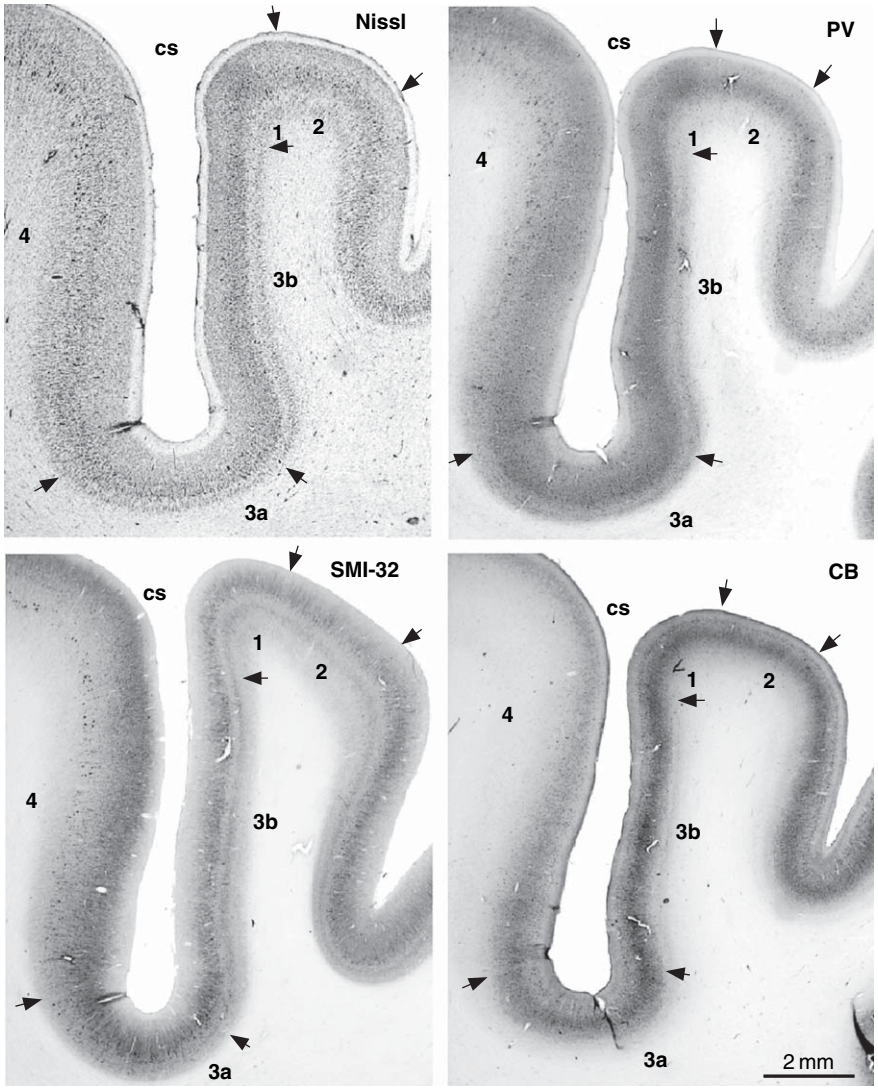

Figure 15 Photomicrographs of a series of adjacent parasagittal sections from the somatosensory cortex of a chimpanzee (case 95–93), illustrating the boundaries of areas 4, 3a, 3b, 1, and 2 in brain sections immunostained for calbindin, parvalbumin, or SMI-32 and a traditional Nissl stain for cell bodies. The deep central sulcus (CS) is indicated, while the more caudal sulcus is the intraparietal sulcus. Arrows mark the boundaries of areas 4, 3a, 3b, 1, and 2. Rostral is to the left. Scale bar = 2 mm. Unpublished illustration from Qi, H.-X., Jain, N., Preuss, T. M., and Kaas, J. H. 1997. Histochemical organization of somatosensory area 3b and surrounding cortex in chimpanzees. Soc. Neurosci. Abst. 23. Qi, H.-X., Jain, N., Preuss, T. M., and Kaas, J. H. 1998. Comparative architecture of areas 3a, 3b, and 1 of somatosensory cortex in chimpanzees, humans and macaques. Soc. Neurosci. Abst. 24, 1125.

denser expression of the Cat-301 antigen in layer 3 in area 4. In chimps, despite overall weak staining for the Cat-301 antigen (which has been noted in other cortical regions; Preuss, T. M. and Coleman, G. Q., 2002), it was still possible to detect the transition from the lighter staining of area 3a to the darker staining in area 4. As parvalbumin was more strongly expressed in layers 4 and 3 of area 3a than of area 4, this preparation also helped identify the rostral border of area 3a.

In Nissl preparations of area 1, layers 4 and 6 were less densely packed with neurons and less densely stained than in area 3b. In area 2, however, both of these layers were more pronounced, so that the border of area 1 with area 2 was reliably detected in macaques, chimps, and humans (Figures 13, 14, and 15). A similar change in appearance can be observed in brain sections processed for parvalbumin, which was more densely expressed in layer 4 and inner layer 3 of area 3b than

in area 1. Cat-301 preparations were also useful in delineating area 1, as area 2 expressed more of the antigen for Cat-301 than area 1 in all these primates, thereby marking the border of area 1 with area 2. The caudal border of area 2 with area 5 is not so obvious, and this has resulted in uncertainties and different opinions about where this border is located. However, patterns of somatotopic organization and connections with other areas and thalamic nuclei have helped to locate this border in macaques (Pons, T. P. *et al.*, 1985; Pons, T. P. and Kaas, J. H., 1985; 1986), and it corresponds in location in Old World monkeys to where the caudal boundary of area 2 was placed by Brodmann K. (1909), while others (e.g., Vogt, C. and Vogt, O., 1919 and Powell, T. P. and Mountcastle, V. B., 1959a; 1959b) placed the border further caudally in the rostral bank of the intraparietal sulcus. At the caudal border of area 2, cells in layers 4 and 6 became less darkly stained and less densely packed than in area 2 (Pons, T. P. *et al.*, 1985). The location of the physiological border in macaques also corresponds to a change in the laminar distribution of myelin and the neurofilament protein labeled by the SMI-32 antibody (Lewis, J. W. *et al.*, 1999). In chimps and humans, the border of area 2 with area 5 can be detected in similar fashion (Figures 13 and 15), although it is not always obvious. In sections processed for parvalbumin, the expression of parvalbumin in layer 4 and deeper layer 3 was somewhat less diffuse and more focused in area 2 than in area 5, providing some suggestion of a border. The Cat-301 preparations provided inconsistent results across these primates: chimpanzees exhibited stronger labeling of area 2 than of area 1, but the distinction between the areas was less clear in humans and macaques. The medial and lateral boundaries of area 2 have not been established (Lewis, J. W. *et al.*, 1999), but area 2 is generally depicted as extending along the full border of area 1.

Recent descriptions of the cytoarchitecture of the anterior parietal cortex of humans include those of Rademacher J. *et al.* (1993), White L. E. *et al.* (1997), and Geyer S. *et al.* (1999). The study of Geyer S. *et al.* (1999) is particularly noteworthy as it introduces an objective, observer-independent method of determining areal borders based on changes in Nissl-staining density profiles taken through the thickness of the cortex from pia to white matter. The results produced borders of areas 3a and 3b similar to those indicated in Figure 13(b), but area 1 was more extensive, including cortex onto the rostral bank of the postcentral sulcus, and area 2 was placed deep within the postcentral sulcus. Although the use of density profiles allows an objective determination of borders, the authors recognized that the classification (naming) of areas is an interpretation. In our view, area 1 was too extensive, and area 2 was misplaced in the study of Geyer S. *et al.* (1999). This supposition is supported by the results of a recent functional MRI study in humans that placed the systematic representation of the hand that characterizes area 3b on the caudal bank of the central sulcus, as expected, and the mirror image representation that denotes area 1 in the cortex extending from the upper part of the caudal bank of the central sulcus onto the crown of the postcentral gyrus (Blankenburg, F. *et al.*, 2003), similar to the extent of area 1 in Figure 13. This interpretation would also relocate the border of area 2 with area 1 to a more rostral position.

Differences in CO activity also have been used to characterize areas of the anterior parietal cortex in humans, as areas 3a and 3b have a darkly stained band in layer 4 and inner layer 3 that distinguishes these areas from areas 1 and 2 (Eskenasy, A. C. and Clark, S., 2000). In addition, Hilbig H. *et al.* (2001) have used a plant lectin, *Wisteria floribunda* agglutinin (WFA), which like Cat-301 is a marker of the proteoglycan-rich perineuronal nets, to distinguish area 3a from areas 3b and 4 in the human somatosensory cortex. Regional and laminar patterns in the distribution of neural receptors are also used to identify areas of the anterior parietal cortex in humans (.Geyer, S. *et al.*, 1997; Zilles, K. *et al.* 2002) and macaques (e.g., Huntsman, M. M. *et al.*, 1995). In humans, area 3b is associated with the expression of high levels of receptors for acetylcholine (muscarinic cholinergic M2 and nicotinic cholinergic receptors). These various architectonic approaches have the potential for revealing a number of other proposed divisions of the somatosensory cortex.

6.08.8 Architectonic Areas of Lateral and Posterior Parietal Cortex

Additional areas of the somatosensory cortex have been described and characterized architectonically in macaques and humans. These areas typically are difficult to distinguish from each other, so there are a number of uncertainties. Descriptions of the subdivisions and names of lateral and posterior parietal cortex vary across reports. In the lateral parietal cortex of macaques, where areas S2, PV, and VS are contained, Preuss T. M. and Goldman-Rakic P. S. (1989) described a large SII region that may include both S2 and PV. Jones E. G. and Burton H. (1976) and

Mesulam, M. M. and Mufson E. J. (1982) provide a similar description that includes a large SII, the retroinsular cortex, and granular, dysgranular, and agranular insular regions. Another region identified by Eickhoff S. B. *et al.* (2006a) may correspond to the parietal ventral area (Coq, J. O. *et al.*, 2004). A fourth architectonic region appears to correspond to the parieto-insular vestibular cortex of macaques (Eickhoff, S. B. *et al.*, 2006b). Other regions identified by Eickhoff S. B. *et al.* (2006b) and Eickhoff S. B. *et al.* (2007) may correspond to rostral and caudal divisions of the parietal ventral area (Coq, J. O. *et al.*, 2004).

The posterior parietal cortex of Old World monkeys, apes, and humans includes at least two major divisions, the caudal part being largely dominated by visual inputs and the rostral part by somatosensory and, to a lesser extent, auditory inputs (Lewis, J. W. and Van Essen, D. C., 2000; Kaas, J. H., 2004). The most significant outputs, in terms of sensorimotor function, are to motor and premotor areas of the frontal cortex. A number of alternative ways of subdividing the posterior parietal cortex have been proposed. Brodmann K. (1909) suggested a division into areas 5 and 7, and Vogt C. and Vogt O. (1919) subsequently divided these areas further, recognizing areas 5a, 5b, 7a, and 7b. More recent studies have proposed additional subdivisions, based either on Brodmann's nomenclature (e.g., the subdivisions of area 7 suggested by Cavada, C. and Goldman-Rakic, P. S., 1989, and by Preuss, T. M. and Goldman-Rakic, P. S., 1991a), or on extensions of von Economo's C. V.(1929) nomenclature (i.e., PE, PF, PFG, PG, Opt; see Pandya, D. N. and Seltzer, B., 1982). In addition, differences in connection patterns and physiological evidence, together with architectonic distinctions, have been used to divide the cortex of the intraparietal sulcus of macaque monkeys into medial (MIP), lateral (LIP), ventral (VIP), and anterior (AIP) areas, with MIP sometimes included in a larger parietal reach region (PRP) (see Lewis, J. W. and Van Essen, D. C., 2000; Kaas, J. H., 2004). Similar subdivisions have been proposed for the human posterior parietal cortex (e.g., Bremmer, F. *et al.*, 2001; Grefkes, C. *et al.*, 2002; .Simon, O. *et al.*, 2002), although there are uncertainties about how similar or different these regions are in humans and macaques (see Rushworth, M. F. *et al.*, 2001). While Brodmann K. (1909) argued that the inferior parietal lobule of humans contained areas (39 and 40) not found in monkey brains, several later investigations concluded that areas 39 and 40 are homologous to the inferior parietal lobe areas (areas 7b and 7a, respectively) of macaques (Bonin, G. and Bailey, P., 1947; Eidelberg, D. and Galaburda, A. M., 1984). In contrast, Zilles K. and Palomero-Gallagher N. (2001) concluded that area 7 of monkeys is not the same as area 7 of humans. Thus, considerable caution is needed in considering any view of how the posterior parietal cortex is subdivided into areas based on architecture or other types of data.

The difficulty in obtaining a reliable parcellation of the posterior parietal areas of macaque monkeys has been stressed by Lewis J. W. and Van Essen D. C. (2000), who illustrated six current partitioning schemes for this cortex, while they themselves charted 17 architectonic subdivisions in and near the intraparietal sulcus. These proposed subdivisions were characterized in terms of the density and laminar pattern of myelination and SMI-32 immunoreactivity. They denoted new areas as subdivisions of previously identified areas. Thus, LIP had ventral (LIPv) and dorsal (LIPd) subdivisions, while VIP had medial (VIPm) and lateral (VIPl) subdivisions. In the intraparietal cortex of humans, Zilles and coworkers (Choi, H. J. *et al.*, 2006) have recently identified two cytoarchitectonically different fields, human IP1 and IP2, that they propose correspond to VIP and AIP of monkeys.

6.08.9 Conclusions

1. Even small-brained mammals with little neocortex appear to have at least five areas of the somatosensory cortex, including a primary area S1, rostral (SR) and caudal (SC) somatosensory bands of cortex along the borders of S1, and the second (S2) and parietal ventral (PV) areas just lateral to S1. S1 is architectonically distinct in most histological preparations: S1 has a well-developed layer 4 that is densely packed with small neurons, although not to the same extent as in most anthropoid primates where this cortex (area 3b) is referred to as koniocortex because of the very small cells of layer 4. The bordering strips of the somatosensory cortex, SR and SC, have less distinct architectonic features, but they are easily distinguished from S1 and, if present, motor cortex. S1 is activated by cutaneous afferents via projections from the ventroposterior nucleus of the thalamus. Area SR is in the position of area 3a of primates, and may get proprioceptive information from the thalamus, in common with area 3a of primates. Area SC is in the position of area 1

or areas 1 plus 2 of primates. It is tempting to consider SC as a homologue of area 1 or of areas 1 and 2 combined, but the evidence for this is limited. S2 and PV resemble each other architectonically.

2. S1 of many mammals is not uniform in architectonic appearance, but instead is subdivided into patches or modules of granular cortex that receive dense inputs from the ventroposterior nucleus and express high levels of CO. These modules are separated by dysgranular cortex with low levels of CO. The narrow separation zones of dysgranular cortex separate the representations of distinct body parts in S1, such as the representations of individual mystacial vibrissae on the faces of rodents, where the CO-dense modules make up the so-called barrel field. Other types of isolating septa relating to somatotopic divisions are common. The isolated CO-dense, granular zones constitute one type of modular organization that is found in S1.
3. Many mammals have very little cortex that could be properly called posterior parietal cortex. This region of the cortex is greatly expanded in most anthropoid primates.
4. The somatosensory cortex of prosimian primates that have been examined has not been greatly modified from the pattern of organization commonly found in other mammals. SR clearly corresponds to area 3a of anthropoid primates, but the relationship of SC to areas 1 and 2 of anthropoid primates is still in question. The lateral parietal cortex includes one or more divisions of the ventral somatosensory area, VS, and there is evidence for a parietal rostral area, PR. A posterior parietal region is clearly present, and it is divided into a rostral region with connections with areas of the somatosensory and motor cortex, and a caudal region with visual inputs and projections to the rostral half of the posterior parietal cortex. Together, they presumably guide visuomotor behavior via connections with the primary motor cortex and premotor areas. The broad rostral and caudal regions of the posterior parietal cortex have functional subdivisions that have not been well defined.
5. New World monkeys differ from prosimians in that the posterior parietal cortex is usually more extensive, although functional subdivisions have not been well defined. In the anterior parietal cortex, an area 2 that represents both deep and cutaneous receptor is usually present (although not clearly so in marmosets and several other smaller New World monkeys). Areas 3a and 2 have been shown to receive proprioceptive information via projections from a distinct subdivision of the ventroposterior thalamus, the ventroposterior superior nucleus.
6. In both New World and Old World monkeys, dysgranular septa are often apparent that separate the face from the hand representations in area 3b (S1), digits from each other in the hand representation, and parts of the face, the tongue, and the teeth from each other in the face–mouth portion of area 3b. In addition, at least the hand representation of area 3b is divided into small territories or modules receiving either SA afferent activation or RA afferent activation from the ventroposterior nucleus. Thus, area 3b has modules that reflect somatotopic disjunctions and modules that reflect classes of activating neurons.
7. The anterior parietal cortex of Old World macaques, apes, and humans is divided into areas 3a, 3b, 1, and 2, with each of these areas being architectonically distinct. Other areas of the lateral and the posterior parietal cortex have been defined by architectonic and other criteria, but some of these areas, especially in the greatly expanded posterior parietal cortex, have not been well defined. However, a series of areas of the cortex of the intraparietal sulcus of macaques and humans are similar enough in relative position and functional roles to suggest that they are homologous.

Glossary

adenylate cyclase type I (AC1) Adenylate cyclases are enzymes that catalyze the conversion of ATP to cAMP and pyrophosphate. There are nine members of adenylate cyclases; AC1 is neuronal and is activated by glutamate. AC1 knockout mice, also known as barelless mice, fail to develop whisker-specific cellular aggregates, barrels, in their somatosensory cortex.

areal specification Division of the neocortical mantle into distinct functional and cytoarchitectural zones that represent various sensory and motor modalities and association areas. Both intrinsic and extrinsic molecular cues play a role in this specification during development. Neural activity plays a role in sharpening of the boundaries and specializations within them.

barrel cortex Region of the parietal cortex where layer IV cells form cylindrical, barrel-like modules that correspond to single whiskers, sinus hairs or receptor densities in the digits.

barreloids Whisker- and digit-specific neural modules that develop in the somatosensory thalamus.

cajal-retzius cells One of the earliest generated cells of the telencephalic vesicles that ultimately reside in layer I.

cortical maps Topographic representation of the sensory or motor periphery in specific neocortical areas.

dorsal column lemniscal and trigeminal pathways Axonal projections from the dorsal column nuclei *gracilis* and *cuneatus*, and from the brainstem trigeminal nuclei to the ventroposterolateral and ventroposteromedial nuclei of the thalamus, respectively. These inputs relay the somatic sensory information from the peripheral receptors and dorsal root ganglia and the trigeminal ganglion to the thalamus.

FGF 8 Fibroblast growth factor 8 FGFs are a family of growth factors involved in a variety of cellular and developmental processes. There are about 22 members of the FGF family.

GABA-ergic neurons Generally inhibitory interneurons that synthesize and release gamma-aminobutyric acid.

GAP-43 A 43kD growth-associated phosphoprotein involved in developmental and synaptic plasticity.

glutamate glutamic acid (Glu) A major excitatory neurotransmitter in the nervous system.

mGluR5 Metabotropic glutamate receptor subtype 5. Metaboptropic glutamate receptors are members of the C family of G-protein coupled receptors that bind glutamate.

MAOA Monoamine oxidase A. Monoamine oxidases catalyze the oxidation of monoamines. MAOA mainly breaks down serotonin and also other monoamines norepinephrine and epinephrine. *MAOA* knockout mice lack the gene that

encode MAOA, thus have increased brain serotonin levels.

NMDA receptor N-methyl d-aspartate receptor NMDAR is an ionotropic glutamate receptor. It is both voltage-dependent and ligand-gated. When the postsynaptic neuron is sufficiently depolarized, glutamate binding results in activation of NMDARs which then allow flow of Ca^{2+} ions. Calcium influx through NMDARs leads to intracellular signaling mechanisms that are thought to play a critical role in various forms of synaptic plasticity during development and at mature state.

serotonin 5-Hydroxytryptamine, or 5-HT a monoamine neurotransmitter synthesized by serotonergic neurons mostly located in the midbrain raphe nuclei. It has regulatory effects on excitatory neurotransmission in the mammalian brain.

somatosensory cortex Portions of the parietal cortex that receive primary and secondary ascending somatosensory inputs from the thalamus.

thalamocortical axons (TCAs) Axonal projections from various thalamic nuclei to predominantly layer IV of neocortex.

transcription factor Proteins that mediate RNA polymerase binding and initiation of transcription. These factors either stimulate or repress transcription of a specific gene.

ventricular zone Layer of proliferating cells along the ventricles of the telencephalic vesicles. These cells give rise to multiple layers of the neocortex, and different classes of neurons glia.

6.09.1 Introduction

In all mammals, the position of the somatosensory cortex (as are the cases with other primary sensory and motor cortices) is relatively constant, located within the parietal aspect of the cortical mantle. Areal specification of the somatosensory cortex (as well as other sensory-motor and association cortices), and the role of afferent innervation from the sensory thalamus in this process have been the focus of long-standing research. In late 1980s, results from a variety of experimental studies led to two contradicting hypotheses: The protomap and the protocortex (Rakic, P., 1988; O'Leary, D. D. M., 1989). Does the cortical ventricular zone impart its signature on areal specification of the neocortex (protomap), or do thalamocortical afferents (TCAs) claim specific territories and parcellate an otherwise a tabula rasa cortical sheet (protocortex)? Experiments involving lesioning of peripheral sensory receptor organs, before these inputs reach the sensory thalamus or genetic aberrations, that interfere with this connectivity lent support for the former, while observations on the whisker-specific patterning of the somatosensory cortex in mice with supernumerary whiskers, rerouting of sensory thalamic inputs to different cortical loci, or heterotopic neocortical transplants in newborn rodents lent support for the latter (reviewed in O'Leary, D. D. *et al.*, 1994). Since then, advanced technical tools in the fields of molecular genetics, *in vivo* imaging, and functional assays dissolved the dichotomous views. Areal specification of the neocortex and the positioning of the somatosensory cortex involve a cascade of molecular cues intrinsic to the developing cortical primordium. It is within this *tabula praeforma* engraved with multiple guidance cues, that TCAs find their proper targets and confer specificity and patterning through activity-dependent mechanisms.

6.09.2 Differentiation of the Somatosensory Cortex

6.09.2.1 Areal Specification

Regionalization or areal specification of the neocortex, and subsequent positioning of the primary somatosensory cortex, is a result of the coordinated action of secreted proteins from patterning centers and gradients of transcription factor expression in the ventricular zone, which eventually gives rise to the six-layered neocortex. The first clear indication of such intrinsic cues came from a transgenic mouse line, in which beta-galactosidase expression in the neocortex was largely restricted to the layer IV neurons of the somatosensory cortex, revealing a distinct body map with patterned whisker representations (Cohen-Tannoudji, M. *et al.*, 1994). Ectopic transplantation of embryonic parietal cortex from these mice further confirmed the intrinsic nature of the

transgene expression. In recent years, molecular identities of positioning cues have been emerging.

A striking example of this is the fibroblast growth factor (FGF) 8 secreted in the rostral pole of the cortical primordium, the commissural plate. Overexpression of FGF 8 by the commissural plate pushes the location of the somatosensory cortex caudally, soaking up endogenous FGF 8 by FGF receptors, or FGF 8 hypomorphism pulls it rostrally, and misexpression of FGF 8 caudally leads to duplication of the somatosensory cortical map in a mirror image (Fukuchi-Shimogori, T. and Grove, E. A., 2001; reviewed in Shimogori, T. and Grove, E. A., 2006). Curiously, the duplicated barrel cortex seems to attract branches of TCAs destined for the primary barrel cortex (Shimogori, T. and Grove, E. A., 2005). Other factors such as Wnt3a, Wnt8b, bone morphogenetic proteins (BMPs), and sonic hedgehog (Shh) are secreted along the telencephalic vesicles (Sur, M. and Rubenstein, J. L. R., 2005; Rash, B. G. and Grove, E. A., 2006), indicating a highly orchestrated signaling from multiple patterning centers that play a role in allocation of specific territories to the somatosensory and other primary sensory and motor cortical areas (Figure 1).

Several genes encoding transcription factors (e.g., Foxg1, COUPTF1, Emx2, Lef1, Lhx2, Pax6) are expressed in gradients along the rostracaudal and mediolateral axes of the developing cortical mantle, and they regulate neurogenesis, proliferation, migration and survival of neurons, and possibly axon guidance during wiring of the cortex (Sur, M. and Rubenstein, J. L. R., 2005; Pratt, T. and Price, D., 2006; Shimogori, T. and Grove, E. A., 2006). Potential consequence of secreted molecules from patterning centers described above could be in the patterning of the graded expression of transcription factors, and subsequent parcellation of the cortical sheet.

Targeted deletions of the homeodomain-containing transcription factors *Emx2* and *Pax6* in mice revealed some clues. In the embryonic mouse cortex, Emx2 is expressed along a caudal to rostral gradient (complementary to that of FGF 8 expression), and Pax6 expression follows a rostral to caudal gradient. *Emx2* knockout mice display a compression of caudal cortical areas and expansion of rostral areas such as the somatosensory and motor cortices (Bishop, K. M. *et al.*, 2000; Mallamaci, A. *et al.*, 2000), while *Pax6* knockout mice, or transgenic mice over-expressing Emx2

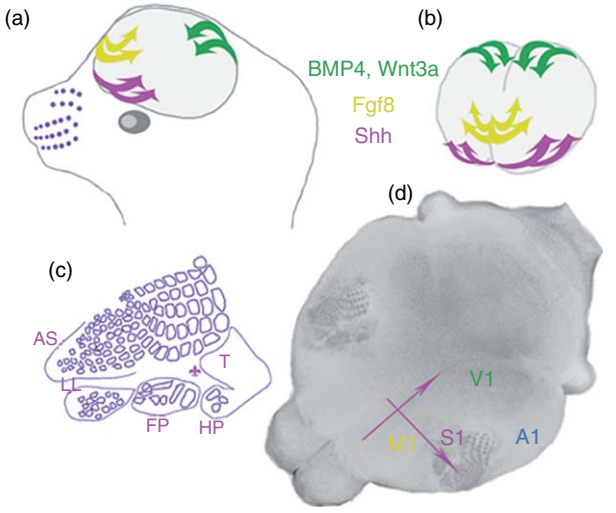

Figure 1 Regionalization and areal specification of the neocortex. Graded expression of transcription factors and secreted proteins from signaling centers help position sensory maps. (a) and (b) side and frontal views of the embryonic telencephalic vesicles with signaling centers expressing BMP4, Wnt3, Fgf8, and Shh. (c) and (d) illustrate parcellation of the somatosensory body map and its relative position with respect to other primary sensory coprtical areas such as visual (V1), auditory (A1), and primary motor cortex (M1). It is within this molecular regionalization that subcortical cues direct the space claimed by different thalamic nuclei resulting in areal specification of the neocortex. Experimental manipulations of the expression of a variety of proteins and transcription factors can alter the relative position and size of the sensory cortical parcels along the rostrocaudal and mediolateral axes. In the somatosensory map cartoon illustrated in **C**: AS: anterior snout, LL: lower lip, FP: fore paw, HP: hind paw, and T: trunk representation areas.

caudally display reduced somatosensory and motor cortical areas and expansion of caudal visual cortical and possibly auditory cortical areas (Bishop, K. M. *et al.*, 2000; Mallamaci, A. *et al.*, 2000; Hamasaki, T. *et al.*, 2004). Unaltered expression of FGF 8 but altered expression of Pax6 in Emx2 over-expressing cortex suggest that Emx2 action in cortical arealization is independent of FGF 8 action, but might take place by repressing *Pax6* expression (Hamasaki, T. *et al.*, 2004). An earlier study, employing electroporation-mediated gene transfer *in utero,* noted that over-expressing *Emx2* altered the cortical area map when ectopic Emx2 overlapped with the FGF 8 source (Fukuchi-Shimogori, T. and Grove, E. A., 2003). In addition, FGF 8 levels were decreased by excess Emx2, and increased in *Emx2* knockout mice. Thus, FGF 8 and Emx2 may act independently or in cooperation.

Clearly, overall positioning of different cortical areas, and the space allocated to each are determined by secreted proteins from patterning centers and graded expression of transcription factors (reviewed in Pratt, T. and Price, D., 2006; Rash, B. G. and Grove, E. A., 2006). On the other hand, patterning within sensory maps can be altered without affecting expression of positional markers or conversely, can occur in their absence. For example, while various manipulations of FGF 8 expression have been shown to shift the positioning of the somatosensory cortex (even duplication of it), whisker-specific patterning within the face representation area of the body map still develops. Another recent example is unaltered expression of primary sensory cortex layer-specific molecular markers Cux-1 and Cux2 (orthologues of the Drosophila homeobox *Cut* gene) in layer IV of barrel-defective mouse strains (Ferrere, A. *et al.*, 2006).

6.09.2.2 Laminar Specification

As in other primary sensory areas, the somatosensory cortex is characterized by six laminae with distinct cytoarchitecture and connectivity patterns (Figure 2). Glutamatergic neurons of the subplate and layers VI to II are produced sequentially in an inside-out fashion by the progenitors along the ventricular zone. Gamma-aminobutyric acid-(GABA)-ergic interneurons are mostly produced by the subcortical progenitors along the ganglionic eminence and migrate into the neocortex (Parnavelas, J. G. *et al.*, 2002). Cajal-Retzius cells of layer 1, which are generated about the same time as subplate neurons, are produced in the dorsal-most ventricular zone of the cortical anlage. Layer VI cells send projections to the thalamus; layer V cells project to subcortical targets such as the basal ganglia, midbrain, and brainstem. Layer IV cells receive projections from the thalamus and project to upper cortical layers. Layers II and III house neurons that project to other cortical areas (reviewed in Marin, O. and Rubenstein, J. L., 2003). Molecular specification of cortical laminar identity has been suspected for a long time, beginning with *in vitro* studies employing cocultures of thalamus and cortex or other targets of cortical cells (reviewed in Bolz, J., 1994). In cocultures of the developing neocortex with a variety of afferent–efferent sources, incoming fibers and cortical projection neurons establish layer-specific connectivity. Recent studies have begun to address molecular profiling of specific subsets of neurons that reside in different layers such as corticospinal projection neurons of Layer V and glutamatergic neurons of Layer IV (Arlotta, P., *et al.*, 2005; Ferrere, A. *et al.*, 2006) (Figure 2).

Thalamocortical axons have a specific affinity for Layer IV neurons (reviewed in Yamamoto, N. *et al.*, 2006). Whether in cocultures of thalamic neurons seeded on a cortical sheet (Emerling, D. E. and Lander, A. D., 1994), in explant cocultures of thalamus and cortex (Bolz, J., 1994), or in Reeler mouse with an inverted cortical lamination due to migration defects, TCAs seek layer IV neurons and terminate there (López-Bendito, G. and Molnár, Z., 2002). Membrane carpet assays have also indicated the presence of a stop signal in Layer IV (Castellani, V. and Bolz, J., 1997). A number of studies suggest that cell adhesion molecules such as N-cadherin (Poskanzer, K. *et al.*, 2003); neurotrophins BDNF and NT-3 (Yamamoto, N. and Hanamura, K., 2005), axon guidance molecules, such as Ephrins (Vanderhaeghen, P. and Polleux, F., 2004), as well as NMDA receptor-mediated signaling from postsynaptic cells (Lee, L. J. *et al.*, 2005) play a role in layer-specific terminations of TCAs (also reviewed in López-Bendito, G. and Molnár, Z., 2002; Polleux, F., 2005; Molnár, Z. *et al.*, 2006). Clearly multiple signals must act cooperatively in layer-specific targeting of TCAs.

6.09.3 Development of Thalamocortical Projections

6.09.3.1 Thalamocortical Axon Guidance

Motor and specific sensory (somatosensory, auditory and visual) thalamic nuclei are roughly aligned along the rostrocaudal axis of the developing dorsal

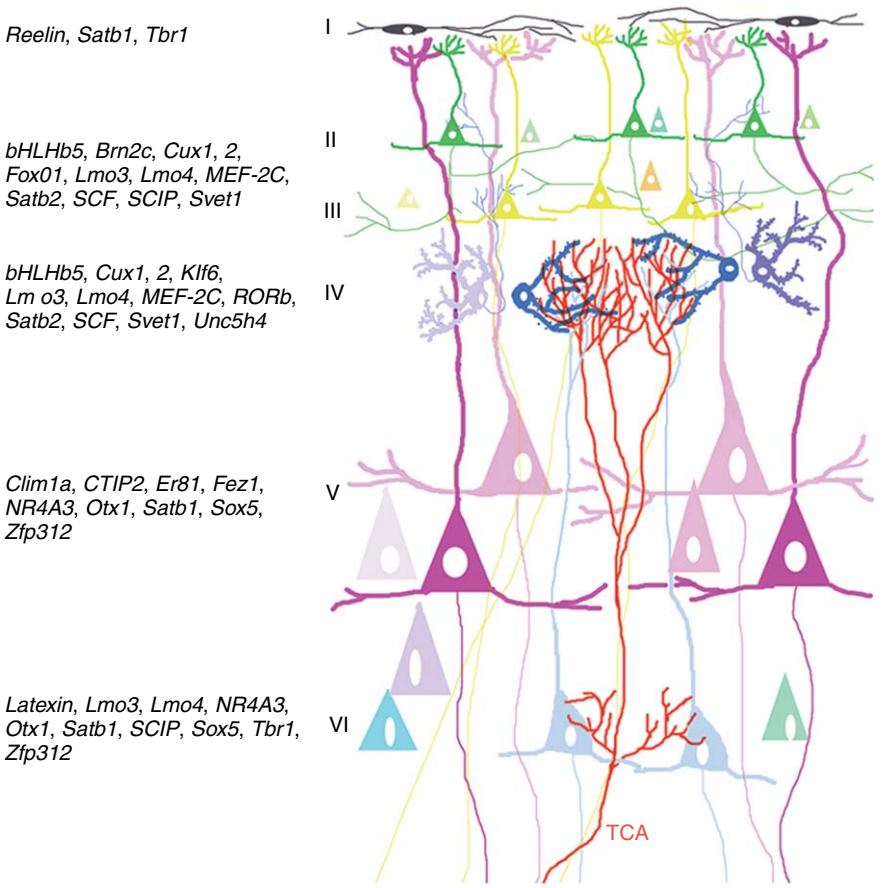

Figure 2 Layer- and cell type-specific genetic markers and lamination of the somatosensory cortex. During late embryonic development, the six-layered sensory cortex is generated in an inside out fashion. Overall, each cortical lamina is comprised of cells that receive specific inputs and project to distinct cortical or subcortical targets. In the rodent primary somatosensory cortex, whisker-specific thalamocortical afferents (TCAs) form discrete clusters that replicate the patterned array of whiskers on the contralateral snout. Their primary postsynaptic partners, layer IV spiny stellate cells, orient their dendrites towards these presynaptic terminal clusters, and their cell bodies form cylindrical aggregate, the barrels. In recent years, increasing numbers of molecular cues, genes, and transcription factors have been associated with specific cortical laminae, and subclasses of cells within each lamina; some are indicated on the left of the diagram (compiled from (Arimatsu *et al.*, 1999; Arlotta, P. *et al.*, 2005; Bulchand *et al.*, 2003; Chen *et al.*, 2005; Ferrere, A. *et al.*, 2006; Frantz *et al.*, 1994; Hevner *et al.*, 2003; Molyneaux *et al.*, 2005; Nieto *et al.*, 2004; Tarabykin *et al.*, 2001; Weimann *et al.*, 1999; Yoneshima *et al.*, 2006; Zhong *et al.*, 2004; Zimmer *et al.*, 2004.)

thalamus. Projections from each of these nuclei follow stereotypic routes to the neocortex where they colonize well-delineated territories along a similar axis. Several axon guidance cues, in particular ephrins and their receptors, are expressed in a graded fashion and in complementary patterns in the dorsal thalamus and neocortex, suggesting a role for these molecules in interareal topography formation between the thalamus and cortex (reviewed in Marin, O., 2003; Uziel, D. *et al.*, 2006). It has also been suggested that as the developing TCAs and corticothalamic axons (CTAs) meet in the internal capsule, axon–axon interactions guide the reciprocal topographic projections (the handshake hypothesis of Molnár, Z. and Blakemore, C., 1995; Molnár, Z. *et al.*, 1998).

Evidence from a variety of mutant mice is consistent with this hypothesis. For example, in the absence of transcription factors Tbr1, Gbx2, Pax6, or Emx2 (which pattern the cortex or thalamus), TCA and CTA axon pathfinding is disrupted (reviewed in Molnár, Z. *et al.*, 2006).

More recent studies, however, have underscored the role of positional cues such as graded expression of ephrins in the ventral telencephalon in guidance of TCAs (reviewed in Garel, S. and Rubenstein, J. L.,

2004; Polleux, F., 2005; Uziel, D. *et al.*, 2006). While EphA/ephrin-A signaling in the target tissue guides reciprocal TCA and CTA projections, it does not appear to be interdependent as predicted by the handshake hypothesis (Tori, M. and Levitt, P., 2006).

6.09.3.2 Arrival of Thalamocortical and Other Afferents to the Somatosensory Cortex

The primary somatosensory cortex receives inputs from a variety of sources, such as the somatosensory thalamus (glutamatergic inputs), serotonergic projections from the midbrain raphé nuclei, noradrenergic projections from locus coeruleus (D'Amato, R. J. *et al.*, 1987; Bennett-Clarke, C. A. *et al.*, 1991; Simpson, K. L., *et al.*, 2006). Afferents from the dorsal thalamus, as well as raphé cortical projections, show patterning in the barrel cortex. Noradrenergic inputs are not patterned according to cytoarchitectural landmarks.

Immunohistochemical localization of serotonin (5-HT) combined with autoradiographic imaging of serotonin-uptake sites in the neonatal rat somatosensory cortex showed a transient, dense, serotonergic innervation with dense patches over the cortical barrels (D'Amato, R.J. *et al.*, 1987).

Later studies confirmed the origin of these terminal patches from the raphé nuclei and raised the possibility that serotonergic inputs may aid TCAs in barrel-specific patterning. A dual labeling study with lipophilic tracers in fixed embryonic brains showed that thalamic afferents arrive in the somatosensory cortex well ahead of those projections from the raphé nuclei (Erzurumlu, R. S. and Jhaveri, S., 1992). Thus, it became apparent that TCAs are the first corticopetal projections to arrive in the somatosensory cortex and confer periphery-related patterns (Erzurumlu, R. S. and Jhaveri, S., 1990, 1992). Double labeling experiments further demonstrated that the patterning of TCAs in the rodent somatosensory cortex precedes other afferent terminals and extracellular matrix patterning seen in the developing barrel cortex (Blue, M. E. *et al.*, 1991; Jhaveri, S. *et al.*, 1991).

In mice, TCAs reach the somatosensory cortex after embryonic day 15, and begin probing the developing cortical plate by E18. Topographically organized TCAs invade the cortical plate by birth (gestation 19 days), as simple axons with very few branches (Senft, S. L. and Woolsey, T. A., 1991; Rebsam, A. *et al.*, 2002; Lee, L. J., *et al.*, 2005). Two days later, focalized terminal branches can be seen in layer IV and to a lesser extent in layer VI. Very few branches are seen in other layers. Developing TCAs can be visualized *en masse* by immunostaining for markers such as serotonin transporter. This approach allows for detection of emergence of the entire body map from a diffuse projection to partitioning of it into hindpaw and forepaw (lemniscal afferents) representation zones, lower lip and mystacial vibrissae representation zones (the posteromedial barrel subfield, and the representation area of the anterior snout with small sinus hairs. Once the body map is partitioned into these subterritories on postnatal day 2, further patterning into whisker-related rows (postnatal day 3), and between postnatal days 35 sensory periphery-related patterning, that is, patchy distribution of TCAs emerge (Rebsam, A. *et al*, 2002; Rebsam, A. and Gaspar, P., 2006) (Figure 3). As barreloids (whisker- and digit-specific neural modules) develop in the thalamus, TCA terminal fields and arbors in the cortex partition into Gaussian patches (Senft, S. L. and Woolsey, T. A., 1991), before the barrels appear as cellular modules (Figure 3). From postnatal day 5 onwards, selective pruning of overshooting collaterals, addition of more branches within focalized fields take place and TCAs consolidate their focal terminal arbors in layer IV with fewer terminal arbors in layer VI. Bifurcation points of axon arbors and terminal tips are mostly distributed in layer IV (about 75–80% of the total number), with some in layer VI (10–15%) (Lee, L. J. *et al.*, 2005).

6.09.3.3 Patterning of Afferent Projections

6.09.3.3.1 Positional cues underlying topography

The current understanding is that the general topography of TCA projections (as other axonal links along the subcortical somatosensory pathways) is established via gene expression gradients and chemoattractive and repulsive cues present along the route of the TCAs, as well as in their targets (reviewed in López-Bendito, G. and Molnár, Z., 2002; Molnár, Z. *et al.*, 2006). For example, ephrins and their Eph receptors have been implicated in topographic alignment of TCAs in the barrel cortex, as well as their topographic positioning along the ventral telencephalon (reviewed in Marin, O., 2003; Vanderhaeghen, P. and Polleux, F., 2004; Polleux, F., 2005). Developing TCAs also express high levels of the growth-associated phosphoprotein GAP43 (Erzurumlu, R. S. *et al.*, 1990). In *GAP43* knockout mice, TCA topography is disrupted, and TCA

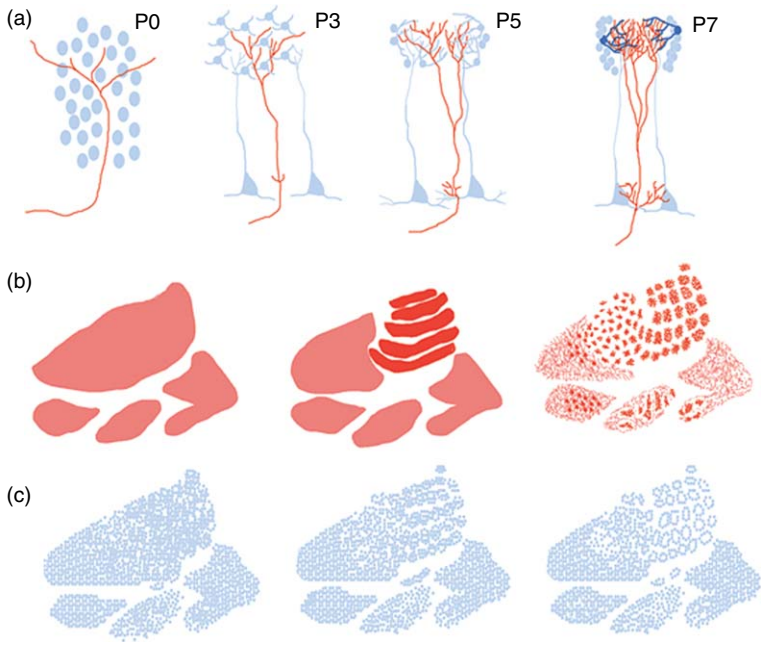

Figure 3 Development of thalamocortical axons (TCAs) projections to the barrel cortex and patterning of the somatosensory map. (a) Between postnatal days 0 and 7, TCAs develop focalized terminal arbors in layer IV and layer IV spiny stellate cells orient their dendrites toward these terminal clusters forming the barrels. (b) Cartoons illustrating emergence of first the body map, then the rows representing whiskers, and finally the patterning between P0 and P5. (c) Cellular organization in layer IV as routinely seen in tangential sections of the flattened cortex between P0 and P5.

terminals form aberrant patches (Maier, D. L. *et al.*, 1999). However, since these mice also have disrupted serotonergic projections to the neocortex (Donovan, S. L. *et al.*, 2002) it is not clear to what extent absence of GAP-43 in TCAs alone contribute to the barrel cortex phenotype. Once the molecular cues help guide and shape TCA topography, neural activity-mediated mechanisms play a major role in patterning of neural connections and consolidation of synapses in the somatosensory cortex.

6.09.3.3.2 Role of neuronal activity in patterning of the somatosensory cortex

Glutamatergic transmission and its regulation by serotonin in the early postnatal somatosensory cortex are key players in patterning of pre- and postsynaptic elements (reviewed in Erzurumlu, R. S. and Kind, P. C., 2001; Gaspar, P. *et al.*, 2003). Knockout mice with disrupted glutamatergic synaptic transmission (Iwasato, T. *et al.*, 1997, 2000; Hannan, A. J. *et al.*, 1998; 2001; Erzurumlu, R. S. and Iwasato, T., 2006), serotonergic modulation of presynaptic activity (Cases, O. *et al.*, 1996; Vitalis, T. *et al.*, 1998; Salichon, N. *et al.*, 2001; Rebsam, A. and Gaspar, P., 2006), downstream signaling molecules (Welker, E. *et al.*, 1996; Abdel-Majid, R. M. *et al.*, 1998; Hannan, A. J. *et al.*, 2001), all show abnormal patterning of the primary somatosensory cortex (Figure 4).

NMDA receptors have been shown to play a significant role in the patterning of body maps all along the murine somatosensory pathway leading to the somatosensory cortex (reviewed in Erzurumlu, R. S. and Iwasato, T., 2006). Recent evidence also indicates that NMDA receptor-mediated signaling is involved in parcellation of body map subdivisions (Lee, L. J. and Erzurumlu, R. S., 2005). In transgenic mice with low levels of *NR1* (the essential subunit of NMDAR), expression along the trigeminal pathway, subcortical and cortical face representation areas are reduced. Cortex-specific *NMDAR1* knockout (Cx*NR1*ko) mice show distinct somatosensory cortical defects. These mice fail to develop barrels as cellular modules and asymmetrical dendritic orientation of normal barrel cells is absent (Iwasato, T. *et al.*, 2000; Datwani, A. *et al.*, 2002). In these mutants, TCAs, corresponding to large whiskers develop small, faint patches as seen with histochemical and immunohistochemical markers. Single axon analyses between postnatal days 1–7 (Lee. L. J. *et al.*, 2005) revealed that in the somatosensory cortex without functional

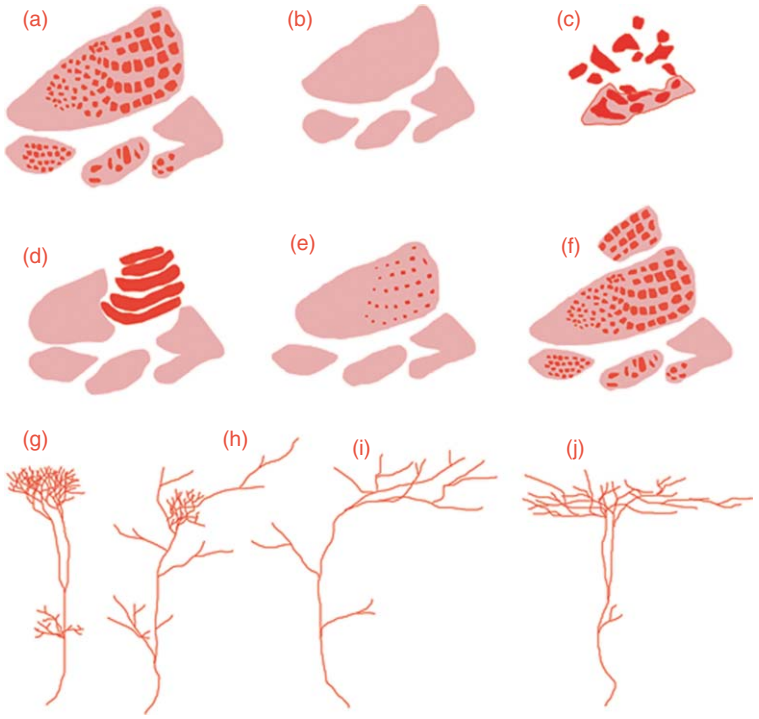

Figure 4 Examples of aberrant barrel cortex phenotypes in mutant or experimentally altered mice. (a). Normal body map and patterning of TCAs within it. In most mutants depicted in this cartoon there is no cellular patterning. In *PLCβ1* and *PKARIIβ* (protein kinase A IIβ subunit) knockout mice, TCAs form patterns similar to normal but there is no cellular (barrel) patterning (Hannan, A. J. *et al.*, 1998; Watson *et al.*, 2006) or there is partial patterning (Inan *et al.*, 2006). Body map can be discerned without the patterning of TCA projections (b) in *MAOA* knockout and barrelless (*Ac1* knockout) mice (Cases *et al.*, 1996; Abdel-Majid, R. M. *et al.*, 1998). In *GAP-43* knockout mice (Maier, D. L. *et al.*, 1999), there is no cellular patterning and TCAs form aberrant clusters, which can also be visualized with other histochemical markers (c). (d) In some mutants, without barrels, TCA projections into rows can be detected as in *MgluR5* and *Syngap* (Synaptic RAS GTPase activating protein) knockout mice (Hannan, A. J. *et al.*, 2001; Barnett, M. W. *et al.*, 2006b). (e) In Cx*NR1* knockout mice, there are small patches of clustered TCAs in the large whisker representation area (Iwasato, T. *et al.*, 2000; Lee, L. J. *et al.*, 2005). (f) Ectopic expression of Fgf8 in caudal cortex leads to partial duplication of the large whiskers (Fukuchi-Shimogori, T. and Grove, E. A. 2001). So far, single axon terminals have been examined only in a few of these mutants. (g-j). Stylized illustrations of single axons and their terminals. (g) An example of a normal TCA in P5 mouse cortex. (h) In Cx*NR1* knockout mice, TCA terminals are widespread with small focalizations in layer IV. TCAs are widespread without any patterning in *MAOA* (i) and spread out in layer IV in *AC1* (j) knockout mice.

NMDARs in excitatory cell, TCAs initially target proper cortical layers and begin arborization similar to that seen in controls. However, over time, these axons develop exuberant arbors in multiple cortical layers and fail to focalize within layer IV. In addition, their arbors are wider along the mediolateral extent. Despite these large arbors, zones of terminal condensations are seen in layer IV, which correspond to the rudimentary patterning seen with histochemical and immunohistochemical markers. Defects similar to those of Cx*NR1*ko mice are also observed in metabotropic glutamate receptor, *mGluR5* knockout mice (Hannan, A. J. *et al.*, 2001; Barnett, M. W. *et al.*, 2006a), which display segregation of TCAs representing large whiskers into rows but not individual whisker-specific patches within rows, and completely lack cellular, barrel organization. Loss of barrels indicates that mGluR5 signaling is critical for the normal development and transfer of patterns from TCAs to their postsynaptic partners. These results suggest that NMDARs and mGluR5 act synergistically during pattern formation.

Presynaptic, and subsequently postsynaptic, pattern defects in the barrel cortex can also be seen following disruption of the cortical serotonin levels which regulate glutamatergic transmission from TCAs (Rebsam, A. and Gaspar, P., 2006). *In vitro* recordings from thalamocortical slices indicate that 5-HT has a strong presynaptic inhibitory effect on glutamatergic transmission between TCAs and barrel

cortex cells via the activation of 5-HT1B receptors (Rhoades, R. W. *et al.*, 1994; Laurent, A. *et al.*, 2002). Developing TCAs express serotonin 1B (5HT-1B) receptors, serotonin transporters and autoregulate their glutamatergic transmission via presynaptic mechanisms using 5-HT present in their target field (Gaspar, P. *et al.*, 2003). In monoamine oxidase A (*MAOA*) knockout mice, excess brain serotonin levels prevent segregation of TCAs in the barrel cortex and subsequently formation of barrels as cellular entities (Cases, O. *et al.*, 1996; Vitalis, T. *et al.*, 1998; Gaspar, P. *et al.*, 2003). This defect can be corrected both at the pre- and postsynaptic levels by treatment with para-chlorophenylalanine (PCPA), which reduces excess serotonin levels in *MAOA* knockout mice (Rebsam *et al.*, 2005) or by genetic deletion of 5HT1B receptors (Salichon *et al.*, 2001). Rebsam *et al.* (2002) described the development of barrel patterns and TCA arbors in *MAOA* knockout and *MAOA/5-HT1B* receptor double knockout mice. In both of these phenotypes, TCAs target the barrel cortex and appropriate cortical laminae by P1 as in normal mice. At P7, however, a significant reduction of terminal branches in layer IV and an increase in the mediolateral span of TCA arbors become apparent in *MAOA* knockout mice. In contrast, these defects were not seen in double knockout animals. Presently, the specific roles of serotonin in the patterning and plasticity of the barrel cortex are not clear. While excess cortical serotonin prevents formation of barrel patterns, significant pharmacological reductions of cortical serotonin in neonatal rodents does not affect the TCA patterning and barrel formation, except for a delay of 1 day in the emergence of patterns (Blue, M. E. et al., 1991). Similarly, delaying the emergence of barrel patterns by a combination of genetic and pharmacological approach also does not change the time course of the critical period plasticity following neonatal whisker lesions in mice (Rebsam, A. et al., 2005).

6.09.3.3.3 Intracellular signaling pathways

Intracellular signaling pathways downstream from glutamatergic signaling and regulation by serotonin, which lead to communication between pre- and postsynaptic elements, leading to distinct neural patterns in the barrel cortex, are emerging (reviewed in Barnett *et al.*, 2006a; Rebsam and Gaspar, 2006). A spontaneous mutation with absent barrel phenotype was noted in 1996 (Welker *et al.*, 1996). These mice termed barrelless exhibited normal laminar and topographic distribution of TCAs, but the overall thalamocortical projection field was larger, much like that seen in *MAOA* knockout mice. The mutation was later identified as the adenylate cyclase type I (*AC1*) gene (Abdel-Majid, R. M. *et al.*, 1998). While there are several members of adenylate cyclases, AC1 is exclusively neuronal and is activated by glutamate, NMDA receptor stimulation, and voltage-gated calcium channels. This membrane-bound enzyme regulates production of cAMP and protein kinase A (PKA) in response to calcium entry. Presence of AC1, both at the pre- and postsynaptic sites, has made it difficult to pinpoint whether TCA and barrel defects seen in AC1 knockout mice arise from pre- or postsynaptic effects. Other mutant mice relevant to intracellular signaling molecules include phospholipase C-β1 (*PLC-β1*) knockout mice, which exhibit barrel cortex defects (Hannan *et al.*, 2001). Phospholipase C (PLC) subtypes beta, gamma, and delta are activated by cell surface receptors. These phosphodiasterases hydrolyze lipid phosphatidylinositol 4,5-bisphosphate [PI(4,5)P2], generating inositol 1,4,5-trisphosphate (InsP3), a calcium-mobilizer from internal stores, and diacylglycerol (DAG), an activator of protein kinase C (Rebecchi and Pentyala, 2000; Rhee S.G. 2001). PLC-β1 class of phospholipases are downstream from synaptic activity, hence a role in activity-dependent refinement and patterning in the barrel cortex. SynGAP, a synaptic Ras GTPase activating protein also appears to be essential in patterning of the somatosensory thalamocortical projections. Examination of the *SynGAP* knockout mouse phenotype revealed that somatosensory thalamic patterning as well as TCA patterning is impaired and barrels failed to form (Barnett *et al.*, 2006b). Collectively, all of these experimental findings reveal multifaceted role of neural activity in patterning connections within topographically organized sensory maps in the brain, in particular in the somatosensory cortex. Targeted gene mutations or experimental alterations will undoubtedly reveal many if not all the key players of developmental mechanisms underlying somatosensory cortical differentiation and patterning.

Glossary

acallosal A neural pathway that does not project to the contralateral hemisphere and does not receive inputs via the corpus callosum. Such a region can be determined in studies of callosal connections by noting an absence of callosally projecting axon terminals in an otherwise terminal-rich area.

analogous A structure that has the same function. An analogous structure need not be homologous.

callosal A neural pathway that projects to the contralateral hemisphere via the corpus callosum. A callosal zone refers to a region of the cortex that receives inputs via the corpus callosum.

caudal Anatomical location – toward the tail.

contralateral A relative term referring to the opposite side of the brain or body.

deep receptors Peripheral receptor in the skin, muscles, or joints.

extrastriate Visual cortex that does not include V1 (striate cortex).

glabrous Regions of the skin lacking hairs, e.g., the pads of hands and feet.

homologous A structure that is inherited from a common ancestor. A homologous structure is not always analogous.

interdigitate To interweave two or more structures.

lateral Anatomical location – away from the midline of the brain or body.

medial Anatomical location – toward the midline of the brain or body.

myelin A material composed of lipids and lipoproteins that surrounds certain axons and functions as an electrical insulator. Myelin stains are often used to demarcate cortical areas and thalamic nuclei.

optokinetic Movement of the eyes when a moving visual stimulus is viewed.
rapidly adapting receptor A mechanoreceptor that responds to the initial presentation of a stimulus but stops responding or reduces its firing rate throughout the presentation of a sustained stimulus.
rostral Anatomical location – toward the rostrum or snout.
slowly adapting receptor A mechanoreceptor that responds throughout the presentation of a sustained stimulus.
topographic organization A feature of cortical organization in which adjacent points within a cortical field represent adjacent points on the sensory epithelium.
vibrissae Whiskers and/or stiff hair located on the face of an animal that often function as a tactile organ.

6.10.1 Introduction

Anthropocentric /, anθrəpəˈsɛntrik/*a.* M19. [f. prec. + CENTRIC] Centering in humans; regarding humanity as the central fact of the universe (*The New Shorter Oxford English Dictionary*).

As a beginning for a review on areas of the primate brain involved in generating frames of reference and ultimately a sense of self, the definition of anthropocentrism may seem misplaced. Yet anthropocentrism is, paradoxically, central to this scientific endeavor: our fascination with ourselves is simultaneously the driving force behind our desire to understand biological organisms and the activities they generate (including anthropocentrism itself) and probably the largest stumbling block to achieve an objective understanding. That we are anthropocentric is without question. Indeed, when not actually pursuing activities necessary for our literal survival, we spend the majority of our time pursuing an understanding of ourselves. We strive to understand our uniqueness, our past, our future, how we behave together, how we behave individually, how we think, how we expend our resources, and how to determine if there is any other sentient being out there like us. These pursuits encompass a variety of disciplines such as psychology, sociology, philosophy, anthropology, history, and economics, to name a few. All of these disciplines are based on the premise that humans are radically different from other animals – that we abide by a different set of rules, that we are unconstrained by evolution, and that we have miraculously developed emergent properties, such as a mind, intelligence, language, and even a soul. While we poke fun at this egocentric drive that all of us possess and the anthropocentric nature of our institutions, we must concede that this magnificent sense of self is biologically driven. Specifically, there are regions of the neocortex that are involved in generating a sense of our own body with respect to the world around us. These regions allow us to distinguish ourselves from external animate and inanimate objects and to interact with them via highly specialized morphological tools, such as our hands.

Despite this natural preoccupation with ourselves, and our need to understand how complexity has arisen in our species, many authors believe that it is more informative, when trying to appreciate our unique attributes with respect to other species, to examine similarities across groups, rather than trying to explain this uniqueness or variability in isolation. For example, are there similar principles of organization for all mammal brains? Once this question has been answered, then one can examine the departures from the common plan of organization to determine how these departures or modifications are achieved, and ultimately how they generate variable behavior like that described above for humans. A good illustration of this approach, and the focus of this review, is provided by an examination of the somatosensory areas of anterior and posterior parietal cortex in both primate and nonprimate mammals. These regions appear to have expanded in humans and are proposed to be associated with a number of sophisticated behaviors.

6.10.2 Sensory Versus Association Cortex

Traditionally, the mammalian neocortex has been divided into three broad categories: motor cortex, sensory cortex (including primary and second sensory fields such as S1, S2, V1, V2, A1, and R), and association cortex. This broad classification became popular in the middle part of the twentieth century, at which time electrophysiological mapping studies demonstrated that all mammals possessed

motor cortex and primary and second sensory cortices, and that primates in particular had a great deal of association cortex (Woolsey, C. N. and Fairman, D., 1946; Woolsey, C. N., 1958; see Kaas, J. H. and Collins, C. E., 2004, for review). Association cortex, as defined by modern textbooks, includes temporal, prefrontal, and posterior parietal cortex and is hypothesized to mediate complex behaviors such as perception, attention, cognition, and other high-level mental functions (Saper, C. B. *et al.*, 2000). The argument for defining cortex as association is somewhat circular and is based on the premise, which emerged from earlier mapping studies of Woolsey and colleagues, that the amount of cortex that could not be defined as unimodal sensory cortex in primates was relatively large compared to other mammals (Figure 1). Since primates were thought to be more cognitively complex than other mammals, this expanded cortex became associated with higher mental processes and was considered a primate phenomenon.

Unfortunately, the early mapping studies that provided support for these ideas were hampered by technical difficulties such as suboptimal anesthetics, recording methods, and stimulation parameters, all of which made it difficult to elicit responses from neurons in cortex other than primary and secondary sensory fields. Despite these limitations, these early studies fostered several ideas regarding the human brain that still persist today. Probably the most noteworthy are that primary fields are evolutionarily older, and that association cortex is a new evolutionary phenomenon found mainly in human and nonhuman primates. Thus, association cortex is proposed to be the hallmark of human brain evolution.

These ideas were firmly entrenched for most of the twentieth century. Indeed, a number of psychologists still hold this view, and it is currently circulated as the reigning model in most popular textbooks (e.g., Carlson, N. R., 1998; Saper, C. B. *et al.*, 2000). However, work in the early 1970s by Allman J. M. and Kaas J. H. (1971; 1974; 1975; 1976) upended these traditional views by demonstrating in nonhuman primates that much of extrastriate cortex that was considered association cortex actually contained a number of unimodal visual fields (also see

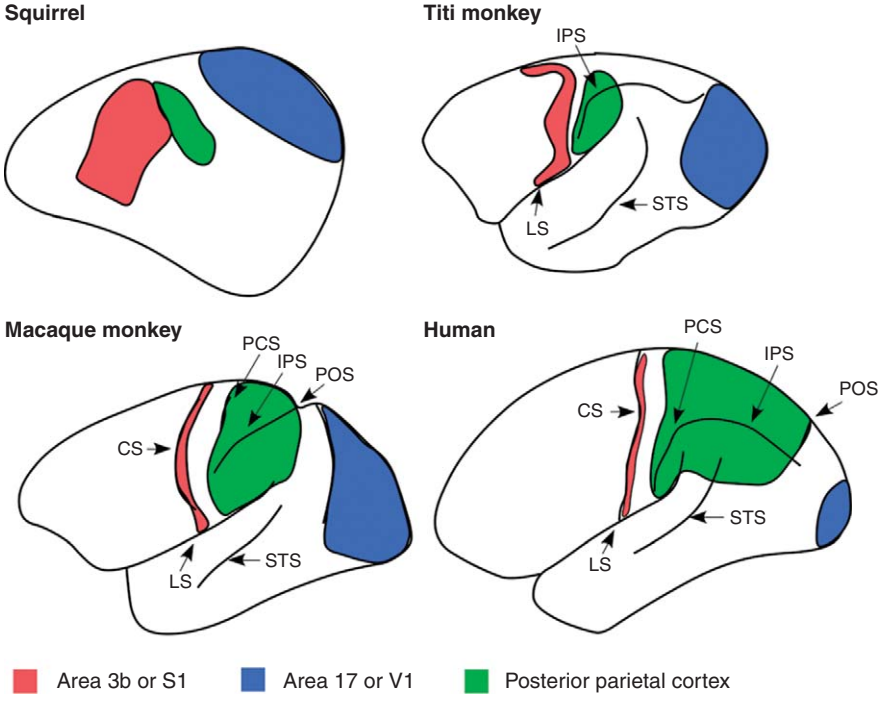

Figure 1 The location of association cortex (green) relative to the primary somatosensory area (red) and the primary visual area (blue) in four mammalian species. In mammals with a small neocortex, such as the gray squirrel, primary sensory areas occupy a relatively large portion of the cortical sheet. In mammals with a large neocortex such as monkeys, these primary sensory areas occupy relatively less cortex. In human primates, primary sensory areas occupy a very small portion of the neocortex, while association cortex, including posterior parietal cortex, occupies a large expanse of the cortical sheet.

Felleman, D. J. and Van Essen, D. C., 1991). Somewhat later, work in both somatosensory (Merzenich, M. M. *et al.*, 1978; Robinson, C. J. and Burton, H., 1980a; 1980b; Pons, T. P. *et al.*, 1985; Krubitzer, L. A. and Kaas, J. H., 1990; Krubitzer, L. *et al.*, 1995a) and auditory cortex (e.g., Imig, T. J. *et al.*, 1977; Hackett, T. A. *et al.*, 1998) demonstrated that parietal cortex and portions of temporal cortex that were thought to be association regions were occupied by somatosensory and auditory cortical fields, respectively (see Kaas, J. H. and Collins, C. E., 2004, for review).

Despite the ever-dwindling classical association cortex in primate brains (including human primates), there are still a few strongholds that seem indomitable, namely, prefrontal and posterior parietal cortex. Work on prefrontal cortex in humans demonstrates that it is involved in higher-order cognitive processes such as the ability to detect and respond to novel events, to discriminate internally motivated versus externally driven models of the world, and to "extract oneself from the present and fluidly move forward and backward in time" (p. 1319; Knight, R. T. and Graboweicky, M., 2000, for review). However, this region of cortex also has a number of visuomotor, olfactory, and limbic functions.

In humans, posterior parietal cortex is considered to be involved in coding the spatial location of objects within a particular frame of reference, both egocentric and extracentric (e.g., Mishkin, M. *et al.*, 1983; Behrmann, M., 2000; Robertson, L. C. and Rafal, R., 2000, for review). In nonhuman primates, posterior parietal cortex is divided into a number of cortical areas that are thought to be involved in visuospatial processing related to limb and hand use such as monitoring limb location during visually guided reaching and grasping, converting sensory locations into motor coordinates for intentional movement, and perceiving the movements of the body in extrapersonal space (Andersen, R. A. *et al.*, 1997; Snyder, L. H. *et al.*, 1997; Wise, S. P. *et al.*, 1997; Debowy, D. J. *et al.*, 2001; Andersen, R. A. and Buneo, C. A., 2002). Thus, much of the region traditionally defined as posterior parietal association cortex has actually evolved in primates as a consequence of and for the generation of specialized hand use rather than for general higher mental functions.

The following review will focus on several fields in anterior parietal cortex (areas 3a, 3b, 1, and 2) involved in processing somatic inputs from the skin, muscles, and joints, as well as one area of posterior parietal cortex (area 5) involved in manual dexterity, bilateral coordination of the hands, intentional reaching and grasping, and interhemispheric transfer of information. We contend that our sense of self, or an internal representation of our body with respect to the external world, is a concrete characteristic common to all mammals. This internal representation is generated by interactions between visual, proprioceptive, and vestibular systems, all of which are intricately intertwined with the motor system. Such an interaction allows an individual to interface an internal representation of self with the external world via a particular morphological structure, such as a hand, thereby generating a sensorimotor feedback loop that allows one to distinguish self from nonself.

6.10.3 Organization of Anterior Parietal Cortex in Primates (Areas 3b, 3a, 1, and 2)

Somatosensory cortex in primates is divided into three major divisions: anterior parietal cortex, posterior parietal cortex, and cortex of the lateral sulcus (see Kaas, J. H. and Pons, T. P., 1988, for review). Each of these major divisions contains several cortical areas. Anterior parietal cortex includes the primary somatosensory area, S1, which corresponds to area 3b in primates (see Kaas, J. H., 1983, for review), area 3a, area 1, and area 2. Posterior parietal cortex has been subdivided differently by different investigators, but most would agree that at least one of these regions, area 5, processes somatic inputs. Finally, like posterior parietal cortex, cortex in the lateral sulcus has been subdivided differently by different investigators. Recently, our laboratory and others have examined this region of cortex using multiunit electrophysiological recording techniques and neuroanatomical tracing methods combined with architectonic analysis, and we have divided this cortex into several fields including the second somatosensory area, S2, the parietal ventral area, PV, the ventral somatosensory area, VS, and the rostroventral parietal area, PR (e.g., Krubitzer, L. A. and Kaas, J. H., 1990; Krubitzer, L. *et al.*, 1995a; Disbrow, E. *et al.*, 2002; 2003; Wu, C.-H. and Kaas, J., 2003).

In this chapter we focus only on somatosensory areas of the anterior and posterior parietal cortex. While several anterior parietal fields such as areas 3a, 3b, 1 and 2 are architectonically distinct in some primates, architectonic comparisons across species

are difficult to make for fields other than areas 3b and 3a. Ideally, the consideration of homology should be based on a number of criteria such as architecture, electrophysiological recording data, cortical and subcortical connections, and lesions to cortical fields and resultant behavioral deficits (Kaas, J. H., 1982). Indeed, determining homology based on architecture alone, in the absence of corroborative electrophysiological data, leads to too many inaccuracies in subdividing the neocortex and erroneous conclusions regarding the evolution of cortical fields. For this reason, the following review focuses primarily on electrophysiological recording studies, studies of connections and studies of lesions, rather than studies which only use architecture to subdivide the cortex.

Cortical fields

A1	primary auditory area
AIP	anterior intraparietal area
C1	caudal region 1
C2	caudal region 2
DSG	dysgranular zone
LIP	lateral intraparietal area
M1	primary motor area
MIP	medial intraparietal area
PM	parietal medial area
PP	posterior parietal cortex
PR	rostroventral parietal area
PV	parietal ventral area
R	rostral area
R1	rostral region 1
R2	rostral region 2
S1	primary somatosensory area
S2	secondary somatosensory area
S3	third somatosensory area
SMA	supplementary motor area
UZ	unresponsive zone
V1	primary visual area
VIP	ventral intraparietal area
VPZ	ventral posterior nucleus, recipient zone

Sulci

CS	central sulcus
IPS	intraparietal sulcus
LS	lateral sulcus
PCS	post central sulcus
POS	parietal occipital sulcus
STS	superior temporal sulcus

Thalamic nuclei

CL	central lateral nucleus
MG	medial geniculate nucleus
Pa	anterior pulvinar
PO	posterior nucleus
VL	ventral lateral nucleus
VP	ventral posterior nucleus
Vpi	ventral posterior nucleus, inferior division
VPl	ventral posterior nucleus, lateral division
VPm	ventral posterior nucleus, medial division
VPs	ventral posterior nucleus, superior division

Body parts

6.10.4 Area 3b or S1

6.10.4.1 Functional Organization

The topographic organization of the primary somatosensory area, S1 or area 3b, has been described in a variety of primates including Old World macaque monkeys (Nelson, R. J. *et al.*, 1980); New World monkeys such as owl (Merzenich, M. M. *et al.*, 1978), squirrel (Sur, M. *et al.*, 1982), cebus (Felleman, D. J. *et al.*, 1983), spider (Pubols, B. and Pubols, L., 1971), titi (Padberg, J. P. *et al.*, 2005), tamarin (Carlson, M. *et al.*, 1986), and marmoset monkeys (Krubitzer, L. A. and Kaas, J. H., 1990); prosimian galagos (Sur, M. *et al.*, 1980); and humans (e.g., Penfield, W. and Rasmussen, T., 1968; Woolsey,

C. *et al.*, 1979; Fox, P. T. *et al.*, 1987; Moore, C. *et al.*, 2000; Blankenburg, F. *et al.*, 2003, for review; Hlushchuk, Y. *et al.*, 2003). In all primates investigated, area 3b forms a systematic representation of the contralateral body surface with the tail, genitals and feet represented most medially, followed by the representations of the hindlimb, trunk, forelimb, hand, face, and oral structures in a mediolateral progression (Figure 2).

Single unit studies demonstrate that neurons in area 3b have small receptive fields compared to other anterior parietal fields (e.g., Gardner, E., 1988) and along with optical imaging studies show that neurons are rapidly or slowly adapting to cutaneous stimulation (e.g., Sur, M. *et al.*, 1984; Chen, L. *et al.*, 2001) and respond to high-frequency stimulation (e.g., Lebedev, M. and Nelson, R., 1996), pressure, and flutter (Chen, L. *et al.*, 2001). In awake behaving monkeys, firing rates are modulated by contact with an object (DeBowy, D. J. *et al.*, 2001), and neurons respond prior to wrist movements (Nelson, R. *et al.*, 1991). It is proposed that area 3b is involved in texture and form discrimination (Johnson, K. O. and Lamb, G. D., 1981; Chapman, C. E. and Ageranioti-Bélanger, S., 1991; Sinclair, R. J. and Burton, H., 1991; Ageranioti-Belanger, S. A. and Chapman, C. E., 1992; Tremblay, F. *et al.*, 1996; Jiang, W. *et al.*, 1997; DiCarlo, J. *et al.*, 1998; see Johnson, K. and Yoshioka, T., 2002, for review) as well as topographic tactile learning (e.g., Romo, R. *et al.*, 1998; 2000; Diamond, M. *et al.*, 2002, for review). While most researchers have examined the neural response to stimulation of the hand or have designed behavioral tasks associated with the hand, one group of studies examined the properties of neurons in area 3b in response to tongue and face movements (Lin, L.-D. *et al.*, 1994a; 1994b). These investigators found that neurons in area 3b (and area 1) increase their firing rate for preferred tongue directions and suggest that neurons in 3b and 1 provide sensory inputs to M1 necessary for generating coordinated tongue and facial movements. Such a homologous processing network in primates could form the basis, in a modified form, for the highly derived articulation behaviors that have evolved in humans.

Studies in which area 3b has been lesioned in monkeys are consistent with single unit studies. For example, lesions in area 3b result in an inability to make discriminations of roughness, hardness, and angle of an object (Randolph, M. and Semmes, J., 1974). Other studies demonstrate that lesions in area 3b result in an inability to make static tactile discriminations (detection of edges), as well as tactile discriminations that require movement, such as discriminating a many-sided object (Schwartz, A., 1983). While the studies of Lamotte R. H. and Mountcastle V. B. (1979) support these findings, the lesions in their study encompassed the entire postcentral gyrus, making it difficult to relate a particular deficit with a specific cortical area.

A primary somatosensory area has also been identified in a wide range of nonprimate mammals including monotremes (e.g., Krubitzer, L. *et al.*, 1995b), marsupials (e.g., Pubols, B. H. *et al.*, 1976; Beck, P. D. *et al.*, 1996; Huffman, K. *et al.*, 1999; Frost, S. B. *et al.*, 2000), and eutherians (e.g., Felleman, D. J. *et al.*, 1983; see Kaas, J. H., 1983; Chapin, J. K. and Lin, C.-S., 1984; Ledoux, M. S. *et al.*, 1987; Johnson, J. I., 1990; Catania, K. C. *et al.*, 1993; Krubitzer, L., 1995, for review). Like area 3b in primates, S1 or area 3b in other mammals is topographically organized with the foot represented most medially, followed by the representation of the trunk, forelimb, forepaw, and face in a mediolateral progression (Figure 3). While single units have been recorded in the barrel field of some rodents, a full description of work in barrel cortex is beyond the scope of this chapter. However, Diamond M. *et al.* (2002) propose that S1 in whisking rodents may be involved in topographic learning via the whiskers, as is the hand representation in area 3b in monkeys. For our purpose, it is important to note that not only is the gross topographic organization of S1 similar in all species examined, but also the types of systems-level modifications to S1, or the rules of change, are consistent across species.

Probably the most salient modification in S1 across species is the amount of neocortex that represents body parts associated with specialized use, which we term behaviorally relevant body surfaces. For example, animals such as the duck-billed platypus have evolved electrosensory receptors that run in parallel strips along the bill (Figure 4). Together with mechanosensory receptors, platypus use electrosensory receptors almost exclusively for prey capture, navigation, and most other activities (Scheich, H. *et al.*, 1986; Manger, P. R. and Pettigrew, J. D., 1995; see Krubitzer, L., 1998, for review). The importance of this morphological structure is reflected in the neocortical organization in that a large percentage of S1, and indeed most of the neocortex, is devoted to the representation of the bill (Krubitzer, L. *et al.*, 1995b). Other examples of cortical magnification of specialized morphology (Figure 3) include the nose representation of the star-nosed mole (Catania, K. C. *et al.*, 1993), the

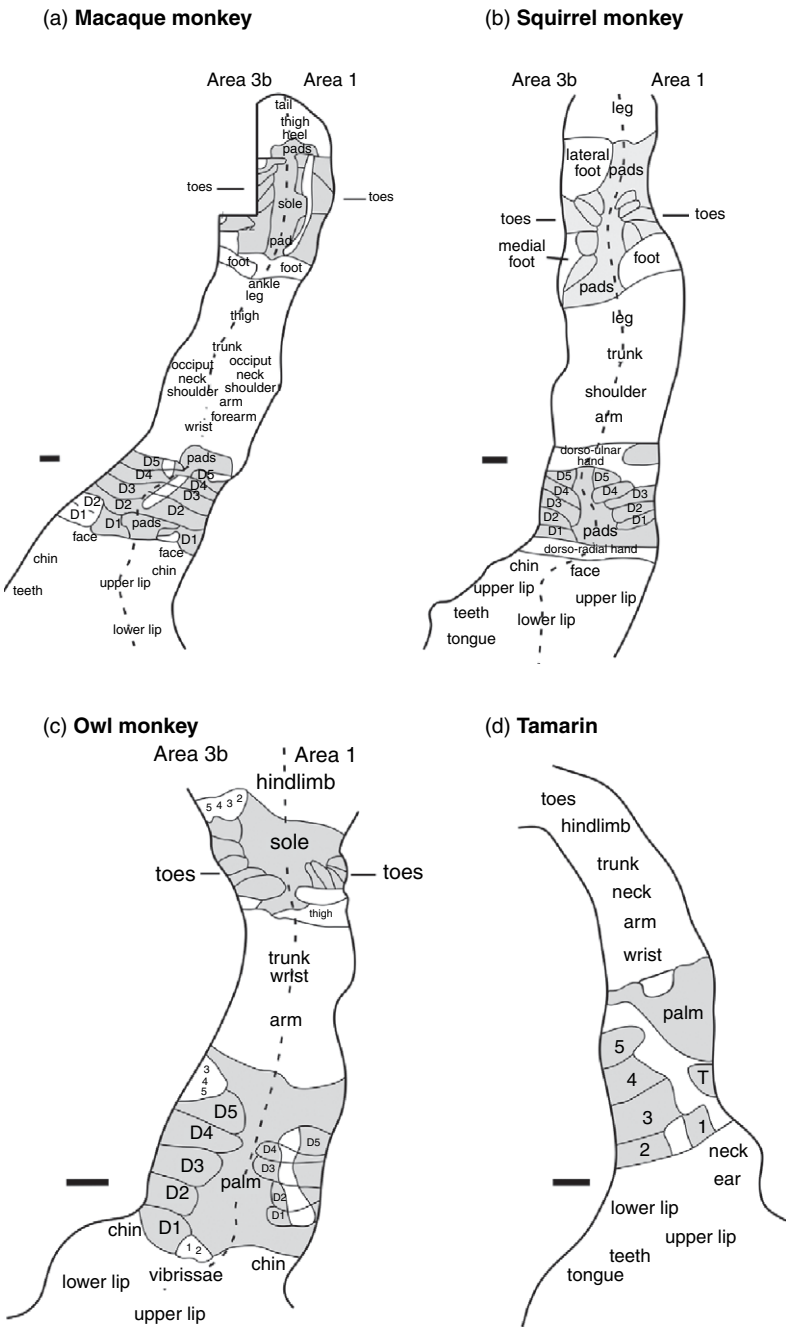

Figure 2 The topographic organization of the primary somatosensory area (S1 or 3b) and area 1 in New and Old World monkeys. Both areas 3b and 1 contain a systematic representation of the contralateral body surface and form mirror representations of each other. In some primates (a–c) area 1 is very well developed, while in other primates (d) area 1 has not been identified. We propose that area 1 coevolved with a well-developed, glabrous hand in some lineages. This is supported by the fact that tamarins have a more primitive hand with claws, compared to the other primates shown. (a) From Nelson, R. J., Sur, M., Felleman, D. J., and Kaas, J. H. 1980. Representations of the body surface in postcentral parietal cortex of *Macaca fascicularis.* J. Comp. Neurol. 192, 611–643; (b) From Sur, M., Nelson, R. J., and Kaas, J. H. 1982. Representations of the body surface in cortical areas 3b and 1 of squirrel monkeys: comparisons with other primates. J. Comp. Neurol. 211, 177–192; (c) From Merzenich, M. M., Kaas, J. H., Sur, M., and Lin, C.-S. 1978. Double representation of the body surface within cytoarchitectonic areas 3b and 1 in ''SI'' in the owl monkey (*Aotus trivirgatus*). J. Comp. Neurol. 181, 41–74; (d) From Carlson, M., Huerta, M. F., Cusick, C. G., and Kaas, J. H. 1986. Studies on the evolution of multiple somatosensory representations in primates: the organization of anterior parietal cortex in the New World Callitrichid, *Saguinus.* J. Comp. Neurol. 246, 409–426.

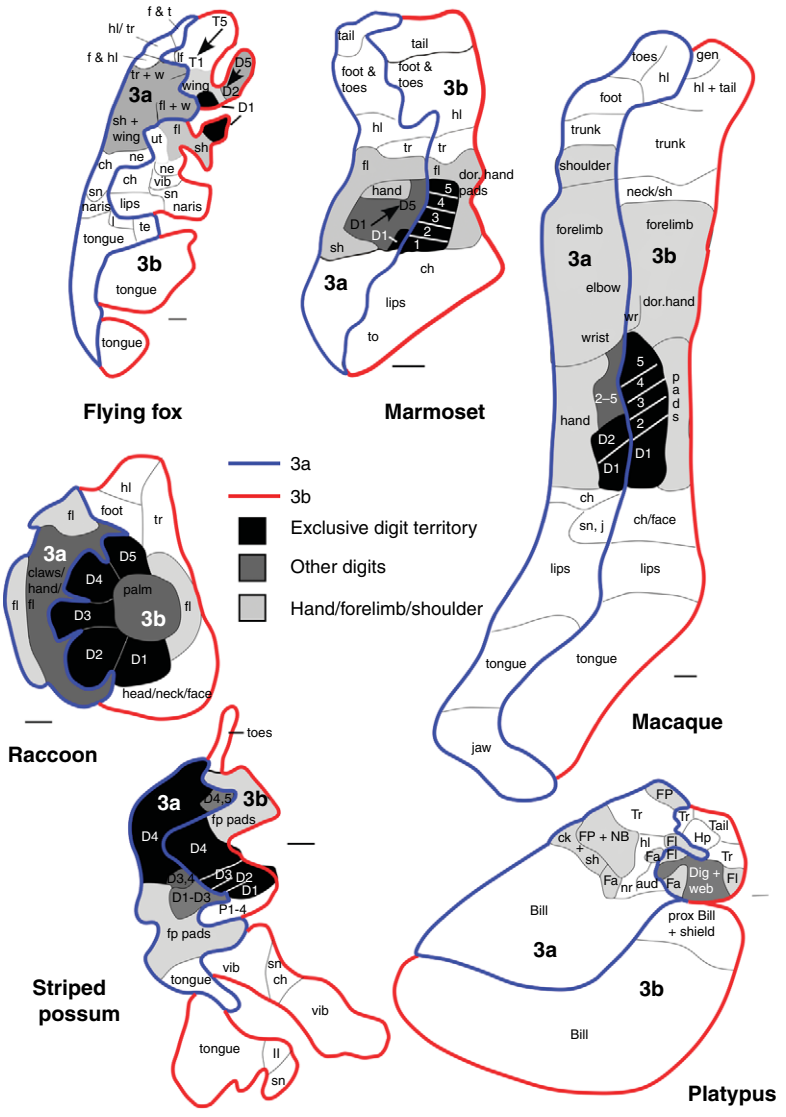

Figure 3 The topographic organization of areas 3b (red) and 3a (blue) in a variety of mammals including primates (macaques and marmosets), megachiropteran bats (flying fox), carnivores (raccoon), marsupials (striped possum), and monotremes (duck-billed platypus). Although the region of cortex immediately rostral to area 3b is termed differently in different mammals, there are a number of features of organization that are similar across groups of mammals including neural responsiveness to stimulation of deep receptors, dense connections with motor and posterior parietal cortical areas, and a large magnification of behaviorally relevant body parts. For these reasons, we believe that area 3a is a homologous cortical field in mammals. The exaggerated representation of specialized peripheral sensory receptor arrays in area 3a argues that the evolution of this field is highly dependent on the use of a particular body part and suggests that the motor system plays a crucial role in the development of area 3a. This figure was adapted from Krubitzer, L., Huffman, K. J., Disbrow, E., and Recanzone, G. 2004. Organization of area 3a in macaque monkeys: contributions to the cortical phenotype. J. Comp. Neurol. 471, 97–111.

digit 4 (D4) representation of the striped possum (Huffman, K. *et al.*, 1999), the D1 and tongue representation of the flying fox (e.g., Calford, M. B. *et al.*, 1985; Krubitzer, L. *et al.*, 1998), and the hand representation of the raccoon (Welker, W. I. and Seidenstein, S., 1959; Johnson, J. I. *et al.*, 1982).

Most primates, including humans, have a large representation of the glabrous hand in area 3b that reflects the special use of the hand in discrimination of texture and form, and a larger representation of oral structures (Figure 4; e.g., Cusick, C. G. *et al.*, 1986), possibly involved in discriminations necessary

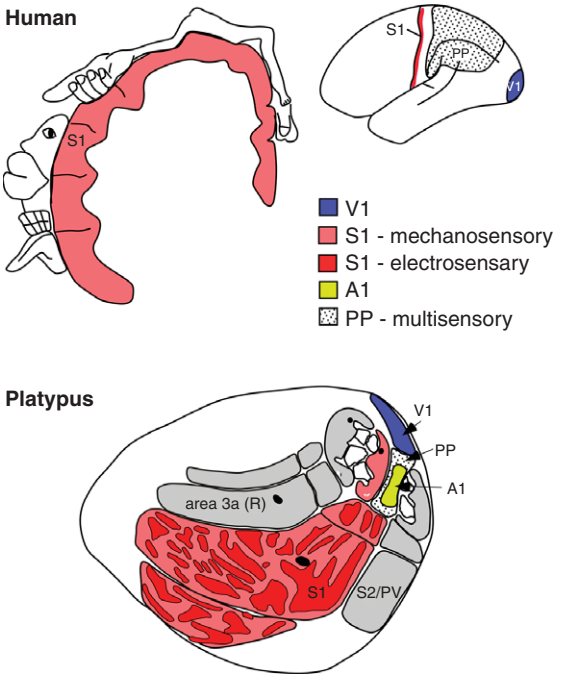

Figure 4 A schematic rendition that demonstrates the cortical magnification of behaviorally relevant body part representations in area 3b across different mammals. In humans, the hand, lips, and oral structure representations are magnified, while in platypus, the bill representation is magnified. Although such magnification occurs for different body part representations, the rules of modification of S1 are similar in both groups of mammals despite approximately 200 million years of independent evolution. This observation indicates that S1 is highly constrained in evolution. The schematic of the human is adapted from Penfield, W. and Rasmussen, T. 1968. Secondary Sensory and Motor Representation. In: Cerebral Cortex of Man. A Clinical Study of Localization of Function (Chapter VI), pp. 109–134. Hafner Publishing Company and the schematic of the platypus is adapted from Krubitzer L. *et al*. (1995).

for omnivorous feeding and for the articulation of species-specific sounds. Similarly, some primates have a relative enlargement of other body parts that are related to specialized use. For example, cebus and spider monkeys have an enlarged representation of their prehensile tail (Felleman, D. J. *et al*., 1983; Pubols, B. and Pubols, L., 1971). While this magnification of S1 in different species is related to innervation density at the periphery (e.g., Lee, K. and Woolsey, T., 1975; Catania, K. C. and Kaas, J. H., 1997), recent evidence also indicates that the use, or the unique pattern of activity from peripheral sensory receptor arrays, also contributes to this cortical magnification (Recanzone, G. H., 1992b; Catania, K. C. and Kaas, J. H., 1997; Xerri, C. *et al*., 1996). It has been proposed that this magnification generates the high spatial resolution necessary for texture and form discriminations made with specialized structures (see Johnson, K. and Yoshiako, T., 2002, for review).

A second type of consistent modification that has evolved in a number of different lineages is the segregation of inputs from similar body parts into distinct isomorphs, or modules, defined electrophysiologically or histochemically (Figure 5). For example, in primates, rapidly adapting and slowly adapting inputs are segregated into separate clusters or bands within S1 (e.g., Sur, M. *et al*., 1984; Chen, L. *et al*., 2001), and the face representation is divided into myelin light and dense zones that segregate different portions of the face and oral structures (Krubitzer, L. A. and Kaas, J. H., 1990; Jain, N. *et al*., 2001). In a number of rodents, inputs from the vibrissae are segregated into cortical barrels (Woolsey, T. A. and Van der Loos, H., 1970), in the star-nosed mole, nose follicles form isomorphs (Catania, K. C. *et al*., 1993), and in the duck-billed platypus, electrosensory and mechanosensory inputs are segregated into interdigitating bands (Krubitzer, L. *et al*., 1995b). The evolutionary and developmental significance of modules has been discussed previously (Krubitzer, L., 1995; Krubitzer, L., and Kahn, D., 2003). In brief, we hypothesize that modules represent a stage in the evolution of a cortical field and that selection for shorter connection length and/or increased speed of transmission has led to the aggregation of modules in different cortical fields and different species over time. If this is the case, then it suggests that a cortical field is actually a pattern of activation (connectivity) from a variety of sources including the thalamus and ipsilateral and contralateral hemispheres that shifts and redistributes across the cortical sheet within an individual lifetime (development) and across species over time (evolution).

6.10.4.2 Connections

The ipsilateral cortical connections of area 3b have been described in macaque monkeys (e.g., Jones, E. G. *et al*., 1978; Pearson, R. C. A. and Powel, T. P. S., 1985; Shanks, M. F. *et al*., 1985b; Juliano, S. *et al*., 1990; Darian-Smith, C. *et al*., 1993; Burton, H. and Fabri, M., 1995; Burton, H. *et al*., 1995), New World titi monkeys (Coq, J. O. *et al*., 2004; Padberg, J. P. *et al*., 2005), marmosets (Krubitzer, L. A. and Kaas, J. H., 1990),

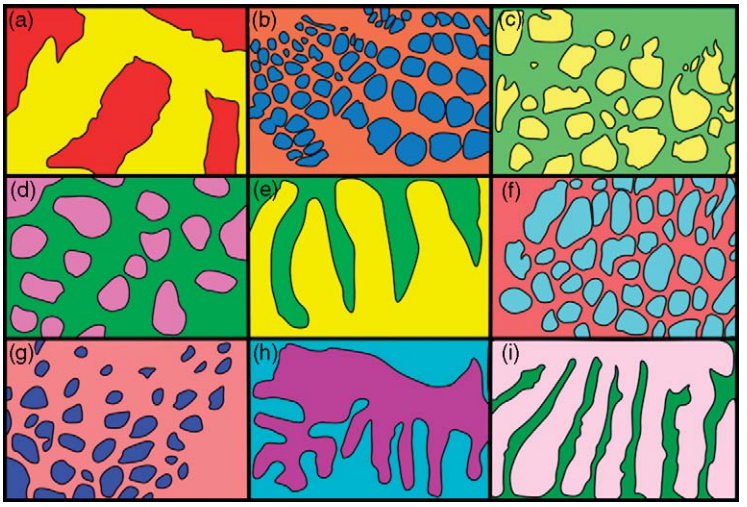

Figure 5 A schematic illustrating a second type of modification, modular organization, that has been observed in slices of flattened sensory cortex in a variety of different mammals. (a) Myelin bands in area 18 of squirrel monkeys; (b) the barrel field in S1 of rats; (c) modules in the insula of dolphin neocortex; (d) entorhinal clusters in macaque monkeys; (e) ocular dominance columns in monkeys; (f) entorhinal clusters in humans; (g) the barrel field in S1 of brush-tailed possums; (h) mechanosensory and electrosensory bands in S1 of duck-billed platypuses; and (i) nose follicle representation of S1 in star-nosed moles. This figure was adapted from Manger, P., Sum, M., Szymanski, M., Ridyway, S., and Krubitzer, L. 1998. Modular subdivisions of dolphin anterior ensular cortex: does evolutionary history repeat itself? J. Cogn. Neurosci. 10(2), 153–166.

and prosimian galagos (Wu, C.-H. and Kaas, J., 2003). In these primates, restricted injections in area 3b result in a relatively tight distribution of connections predominantly with adjacent somatosensory cortical fields including areas 3a, cortex immediately caudal to area 3b (areas 1 and 2 in macaque monkeys, area 1/2 in New World monkeys and galagos), S2 (and PV where described), and primary motor cortex (Figure 6). In primates, thalamic connections of area 3b are predominantly from the ventral posterior nucleus, both VPm and VPl (e.g., Jones, E. G. *et al.*, 1979; Nelson, R. J. and Kaas, J. H., 1981; Mayner, L. and Kaas, J., 1986; Darian-Smith, C. *et al.*, 1990; Krubitzer , L. A. and Kaas, J. H., 1992; Rausell, E. and Jones, E. G., 1995; Coq, J. O. *et al.*, 2004; Padberg, J. and Krubitzer, L., 2006). However, sparse projections from VPi, VPs, and Pa have also been observed (e.g., Cusick, C. G. and Gould, H. J. I., 1990).

Both the cortical and subcortical connections of area 3b (S1) have been described in a number of mammals such as rodents (e.g., Wise, S. P. and Jones, E. G., 1976; Akers, R. M. and Killackey, H. P., 1978; Krubitzer, L. A. *et al.*, 1986; Chapin, J. K. *et al.*, 1987; Krubitzer, L. and Kaas, J., 1987; Koralek, K. A. *et al.*, 1990; Fabri, M. and Burton, H., 1991; Paperna, T. and Malach, R., 1991), carnivores (Alloway, K. D. and Burton, H., 1985; Barbaresi, P. *et al.*, 1987; Herron, P. and Johnson, J. I, 1987), and marsupials (Beck, P. D. *et al.*, 1996; Elston, G. N. and Manger, P. R., 1999; see Johnson, J. I., 1990, for review). As in primates, S1 is densely connected with area 3a (R, UZ, and dysgranular cortex), M1, and S2/PV. The major thalamic projection to S1 is from VPl and VPm, and connections are also observed with the posterior nucleus, PO.

The total pattern of callosal connections of areas 3b, 1, 2, and 5 indicates that the hand representation of area 3b is almost completely acallosal in primates (e.g., Pandya, D. N. and Vignolo, L. A., 1968; Killackey, H. P. *et al.*, 1983; Shanks, M. F. *et al.*, 1985a; 1985b). Surprisingly, specific callosal connections of individual anterior parietal fields have only been described for a few species of primates (e.g., Manzoni, T. *et al.*, 1986; Krubitzer, L. A. and Kaas, J. H., 1990; Padberg *et al.*, 2005). In macaque monkeys it was found that while the hand representation of area 3b does not project to the hand representation of area 3b of the opposite hemisphere, it does project to S2 (e.g., Manzoni, T. *et al.*, 1986). In marmosets, electrophysiologically defined body part representations in area 3b are differentially interconnected across hemispheres. Myelin light portions of area 3b appear to be strongly interconnected, while myelin dense portions of area 3b are acallosal. Furthermore, as described in early studies, the hand representation of area 3b appears to be mostly acallosal. Area 3b is also

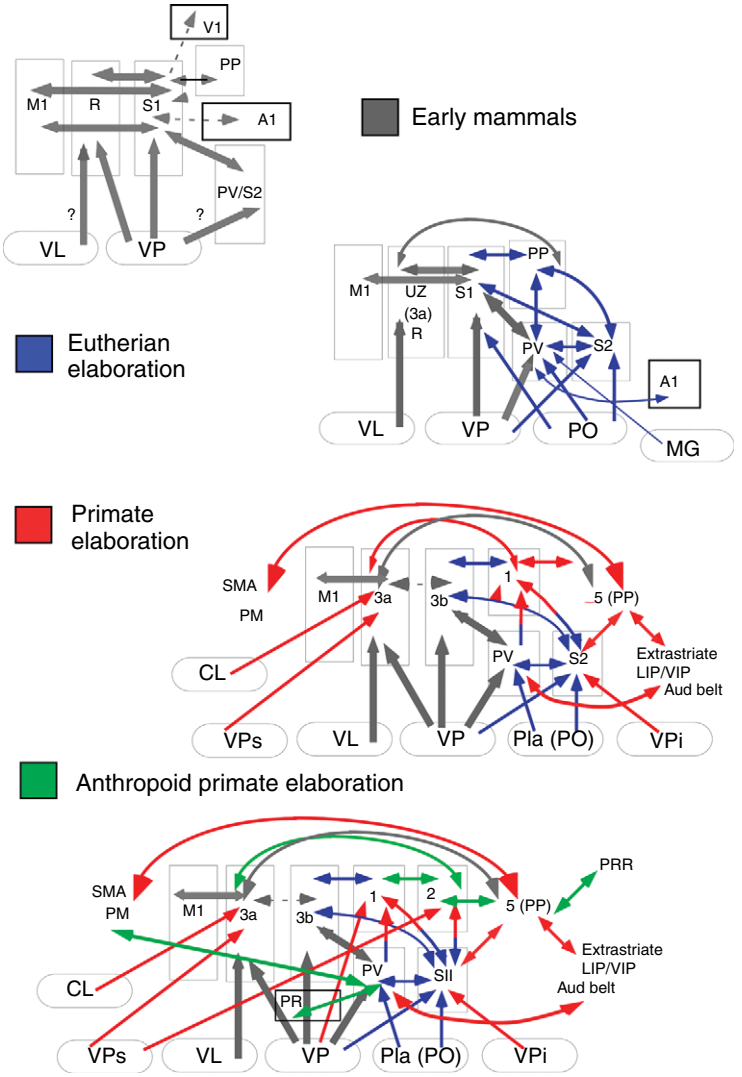

Figure 6 An overview of the cortical and thalamocortical connections of anterior parietal cortical fields, lateral sulcus fields, and posterior parietal area 5 in mammals. This figure is not an exhaustive overview of the connections of particular fields in different mammals. Rather, this figure depicts that particular patterns of connections can be identified in all groups of mammals due to retention from a common ancestor (gray arrows). Such connections are homologous. Additional connections arose later in mammalian evolution and have been added to this retained network in eutherian mammals (blue arrows). In different lineages, such as primates, these networks were further elaborated with the addition of new cortical areas, modules to existing cortical areas, and new thalamic nuclei. Such modifications to the neocortex make determining homologous areas and connection patterns difficult. Furthermore, these types of anatomical modifications suggest that homologous cortical fields may not be analogous (Figure 8).

interconnected with S2 and PV of the opposite hemisphere. Similar findings were reported in titi monkeys in which the hand representation was acallosal, and myelin light regions formed callosal zones in area 3b (Padberg *et al.*, 2004).

Callosal connections have been described for area 3b or S1 in rats (e.g., Wise, S. P. and Jones, E. G., 1976; Akers, R. K. and Killackey, H. P., 1978), mice (White, E. L. and DeAmicis, R. A., 1977), cats (e.g., Ebner, F. F. and Myers, R. E., 1965; Caminiti, R. *et al.*, 1979; McKenna, T. M. *et al.*, 1981), raccoons (Ebner, F. F. and Myers, R. E., 1965; Herron, P. and Johnson, J. I., 1987), flying foxes (Krubitzer, L. *et al.*, 1998), rabbits (Ledoux, M. S. *et al.*, 1987), and tree shrews (Cusick, C. G. *et al.*, 1985; Weller, R. E. *et al.*, 1987; see Krubitzer, L. *et al.*, 1998, for review). As in primates,

there is a heterogeneity of callosal connectivity of different body parts that appear to be associated with use. For example, the representations of specialized body parts in area 3b are acallosal, and zones such as the unresponsive zone in squirrels, the dysgranular zone (septa) in rats, the heterogeneous zones of raccoons, and the myelin light area 1/2 interdigitations in flying foxes are rich in callosal connections, as is the unmyelinated region in monkeys. Thus, studies of callosal connectivity for all mammals investigated report that S1 contains callosal zones related to different body part representations often associated with distinct myelin light zones (Figure 7; see Krubitzer, L. *et al.*, 1998, for review). Body part representations associated with specialized use such as the barrels in rodents, lateral face representations in rabbits, and the hand representations in primates are devoid of callosal connections. Previous studies suggest that callosal free zones are the regions of cortex where thalamocortical afferents terminate (e.g., Wise, S. P. and Jones, E. G., 1976; Gould, H. J. I. and Kaas, J. H., 1981; Krubitzer, L. A. and Kaas, J. H., 1990; Krubitzer, L. *et al.*, 1998). It appears that selection for specialized peripheral morphology in the form of receptor-dense regions like finger tips also operates on cortical representations to both conserve discrete receptive

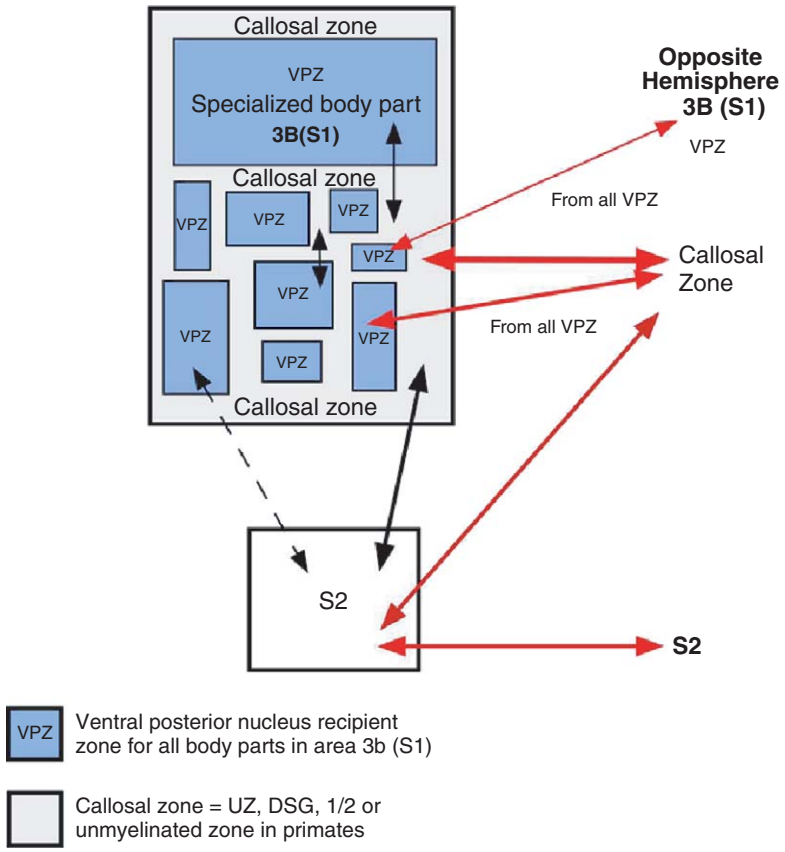

Figure 7 An illustration of the callosal connections of the primary somatosensory area (3b or S1) that depicts some common features of connectivity across all mammals. This figure demonstrates that area 3b appears to be modularly organized based on several important principles. First, S1 is broken into thalamocortical recipient zones (VPZ) and callosal recipient zones. Thalamocortical recipient zones of behaviorally relevant body parts (e.g., hand, bill, nose, and wing) are acallosal. Some of the VPZs have sparse callosal connections with VPZs in the opposite hemisphere and more dense connections to callosal zones in the opposite hemisphere. Finally, information from 3b can also reach the opposite hemisphere indirectly via S2. We and others propose that this type of organization evolved to maintain close intracortical connections between neurons in the same VPZ, uninterrupted by connections from the opposite hemisphere. This type of organization would allow for the maintenance of small receptive fields in neurons over a large region of cortex and would allow the integrity of sensory discriminations derived from inputs from behaviorally significant body parts to be maintained.

fields of neurons created by thalamocortical inputs and preserve neuroanatomical interactions between neighboring specialized skin regions. This conservation of thalamocortical inputs carrying information from specialized skin regions, and of short intrinsic cortical connections within the representation of these specialized skin regions, results in cortical zones or islands that are uninterrupted by callosal afferents (Herron, P. and Johnson, J. I., 1987; Ledoux, M. S. *et al.*, 1987; Krubitzer, L. *et al.*, 1998). We further suggest that in area 3b this type of connection labyrinth may be necessary to maintain the integrity of sensory discriminations derived from inputs from behaviorally significant body parts and as such constrains the evolution of S1.

Taken together, the data illustrate that there is a common organization of S1 across species and that modifications to this field take a similar form reflected as a magnification of the representation of specialized peripheral sensory morphology. How this magnification is related to specialized behavior is not clear, and why this mode of cortical specialization has emerged (compared to any number of potential types of modification) is not known. However, Kaas J. H. (1997) suggests that it is a byproduct of development that has been functionally optimized. Regardless of the functional significance of this magnification, comparative surveys demonstrate that the neocortex must be highly constrained since only a few modifications to S1, other than cortical magnification, have emerged. In addition to cortical magnification, the cortex has been modified to segregate subclasses of input, such as the segregation of rapidly adapting and slowly adapting inputs as well as the callosal and acallosal zones described above. Again, it is not understood why this feature has emerged independently in a number of different lineages, but it has been proposed that it reflects developmental contingencies and is therefore highly constrained (e.g., Krubitzer, L., 1995; Kaas, J. H., 1997; Krubitzer, L. and Kahn, D., 2003).

As with cortical organization, connections of S1 also have similar patterns across mammals. This homologous network may in part subserve similar functions, but it is likely that with the addition of new fields and connections (as in primates), and a reweighting of existing synaptic interactions, new functions or at least a species-specific refinement of particular behaviors is likely to have emerged (Figures 6 and 8). This observation, of course, implies that even for primary fields, direct extrapolation between nonhuman and human primates regarding function is problematic.

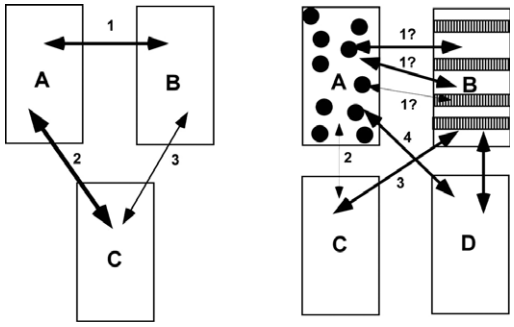

Figure 8 A theoretical rendition of the evolution of cortical fields and their connections. This figure illustrates the difficulties inherent in assigning homology across groups of mammals. It also illustrates the problems with making direct extrapolations regarding analogy of cortical fields, and their circuitry, between any groups of mammals (such as macaque monkeys and humans). Hypothetical cortical fields include field A, B, and C with connection patterns 1, 2, and 3 (*left*). When comparing cortical organization and connections across groups to determine homology, several problems arise. First, new cortical fields have been added in some groups (D). Second, modules may have been added to existing cortical fields (A and B). Third, the density of connections between fields may have changed (connection 2). Fourth, existing connections have been modified by the generation of modules (connection 1). Finally, new connections (4) have developed between retained fields (A) and new fields (D). All of these events are complicated by the fact that connection patterns are often used to determine homology between fields. Thus, even when one can convincingly determine the homology of cortical fields in different groups of animals, it is unlikely that homologous fields are strictly analogous.

6.10.5 Area 3a

6.10.5.1 Functional Organization

A representation of deep receptors of the contralateral body, termed area 3a, is located immediately rostral to area 3b. Area 3a was originally described as an architectonically distinct cortical field in humans by Vogt C. and Vogt O. (1919) but has since been described in a variety of mammals. The functional organization of area 3a in primates has been described for marmosets (Huffman, K. J. and Krubitzer, L., 2001a) and macaque monkeys (Krubitzer, L. *et al.*, 2004) in multiunit recording studies, and recently in humans using modern imaging techniques (Moore, C. *et al.*, 2000). These studies demonstrate that area 3a contains a topographically organized representation of deep receptors and musculature of the contralateral body that parallels that of area 3b (Figure 3) and ultimately receives input

from proprioceptors of the muscles and joints (Phillips, C. B. *et al.*, 1971; Schwarz, D. W. *et al.*, 1973; Heath, C. J. *et al.*, 1975; Hore, J. *et al.*, 1976; see Tanji, J. and Wise, S., 1981, for review). Single unit studies in awake monkeys report that neurons in area 3a modulate activity prior to wrist flexion and extension (Nelson, R., 1987) and are active under a variety of joint movements (Gardner, E., 1988). Neural activity in area 3a increases with maintained limb position and is modulated with the velocity of movement toward a limb position, as well as the ultimate position of the limb (Tanji, J., 1975; Wise, S. and Tanji, J., 1981). Furthermore, lateral portions of area 3a (termed 3aV) contain neurons that respond to vestibular stimulation (Guldin, W. O. *et al.*, 1992). Thus, area 3a in primates is a proprioceptive field that is closely involved in the kinetics of movement. This contention is supported by microstimulation studies in monkeys which demonstrate that body movements can be elicited by stimulating area 3a with very small currents (e.g., Stepniewska, I. *et al.*, 1993).

Studies in other mammals have identified a region of cortex just rostral to area 3b in which neurons respond to stimulation of deep receptors. In carnivores such as cats (e.g., Oscarsson, O. and Rosén, I., 1963; 1966; Oscarsson, O. *et al.*, 1966; Landgren, S. and Silfvenius, H., 1969; Zarzecki, P. *et al.*, 1978; Felleman, D. J. *et al.*, 1983), raccoons (Johnson, J. I. *et al.*, 1982; Feldman, S. H. and Johnson, J. I., 1988), and ferrets (Hunt, D. L. *et al.*, 2000), a region just rostral to area 3b exhibits a number of characteristics of area 3a in monkeys, such as neural response to stimulation of deep receptors, architectonic appearance, and gross topographic organization (Figure 3). This field has been termed area 3a in cats and ferrets and kinesthetic cortex in raccoons. In other mammals such as marsupials (see Huffman,K. *et al.*, 1999), rodents (see Slutsky, D. A. *et al.*, 2000, for review), insectivores (Krubitzer, L. *et al.*, 1997), and monotremes (Krubitzer, L. *et al.*, 1995b), these features are observed in a field just rostral to S1, termed the rostral field, R (Figure 9). In all of these mammals, this cortical area immediately rostral to S1 and caudal to area 4 contains a gross mediolateral organization that mirrors that of area 3b, although there is a great deal of variability across groups. Thus, all mammals have a cortical field located just rostral to area 3b that receives inputs from deep receptors of the contralateral body and is distinguished from motor cortex (area 4) based on a number of criteria including functional organization, neural stimulus preference, architectonic distinctiveness, and when known cortical and subcortical connectivity. We propose that area 3a is homologous in all mammals.

As demonstrated for area 3b, there are several features of area 3a organization that have been consistently modified in different lineages, and these modifications appear to be more related to the use of behaviorally relevant body parts than in area 3b. For instance, when the topographic organization of area 3b is compared with that of area 3a in macaque monkeys, area 3b is observed to be more topographically precise, particularly for representations of the digits where every digit is represented in an exclusive cortical zone. This aspect of representation in area 3b has been observed in every primate examined regardless of the use of the hand or whether the primate in question has an opposable thumb. In contrast, in area 3a in macaque monkeys, exclusive cortical territory is devoted to the representation of D1 and D2, while digits 3 through 5 are represented together. In area 3a in marmosets, little if any cortical territory is devoted to the exclusive representation of a single digit. Digit representation in area 3a in the two species appears to parallel differences in use (Figure 3). Macaque monkeys have opposable thumbs and are highly skilled graspers who employ two general techniques. The first technique is to oppose D1 to D2 (precision grip), and the second technique is to oppose all four remaining digits to the palm (power grip; Welles, J. F., 1976; Roy, A. *et al.*, 2000). Marmoset monkeys, on the other hand, generally employ only a power grip, and their cortical representation in area 3a reflects this behavior. These observations suggest that in primates, area 3a emerges in development and evolution as a result of the actual use of the body part, and therefore, the motor system must play an important role in its construction.

Studies of the organization of area 3a in a variety of other species who use the hand quite differently than primates support this contention (Figure 3). For instance, the flying fox has a highly derived hand in which the digits have evolved membranes that span between them. This digit/membrane configuration functions as a whole unit, the wing, which is adapted for flight. Consequently, all digits form a single representation in area 3a, the wing, and there is no cortical territory that exclusively represents any one digit (Krubitzer, L. *et al.*, 1998), although such exclusive digit representation is present in area 3b in these mammals (Calford, M. B. *et al.*, 1985; Krubitzer, L. A. and Calford, M. B., 1992). Another interesting

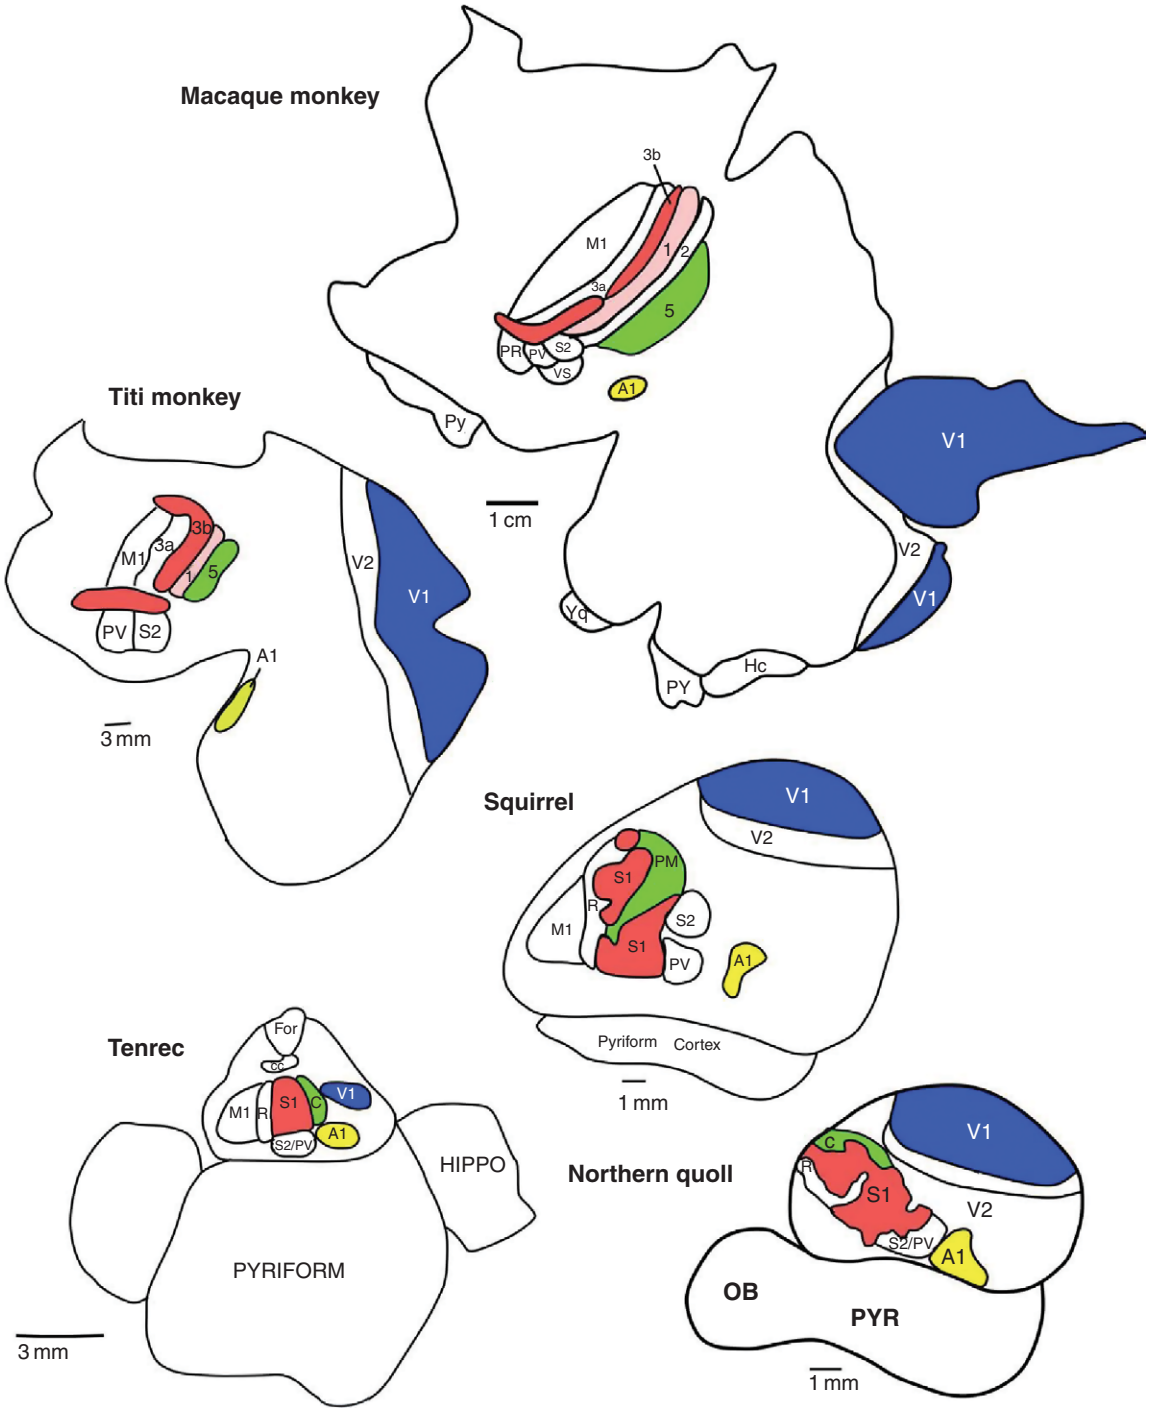

Figure 9 The organization of neocortex in several different mammals. This figure demonstrates that assigning homology of a cortical field based on the location of a particular field relative to another field is problematic. For instance, in mammals with large brains, such as macaque monkeys, area 1 is immediately caudal to area 3b, area 5 is close to the caudal boundary of area 1, and both are very far removed from V1 and V2. In mammals such as squirrels, cortex immediately caudal to area 3b, PM, is relatively close to V2 compared to macaque monkeys. In tenrecs, cortex immediately caudal to area 3b (S1) is also immediately adjacent to V1. If one were to assign homology based solely on location, this cortex in tenrecs could as easily be termed area 1 as it could be termed V2.

example of use-dependent organization of area 3a is the marsupial striped possum. This animal has a specialized D4 that it uses almost entirely to capture insects (Van Dyck, S., 1983). While exclusive cortical territory for all of the digits is observed in area 3b (with a magnification of D4), only D4 is represented in area 3a. Differences in use between members of the same species can produce a good deal of variability in the topographic organization of area 3a (e.g., Recanzone, G. H. *et al.*, 1992b), and this variability is even more pronounced across species due to specialized motor sequences or exaggerated behaviors that coevolved with specialized peripheral morphology and associated sensory receptor arrays (Krubitzer, L. *et al.*, 2004).

6.10.5.2 Connections

There are several studies of the connections of area 3a in primates including macaque monkeys (e.g., Jones, E. G. *et al.*, 1978; Darian-Smith, C. *et al.*, 1993), squirrel monkeys (Guldin, W. O. *et al.*, 1992), and marmosets (Huffman, K. J. and Krubitzer, L., 2001a). These studies demonstrate that area 3a is densely connected with M1, SMA, area 2 (or cortex caudal to area 3b), S2/PV, cingulate cortex, insular cortex, and posterior parietal cortex (area 5; Figure 6). The surprising result from these previous studies is that area 3a has more numerous connections with motor and posterior parietal areas of the neocortex than with traditionally defined somatosensory areas. Studies of thalamic connections of area 3a in Old World (Jones, E. G. *et al.*, 1979; Darian-Smith, C. *et al.*, 1990) and New World monkeys (Akbarian, S. *et al.*, 1992; Huffman, K. J. and Krubitzer, L. A., 2001b) indicate that area 3a receives input from somatic nuclei such as the ventral posterior superior nucleus (VPs, VPLc of Jones, E. G. *et al.*, 1979; Friedman, D. and Jones, E., 1981 and Darian-Smith, C. *et al.*, 1993) and the anterior pulvinar (Pla), some of which (e.g., VPi, VPs, and VLc) are also associated with vestibular processing (e.g., Lang, W. *et al.*, 1979). Area 3a also receives input from nuclei associated with the motor system such as the ventral lateral (VL), ventral anterior (VA), and central lateral (CL) nucleus of the thalamus.

The cortical and subcortical connections of area 3a, or cortex in the location of area 3a, has only been described in a few mammals such as squirrels (Gould, H. J. *et al.*, 1989; dysgranular UZ), flying foxes (Krubitzer, L. *et al.*, 1998), cats (e.g., Avendano, C. *et al.*, 1992), and briefly for ferrets (e.g., Hunt, D. L. *et al.*, 2000). While there is variability in the patterns of cortical connections of area 3a across animals, there are consistent patterns of connections with motor cortex, areas of the lateral sulcus such as S2/PV, and with cortex immediately caudal to S1 (Figure 6; termed area 5, PP, 1/2, and C in different animals). Thalamic connections of the UZ/R region of squirrels (area 3a) were from nuclei situated rostral, dorsal, and caudal to VP and from the central medial nucleus (Gould, H. J. *et al.*, 1989).

As with 3b, in most studies, the total pattern of callosal connections of anterior parietal fields 3a, 3b, 1, and 2 has been examined rather than the specific connections of area 3a (e.g., Jones, E. G. and Powell, T. P. S., 1969a; Killackey, H. P. *et al.*, 1983; Shanks, M. F. *et al.*, 1985a). These studies suggest that like area 3b, the hand representation of area 3a is acallosal. There are only a few studies of callosal connections of area 3a in primates and other mammals. In marmosets, specific connections of the hindlimb and forelimb representation in area 3a have been described (e.g., Huffman, K. J. and Krubitzer, L., 2001a). Interestingly, at least for the marmoset, the hand representation of area 3a does have callosal connections with the hand representation of area 3a in the opposite hemisphere. Furthermore, area 3a is callosally connected to areas M1 and SMA as well. Similar findings were demonstrated for the wing representation of the flying fox (Krubitzer, L. *et al.*, 1998).

Taken together, the data indicate that area 3a is a proprioceptive area that integrates somatic and vestibular inputs with the motor system. This cortical field is involved in the kinetics of movement (determining the load and force), in maintaining posture and limb position, and in regulating the velocity of limb movement.

6.10.6 Area 1

6.10.6.1 Functional Organization

A third somatosensory cortical field just caudal to area 3b, termed area 1, has been described in macaque monkeys and three species of New World monkeys including owl, squirrel, and cebus monkeys (Merzenich, M. M. *et al.*, 1978; Nelson, R, J. *et al.*, 1980; Sur, M. *et al.*, 1982; Felleman, D. J. *et al.*, 1983 respectively). Recent evidence indicates that area 1 is present in humans as well (e.g., Krause, R. *et al.*, 2001; Blankenburg, F. *et al.*, 2003). In some primates, such as macaques, squirrel monkeys, and owl monkeys, area

1 forms a mirror reversal representation of area 3b and contains a precise, topographically organized representation of the contralateral body surface, much like that of area 3b (Figure 2). As in area 3b, there is a magnification of the glabrous hand and oral structures, and receptive fields for neurons are small and limited to single digits. In other primates, only a rudimentary area 1 has been observed (e.g., titi monkeys, Coq, J. O. *et al.*, 2004; Padberg, J. P. *et al.*, 2005) or is absent under similar recording conditions (e.g., tamarins, Carlson, M. *et al.*, 1986; marmosets, Krubitzer, L. A. and Kaas, J. H., 1990; prosimian galagos, Sur, M. *et al.*, 1980). Although we and others have termed cortex caudal to area 3b 'area 1/2' in previous studies in marmoset monkeys (e.g., Krubitzer, L. A. and Kaas, J. H., 1990) and galagos (Wu, C.-H. and Kaas, J., 2003), this terminology was based solely on position with respect to area 3b, rather than any solid electrophysiological data. Indeed, in these species, cortex caudal to area 3b contains neurons that are either unresponsive to any type of sensory stimulation under the anesthetic conditions utilized or are inconsistently driven by stimulation of deep receptors or high-threshold cutaneous receptors of the contralateral body (Figure 11). Thus, area 1 is well developed in only a few primates including Old World macaque monkeys and a few New World monkeys. Given that these species have a well-developed glabrous hand compared to the clawed New World marmoset and tamarin monkeys, we hypothesize that this field coevolved with the highly specialized glabrous hand and is associated with sophisticated hand use.

Single unit studies demonstrate that like neurons in area 3b, neurons in area 1 are modulated by contact with an object (e.g., Debowy, D. J. *et al.*, 2001), are selective for motion across the skin, and are involved in edge orientation (e.g., Gardner, E., 1988). Furthermore, neurons in area 1 respond to noxious stimulation (Kenshalo, D. *et al.*, 2000). Lesions that are restricted to area 1 in primates demonstrate that animals are unable to discriminate between hard versus soft and rough versus smooth objects (Randolph, M. and Semmes, J., 1974; Carlson, M., 1981).

There is very limited evidence for an area 1 in other mammals. While investigators have subdivided cat cortex into architectonic areas 3a, 3b, 1, and 2 (e.g., Hassler, R. and Muhs-Clement, K., 1964), electrophysiological recording experiments in which this cortex was densely surveyed demonstrate that only a single representation of the contralateral body surface (area 3b or S1) resides in anterior parietal cortex of the cat (e.g., Felleman, D. J. *et al.*, 1983). Although cortex caudolateral to area 3b has been electrophysiologically explored and termed S3 by Garraghty P. E. *et al.* (1987), these investigators propose that S3 may be homologous to S2 or PV in other mammals, rather than area 1. The data in ferrets are equivocal. Some laboratories report multiple cutaneous representations in anterior parietal cortex (termed C1, C2, R1, and R2; e.g., LeClerc, S. S. *et al.*, 1993), while others report that neurons in cortex caudal to area 3b respond to stimulation of deep receptors (Hunt, D. L. *et al.*, 2000). In the former study, only the snout representation was explored. It is not clear if indeed four separate cutaneous representations exist in ferrets since the mapping data were limited; or if they do exist, which of the four corresponds to area 3b and area 1. Finally, a field termed area 1/2 has been described for the flying fox (e.g., Krubitzer, L. A. and Calford, M. B., 1992). This region of cortex interdigitates with area 3b and contains neurons that respond to cutaneous stimulation of the contralateral body surface as well as islands of neurons that respond to stimulation of deep receptors. Like area 1 in primates, area 1/2 in the flying fox contains a complete representation of the contralateral body surface.

In all other mammals investigated, cortex caudal to area 3b contains neurons that respond to stimulation of deep receptors (Figure 11). For example, in rodents (Slutsky *et al.*, 2000), insectivores (Krubitzer, L. *et al.*, 1997), monotremes (Krubitzer, L. *et al.*, 1995b), and marsupials (Beck, P. D. *et al.*, 1996; Huffman, K. *et al.*, 1999), cortex immediately caudal to 3b contains neurons that respond to stimulation of deep receptors of the contralateral body, which are often multimodal (e.g., short-tailed possums and platypus). This field has been called the caudal field (C), the caudal somatosensory area (SC), the parietal medial field (PM), PPC, or area 1/2 in different mammals and has been proposed to correspond to posterior parietal cortex including area 5 or a combination of areas 1 and 2 (Reep, R. L. *et al.*, 1994; Krubitzer, L. *et al.*, 1997; 1998; Huffman, K. *et al.*, 1999; Slutsky, D. A. *et al.*, 2000, for review). Interestingly, studies in which the behavioral effects of lesions in PPC were examined in rats report that these animals have deficits in spatial attention and navigation (Kolb, B. *et al.*, 1994). Similar types of deficits are observed when posterior parietal cortex (rather than area 1) is lesioned in primates (see below).

It seems unlikely that cortex immediately caudal to area 3b in nonprimate mammals is homologous to area 1 in primates for three reasons. The first is that there are only two nonprimate mammals in which neurons in

cortex that adjoins area 3b at its caudal boundary respond to cutaneous stimulation, and this cortex has only been thoroughly explored in one of these species (e.g., flying fox). In all other mammals, cortex immediately caudal to 3b contains neurons that respond to stimulation of deep receptors that are often multimodal. Second, the location of an area 1 described in these animals as just caudal to S1 is not a conclusive indicator of homology because in small-brained mammals such as tenrecs and marsupial northern quolls, cortex immediately caudal to area 3b is also immediately rostral to V1 or V2 (Figure 9). Therefore, assigning homology based on position alone is problematic. Finally, prosimians, marmosets, and tamarins do not appear to have an area 1, which suggests that this field arose later in primate evolution and is therefore a purely primate phenomenon, with the cutaneous field immediately caudal to area 3b arising independently in flying foxes (and possibly ferrets, if area 1 does indeed exist in these animals), and serving different, although overlapping functions in these species (see below).

6.10.6.2 Connections

Highly restricted injections into electrophysiologically identified portions of area 1 have only been made in macaque monkeys (Pons, T. P. and Kaas, J. H., 1986; Burton, H. and Fabri, M., 1995; Burton, H. *et al.*, 1995) and titi monkeys (Coq, J. O. *et al.*, 2004; Padberg, J. P. *et al.*, 2005). Connections of area 1 in macaque monkeys are more broadly distributed than those in area 3b and are observed with areas 3b, 2, S2/PV, 5, AIP/7b, and sparsely with areas 3a, M1, and frontal cortex. Previous reports on connections of the architectonically defined area 1 with local parietal cortical areas support these electrophysiological studies (e.g., Jones, E. G. *et al.*, 1978; Vogt, B. A. and Pandya, D. N., 1978; Pearson, R. C. A. and Powell, T. P. S., 1985; Shanks, M. F. *et al.*, 1985b). In macaque monkeys, thalamocortical connections from electrophysiologically identified locations in area 1 indicate that like area 3b, area 1 receives the majority of its inputs from VP proper (e.g., Nelson, R. J. and Kaas, J. H., 1981; Pons, T. P. and Kaas, J. H., 1985). However, in New World titi monkeys, thalamocortical connections of area 1 are also from VL, Pa, and VPs (e.g., Padberg, J. and Krubitzer, L., 2006).

Examination of callosal connections of areas 3a, 3b, 1, and 2 indicates that the hand representation of area 1 is acallosal (e.g., Pandya, D. N. and Vignolo, L. A., 1968; Killackey, H. P. *et al.*, 1983; Shanks, M. F. *et al.*, 1985a; Conti, F. *et al.*, 1986). Recent work in titi monkeys in our laboratory in which the injections in area 1 were made under electrophysiological guidance demonstrates sparse callosal connections for the hand representation in area 1 (Padberg, J. and Krubitzer, L., 2006). In this primate, area 1 was most densely interconnected with areas 5 and AIP/7 of the opposite hemisphere.

Connections, lesions, and single unit studies in macaque monkeys indicate that areas 3b and 1 in primates are involved in integrating local inputs from restricted portions of the glabrous hand necessary for fine tactile discriminations such as ascertaining object texture and form (Randolph, M. and Semmes, J., 1974; LaMotte, R. H. and Mountcastle, V. B., 1979; Carlson, M., 1981; Sinclair, R. J. and Burton, H., 1991; Ageraniotis-Belanger, S. A. and Chapman, C. E., 1992; Jiang, W. *et al.*, 1997). We propose that area 1 is a recently evolved field restricted to primates, although some species (e.g., flying foxes) have independently evolved a cutaneous representation caudal to area 3b. The location of this field in flying foxes is similar to that of area 1 in primates, but comparative data and examination of behavior in this species indicate that it is unlikely that this area is homologous, or strictly analogous to area 1 in primates since flying foxes do not use their wings for making form and texture discriminations of objects. It is possible that this area arose with the modification of the distal forelimb for flight and is involved in making fine tactile discriminations regarding small changes in air pressure and velocity across the wing during flight.

6.10.7 Area 2

6.10.7.1 Functional Organization

The functional organization of area 2 has only been investigated in one species of nonhuman primate, the macaque monkey (e.g., Pons, T. P. *et al.*, 1985; Toda, T. and Taoka, M., 2001; 2002). In macaque monkeys, area 2 contains a complete representation of deep receptors of the contralateral body, and the gross mediolateral topography is much like that described for areas 3b and 1, although the somatotopic organization is not as precise. The representation of the hand and forelimb in area 2 is highly magnified, more so than in areas 3a, 3b, and 1 (Figure 10).

Studies of response properties of neurons in area 2 (e.g., Hyvärinen, J. and Poranen, A., 1978; Taoka, M. *et al.*, 1998; 2000; Iwamura, Y. *et al.*, 2002) report that neurons here respond well to stimulation of deep

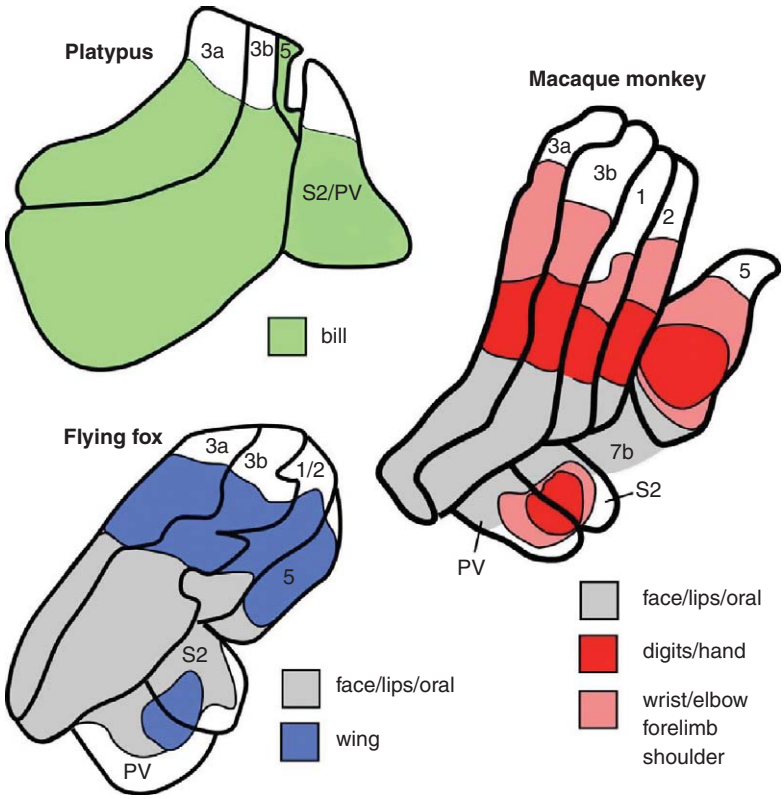

Figure 10 This figure demonstrates that parietal cortex obeys similar rules of construction regardless of which body part has been specialized. For example, the platypus has only three somatosensory areas and, we propose, a posterior parietal area (area 5). The three somatosensory areas are dominated by the representation of the bill, and area 5 exclusively represents the bill. In other groups, more cortical fields have been added between areas 3b and 5, such as areas 1 and 2 in macaque monkeys. These fields contain an enlarged representation of the hand and oral structures, as do 3b and 3a. Like the bill representation of area 5 in the platypus, area 5 in primates almost exclusively represents the hand. Even in species with a derived hand, such as the wing of the bat, similar principles of expansion and magnification are upheld.

receptors, although in some portions of area 2 neurons also responded to cutaneous stimulation (e.g., Pons, T. P. *et al.*, 1985; Ageranioti-Belanger, S. A. and Chapman, C. E., 1992), and may participate with areas 3b and 1 in texture discriminations (e.g., Salimi, I. *et al.*, 1999). Receptive fields for neurons in area 2 are relatively large (sometimes bilateral) when compared to areas 3b and 1 (e.g., Taoka, M. *et al.*, 2000; Iwamura, Y. *et al.*, 2002). In awake behaving monkeys, neurons in area 2 respond to both passive and active flexion of joints (Wolpaw, J., 1980; Gardner, E., 1988) and are facilitated or inhibited during grasping (Debowy, D. J. *et al.*, 2001). Furthermore, neuronal burst duration is correlated with arm movement duration (Burbaud, P. *et al.*, 1991), suggesting that area 2 directly participates in the online maintenance of movement. There is limited evidence for an area 2 in humans, and the organization and the subclass of receptors represented appears to be similar to that of macaque monkeys (e.g., Moore, C. *et al.*, 2000). Lesions in macaque monkeys that include area 2 affect the animal's ability to discriminate object shape, size, and curvature (Randolph, M. and Semmes, J., 1974; Carlson, M., 1981). Furthermore, the animal is unable to make discriminations that require active exploration with the hands (Schwartz, A., 1983).

Cortex immediately caudal to area 1 has been explored in a limited fashion in New World monkeys. Neurons in this region have been reported to be unresponsive to somatic stimulation, responsive only at the caudal border of area 1, or sometimes responsive to stimulation of deep receptors (Figure 11; e.g., Merzenich, M. M. *et al.*, 1978; Carlson, M. *et al.*, 1986; Huffman, K. J. and Krubitzer, L., 2001a). Thus, unlike macaque monkeys, it appears that New World monkeys do not possess an area 2. As noted above, cortex caudal to area 3b in nonprimate mammals contains

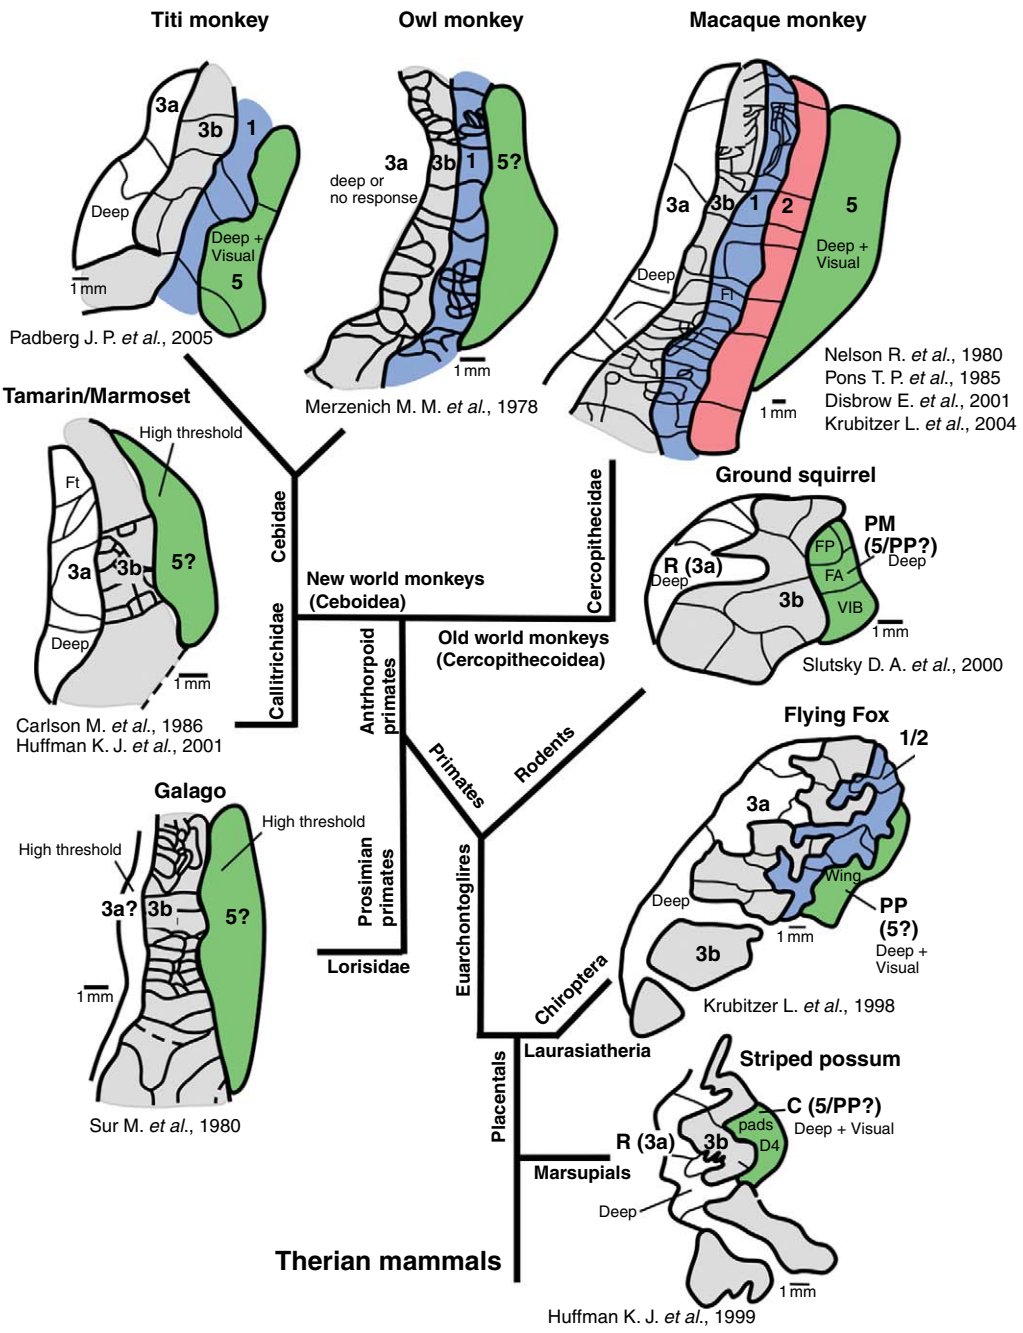

Figure 11 A simplified cladogram depicting the phylogenetic relationship of primates and other mammals and the organization of anterior and posterior parietal cortex in several species. Comparative data from these and other mammals indicate that early therian mammals possessed a primary somatosensory area (3b or S1, light gray), a rostral field (3a or R, white), and a caudal area (5 or PP, green). Some species, such as simian primates, have evolved a low-threshold cutaneous representation just caudal to 3b, termed area 1 (blue). Since area 1 has not been identified in other mammals, or even in prosimian primates, it is likely that area 1 evolved after the simian and prosimian divergence. Area 2 (orange) has only been identified in macaque monkeys. Comparisons across mammals indicate that areas 3a, 3b, and 5 are evolutionarily old fields and that new, unimodal somatosensory fields such as areas 1 and 2 evolved later in some lineages and are interspersed between existing fields (i.e., are not added hierarchically). We propose that areas 1 and 2 evolved with the modified morphology of the hand in anthropoid primates and that older, retained field, such as area 5, were modified both functionally and connectionally for sophisticated hand use. Phylogenetic relationships come from Murphy, W. J., Eizirik, E., O'Brein, S. J., Madsen, O., Scally, M., Douady, C. J., Teeling, E., Ryder, O. A., Stanhope, M. J., de Jong, W. W., and Springer, M. S. 2001. Resolution of the early placental mammal radiation using Bayesian phylogenetics. Science 294, 2348–2351 and Eisenberg, J. H. 1981. The mammalian radiations: an analysis of trends in evolution, adaptation and behavior. Continuum. Cortical organization of different species depicted here is taken from studies listed below each species.

neurons that respond to stimulation of deep receptors. While these regions could correspond to area 2 in these mammals and New World monkeys, it is also possible that they correspond to area 5. We suggest that this is the case based on several lines of evidence including the organization and magnification of representations in these fields, location relative to visual and somatosensory cortex, and the presence of neurons that also respond to stimulation of other sensory modalities (see below) but are often hard to drive under any given anesthetic condition (unlike neurons in area 2).

6.10.7.2 Connections

Studies of connections of area 2 in which injections were placed under electrophysiological guidance indicate that this field is connected with other somatosensory cortical areas such as 3b, 1, 3a, and S2, as well as with M1 and area 5 (Pons, T. P. and Kaas, J. H., 1985). Earlier studies of the connections of architectonically defined area 2 with local parietal cortical areas support these later studies (e.g., Jones, E. G. *et al.*, 1978). Area 2 receives thalamic input predominantly from VPs (VPLc of Friedman, D. and Jones, E., 1981) and the anterior pulvinar (Pa; Pons, T.P. and Kaas, J. H., 1985). The callosal connections of area 2 have only been described collectively with other anterior parietal fields. Unlike areas 3b and 1, the hand representation of area 2 does have callosal connections (see Manzoni, T., 1997). Taken together, all data indicate that area 2 is a proprioceptive area that is involved in the discrimination of shape and in the online maintenance of hand and forelimb movements necessary for reaching and grasping and is only present in Old World monkeys and humans (and likely great apes).

6.10.8 Posterior Parietal Area 5 in Primates

6.10.8.1 Functional Organization

Area 5 was first described as a very large cortical field that occupied the entire rostral bank of the IPS and much of the caudal postcentral gyrus (e.g., Brodmann, K., 1909). However, modern electrophysiological and anatomical studies indicate that area 5 is much smaller and resides in the middle of the rostral bank of the IPS and folds around the sulcal crown to spread onto the adjacent postcentral gyrus (e.g., Pons, T. P. *et al.*, 1985; Iwamura, Y., 2000, for review). Most data pertaining to posterior parietal cortex, and to area 5 in particular, have been collected in macaque monkeys and recently in titi monkeys (Figure 11), with limited information available in humans (Culham, J. C. and Kanwisher, N. G., 2001). In all of these primates, area 5 is dominated by the representation of the hand and forelimb (Figure 10); neurons in area 5 have contralateral, ipsilateral, and bilateral receptive fields (particularly on the hand and forelimb), and most neurons respond to the stimulation of deep receptors of the skin and joints (e.g., Sakata, H. *et al.*, 1973; Mountcastle, V. B. *et al.*, 1975; Taoka, M. *et al.*, 2000; Iwamura, Y. *et al.*, 1994; 2002; Padberg, J. P. *et al.*, 2005; see Iwamura, Y., 2000, for review). Single unit studies in awake behaving macaque monkeys indicate that area 5 is involved in coordinating or programming intention of movement (Snyder, L. H. *et al.*, 1997; Debowy, D. J. *et al.*, 2001), in preshaping the hand before grasping an object (e.g., Debowy, D. J. *et al.*, 2001), and in generating body- or shoulder-centered, rather than eye-centered coordinates for reaching (Ferraina, S. and Bianchi, L., 1994; Lacquaniti, F. *et al.*, 1995; see Wise, S. P. *et al.*, 1997, for review). Furthermore, area 5 appears to be involved in the kinematics (e.g., spatiotemporal coordinates) rather than the kinetics (e.g., load and force of muscle) of reaching (see Kalaska, J. F., 1996; Wise, S. P. *et al.*, 1997, for review). The proposition that area 5 is involved in the kinematics of movement is in part supported by studies which demonstrate that a large proportion of neurons are active prior to an arm movement, that these neurons are direction-selective for arm movement, and that activity is dependent on the behavioral context in which the movement will occur (Burbaud, P. *et al.*, 1991).

Recent studies indicate that neurons in area 5 are involved in generating an internal representation of the body that can be modified by experience (Graziano, M. S. A. *et al.*, 2000). For example, neurons in area 5 can change their receptive field size and location when a limb used to perform a task is artificially extended with a tool (Iriki, A. *et al.*, 1996). Furthermore, Iriki A. and colleagues (2001) demonstrated that monkeys can be trained to recognize an image in a video monitor as part of their own body and that neurons in the IPS, in the location of what we consider to be area 5, change their visual receptive fields to incorporate changes in hand location and size, as viewed on the video monitor, into an internal frame of reference. In these studies, the position and the size of the visual receptive field was

modified with respect to modifications of the image in the monitor (e.g., expansions, contractions, and displacement of the hand). These investigators speculate that a symbolic representation of the self in humans has a precursor in monkeys that is latent and can be activated with training. We would argue that these monkeys always possess an internal frame of reference, much like that in humans, and that the experimenters devised a clever and objective way in which to evaluate this internal representation in a nonhuman mammal. We would further argue that such a representation is a critical characteristic of most living things and constitutes a sense of self. Thus, this sense of self is present in all mammals and the region of cortex we propose to be involved in generating this behavioral characteristic (area 5 or PP) is homologous across groups of mammals.

Our recent studies in New World titi monkeys, as well as preliminary findings in macaque monkeys, indicate that many neurons in area 5 can be driven by visual stimulation (Disbrow, E. A. *et al.*, 2001; Padberg, J. P. *et al.*, 2005; Figure 11). While responsiveness to visual stimulation has not been described in previous studies for area 5, the studies often did not test whether or not neurons would be responsive to visual stimulation. This issue of whether neurons in area 5 respond to visual stimulation is important for our discussion of the evolution of posterior parietal cortex in mammals, since as noted above, cortex immediately caudal to 3b in many primitive mammals contains neurons that respond to both somatic and visual stimulation.

There are several studies in which lesions, that include area 5, were made in posterior parietal cortex in monkeys. For example, studies in which unilateral lesions included areas 5, MIP, and 7b demonstrated that animals had deficits in coordinating arm velocity with hand velocity, that the postural relationship between the arm and wrist was disrupted, and that there were disruptions in coordinating the hand in shoulder-centered space (Rushworth, M. F. S. *et al.*, 1997). However, these lesions did not affect the range or velocity of movements or the hand's trajectory. In a related investigation in which areas 5, 7b, and MIP (which may have also included V6) were bilaterally ablated, the monkey had deficits in reaching to the same target under different starting positions (Rushworth, M. F. S. *et al.*, 1998). Finally, a study in green monkeys in which bilateral ablations were made to area V6A (but may have incorporated portions of area 5) demonstrated that monkeys showed a reluctance to move and had deficits in reaching, grasping, and wrist orientation (Battaglini, P. P. *et al.*, 2002). While previous work on the effects of posterior parietal lesions on behavior are difficult to interpret because the size of the lesion was so large (e.g., Ettlinger, G. and Kalsbeck, J. E., 1962; Hartje, W and Ettlinger, G., 1973; Brown, J. V. *et al.*, 1983), they do indicate that lesions to posterior parietal cortex result in nonvisually guided reaching deficits but spare roughness discrimination abilities (Brown, J. V. *et al.*, 1983; Murray, E. A. and Mishkin, M., 1984).

There are a number of studies in humans on the deficits that occur with insults to posterior parietal cortex. These studies indicate that the most severe deficit, termed spatial hemineglect, is in coding spatial location of objects within a particular frame of reference (see Robertson, L. C. and Rafal, R., 2000; Behrmann, M., 1999, for review). While the data suggest that there are several egocentric frames of reference, including that of the forelimb or shoulder, there are little data on areas of posterior parietal cortex that contribute to these frames of reference. Furthermore, in these studies, the lesions are extremely large and encompass a number of cortical areas, and it is difficult to interpret which area is associated with which aspect of the deficit.

6.10.8.2 Connections

There are only a few studies of connections of area 5 in the macaque monkey, and those that exist are limited in scope. For example, only one study used electrophysiological guidance to place injections in area 5, and in this study, only one injection in one animal was performed, and the injection spread into area 2 (Pons, T. P. and Kaas, J. H., 1986). Furthermore, only local connections, or connections in neighboring fields, were examined. This previous investigation demonstrated connections with areas 1, 7b, S2, M1, and premotor cortex, which is a subset of the connections we describe for area 5 in titi monkeys (Padberg, J. P. *et al.*, 2005). Early studies of connections of architectonically defined area 5 to local parietal cortical areas support these recent findings in macaques (e.g., Jones, E. G. and Powell, T. P. S., 1969b; Jones, E. G. *et al.*, 1978; Pandya, D. N. and Seltzer, B., 1982). In titi monkeys, area 5 connections are widespread compared to anterior parietal fields, and some of the strongest connections of area 5 are with motor and premotor cortex, the supplementary motor area, S2, PV, extrastriate visual areas, 7b, and cingulate cortex (Figure 6; Padberg, J. P. *et al.*, 2005). Studies of vestibular processing in human and

nonhuman primates indicate that cortex at the juncture of areas 5 and 7b projects to vestibular brainstem nuclei, contains neurons that respond to optokinetic and vestibular stimulation, and is interconnected with other areas of the neocortex that process vestibular information (Akbarian, S. *et al.*, 1988; Guldin, W. O. *et al.*, 1992; Akbarian, S. *et al.*, 1993; 1994; Brandt, T. and Dieterich, M., 1999; Lobel, E. *et al.*, 1999; see Guldin, W. and Grüsser, O.-J., 1998, for review).

Most studies that examine callosal connectivity have studied total patterns of connections of large regions of cortex (e.g., Karol, E. A. and Pandya, D. N., 1971; Killackey, H. P. *et al.*, 1983), or connections of several fields grouped together such as 3a, 3b, 1, 2, and 5 collectively (e.g., Jones, E. G. and Powell, T. P. S., 1969a; Boyd, E. H. *et al.*, 1971; Jones, E. G. *et al.*, 1975; Jones, E. G. *et al.*, 1979; Shanks, M. F. *et al.*, 1985a). A consistent observation is that area 5 receives callosal inputs throughout the field (i.e., including the hand representation). There is one study in which the connections of cortex in the location of area 5 were examined, although the location of the injection site was not verified electrophysiologically (Caminiti, R. and Sbriccoli, A., 1985). In this study in macaque monkeys, label in the hemisphere contralateral to that injected was observed throughout area 5, the supplementary motor area, 7b, and on the dorsal bank of the lateral sulcus (in the S2/PV region). Our recent studies in titi monkeys indicate that the hand representation of area 5 has dense callosal connections with the contralateral area 5 in the expected location of the hand representation (Padberg, J. P. *et al.*, 2005). Area 5 in titi monkeys is also connected with areas 7b/AIP, S2/PV, motor, premotor, and cingulate cortex, a finding similar to that of Caminiti R. and Sbriccoli A. (1985). Thus, area 5 is one of the few somatosensory cortical areas involved in integrating inputs between the hands and in the interhemispheric transfer of information necessary for limb and hand coordination.

This latter notion is supported by studies of the behavioral consequences of lesions to the posterior portions of the corpus callosum through which axons from posterior parietal cortex travel (Seltzer, B. and Pandya, D. N., 1983). For example, after lesions to the posterior portion of the corpus callosum, monkeys have deficits in intermanual transfer of information about shape, roughness, or size of an object (Manzoni, T. *et al.*, 1984; Hunter, M. *et al.*, 1976; Myers, R. E. and Ebner, F. F., 1976). However, if animals were allowed to view the manual task to be transferred, thus supplying visual input regarding the task to both hemispheres, there was no noticeable deficit in information transfer across hemispheres (Kohn, B. and Meyers, R. E., 1969). Studies of tactile and tactuomotor transfer in humans who have undergone complete section of the corpus callosum or partial sections of the posterior portion of the corpus callosum indicate a number of abnormalities associated with transferring manual information regarding one hand to the opposite hemisphere. For example, complete section of the corpus callosum (Geffen, G. *et al.*, 1985) or a section in the portion of the callosum through which axons connecting the posterior parietal cortex of each hemisphere travel (Geffen, G. *et al.*, 1985; Risse, G. L. *et al.*, 1989), result in an inability to perform cross-localization, intermanual tasks (Geffen, G. *et al.*, 1985; Lassonde, M. *et al.*, 1986; Risse, G. L. *et al.*, 1989). Other studies demonstrate that with sections of the posterior corpus callosum, individuals cannot perform posture matching tasks (kinesthesis) in which they are required to match the position of one forelimb and hand with the opposite forelimb and hand in the absence of visual guidance (Risse, G. L. *et al.*, 1989). Finally, humans with sections of the corpus callosum performed poorly on the transfer of information regarding object shape, and the magnitude of the effect was dependent on the difficulty of the task (Lassonde, M. *et al.*, 1986). The studies described above in both human and nonhuman primates indicate that the connections between the posterior parietal cortex of each hemisphere, including area 5, transfer crucial information necessary for intermanual tactile learning and coordination of the hands.

Taken together, electrophysiological, connection, and lesion studies in nonhuman primates indicate that area 5 is involved in generating an egocentric, shoulder-centered frame of reference necessary for object exploration with the hands. Related abilities such as kinesthetic-visual matching, which may require an understanding of both object permanence and body part objectification, are proposed to be generated by regions in posterior parietal cortex (possibly area 5) in humans as well (see Mitchell, R. W., 2005, for review). This field also is involved in coordinating both hands to accomplish visually guided and perhaps nonvisually guided tasks and for interhemispheric transfer of information between the hands. While area 5 alone may not be responsible for generating an internal representation of the self, the activity of neurons in area 5 is coincident with tasks that require the animal to have such an internal representation, and receptive fields for neurons in

area 5 are modified in a manner consistent with alterations in the internal frame of reference.

6.10.9 Is Area 5 Homologous Across Mammals?

Throughout the text we intimated that cortex caudal to area 3b or S1 in nonprimate mammals is homologous to area 5. Although traditionally cortex immediately caudal to 3b is considered to be area 1 in nonprimate mammals such as cats, the predominant evidence for this traditional view is that this presumptive area is immediately caudal to area 3b. Furthermore, there is a tendency to make the cat somatosensory system both homologous and analogous to the primate somatosensory system, despite the fact that cats have a derived forepaw that is not used in a fashion analogous to that of the hand of primates. Indeed, Johnson J. I. (1990) states in his comparative analysis of mammal somatosensory cortex:

> Doubtless due to the great number of investigations rather than the specializations of the species, no less than five distinct somatic sensory areas have been identified and formally numbered in cat neocortex. (p. 399)

It should be noted that in a number of species in which cortex caudal to area 3b has been mapped, this cortex is rostrally adjacent to V2 (which would make it V3 if one were to assume homology based solely on relative location; Figure 9). As noted above, cortex immediately caudal to 3b, and immediately rostral to V1 or V2, has been explored using electrophysiological recording techniques in a variety of mammals and has been termed C, PP, PM, or SC. Like area 5 in primates, there is an extreme magnification of particular body parts, such that a complete representation of the body surface is often not present (Figures 10 and 11). For example, in murine rodents, this cortex is dominated by the representation of the vibrissae and in squirrels by the representation of the forepaw. In marsupials such as the striped possum, with its specialized fourth digit, this cortex represents only D4. Also like area 5 and unlike areas 1 and 2, neurons in this cortex often respond to visual stimulation as well as to stimulation of deep receptors. Species such as the flying fox have a cortical field immediately caudal to 3b in which neurons respond to cutaneous and deep stimulation, termed area 1/2 (see above). Just caudal to this region, a cortical field in which neurons respond to the stimulation of deep receptors as well as to visual stimulation has been described and termed the posterior parietal cortex or PP (Krubitzer, L. A. and Calford, M. B., 1992). While studies of connections of this caudal region of cortex in a variety of mammals would allow us to more accurately infer homology, we believe that most evidence supports the hypothesis that this field (termed C, SC, PM, and PP) is more like area 5 in primates than like area 1 or 2.

6.10.10 The Evolution of Anterior and Posterior Parietal Cortex

All mammals examined have a primary somatosensory area, S1 or 3b, in which the organization clearly reflects specializations of peripheral morphology, innervation density of peripheral receptors, and use. Furthermore, there appears to be a basic pattern of interconnections with several cortical and subcortical areas, suggesting that there is a network that has been inherited from a common ancestor but modified in different lineages with the evolution of peripheral morphology, as well as with the addition of new cortical fields and thalamic nuclei to the network. (Figures 6 and 8). While one would like to speculate as to the function of S1, most single unit recording studies in awake behaving animals and/or lesions of S1 have been done in primates, namely, macaque monkeys. Thus, these data must be interpreted with caution when discussing other species since homologous fields need not be analogous. In primates, area 3b appears to be involved in texture and form discrimination, and such discriminations are made with the glabrous hands. Although the representation of the oral structures in area 3b of primates is greatly magnified, suggesting some behavioral specialization related to the mouth, most studies only examine response to stimulation of the hand, or the activity of neurons in area 3b during discriminations made with the hand. If S1 serves as a general-purpose processor of cutaneous inputs necessary for fine discriminations using a morphologically distinct and specialized structure for a particular animal, then one would expect different magnifications of different body parts for different animals. One would also expect that the greatest variability within a species would be for the specialized body part that is used extensively, such as the hand (e.g., Merzenich, M. M. *et al.*, 1987) and lips (Cusick, C. G. *et al.*, 1986) of

primates, versus a less actively used body part such as the trunk, which appears to be the case.

Like area 3b, area 3a appears to be part of a common plan of cortical organization in all mammals (Figure 11). Area 3a is a proprioceptive area involved in integrating somatic and vestibular inputs (at least in primates) with the motor system to generate specialized behavior that allows the animal to maximally interface receptor-dense morphological structures (e.g., hand, nose, and bill) with an external object or animal to be explored. Such a sensorimotor interface likely contributes to an enlarged representation of a specialized peripheral structure not only in area 3a, but also in all anterior parietal fields. While the body part in question may be different for different animals, the same rules of modification are implemented in all mammals.

The presence of an area 1 or a rudimentary area 1 in several New World primates and macaque monkeys, and what appears to be the absence of area 1 in marmosets, tamarins, prosimian galagos, as well as other mammals, indicates that this cortical field arose later in primate evolution (Figure 11). We believe that the most parsimonious explanation for the observations made about anterior parietal cortex in a variety of primates is that in early primates, areas 3b and 3a were present. A rudimentary area 1 arose after the simian and prosimian divergence, and this was lost or greatly reduced in some lineages (e.g., Callitricidae), retained in a primitive form in some lineages (e.g., titi monkeys), or became well developed in some lineages (e.g., squirrel monkeys and macaque monkeys), possibly with the evolution of the hand and consequent tactile abilities associated with hand use. It should be noted that the two species of New World monkey (tamarins and marmosets) that do not possess an area 1 have a modified hand with claws used to a large extent for climbing, and to a lesser extent for tactile discrimination.

The functional organization of area 2 has only been investigated in one species of nonhuman primates, the macaque monkey (Pons, T. P. *et al.*, 1985). While cortex immediately caudal to area 1 has been explored in New World monkeys and prosimian galagos, neurons in this region have been reported to be unresponsive to somatic stimulation, responsive only at the caudal border of area 1, or sometimes responsive to the stimulation of deep receptors, features generally associated with area 5 in macaque monkeys. Thus, if one relies on electrophysiological mapping data, it appears that New World monkeys do not possess an area 2 (e.g., Padberg, J. P. *et al.*, 2005; Figure 11). It is tempting to postulate that area 2 arose or coevolved with the emergence of an opposable thumb and is related to the behaviors associated with using a variety of grips for tactile exploration and identification.

The presence of an area 5 in both New World and Old World monkeys, and a rudimentary form of area 5 (posterior parietal cortex) in most mammals studied, suggests that this posterior parietal field arose early in evolution and has been retained in most or all mammals (Figure 11). While area 5 may be a homologous cortical area in all mammals, the addition of new areas, such as 1 and 2, and new connections likely promotes new functions of this cortical field in primates (Figures 6 and 8). For example, PM in squirrels and PP in flying foxes may be homologous to area 5 in primates, but not strictly analogous. Much like the magnification of behaviorally relevant body parts in area 3b, in area 5 these representations and associated functions are magnified to the extreme in particular lineages. An important point of these observations in primate and nonprimate mammals is that cortical fields are not added in a functional hierarchy in evolution but rather are interspersed between existing fields. Indeed, we believe that the data indicate that areas 3a and 3b and 5 are evolutionarily old fields and that areas 1 and 2 are recent primate phenomenon, likely associated with sophisticated hand use.

With respect to the ideas put forward in the beginning of this chapter regarding the evolution of association cortex, we propose a modified scenario based on data in a variety of other mammals. In primates, unimodal somatosensory cortex has expanded with the addition of areas 1 and 2. Posterior parietal area 5 in primates, although homologous to area 5 in other mammals, has undergone a number of changes including a magnification of the hand and forelimb representation, the preponderance of neurons active under different reaching and grasping paradigms, and the broad distribution of ipsilateral and contralateral connections of the hand and limb representation with proprioceptive, limbic, and motor cortex (Figure 6). All of these features are coincident with the evolution of the hand and opposable thumb in a number of primates, as well as with a larger repertoire of grips and manual and bimanual hand configurations (Napier, J., 1960; 1962; Welles, J. F., 1976). A reasonable hypothesis is that anterior parietal cortex in primates has expanded as a result of sophisticated hand use, which distinguishes primates, and humans in particular, from other

mammals. An evolutionary old cortical area, area 5, has been modified due to the addition of these new anterior parietal fields and the evolution of highly derived manual behavior. Thus, modification of homologous cortical fields (area 5), and the addition of new unimodal cortical fields (e.g., areas 1 and 2) devoted to hand use, is one of the hallmarks of human brain evolution.

The evolution of sophisticated, visually guided, hand use and the addition of anterior parietal fields and the elaboration of posterior parietal cortical areas associated with this behavior may ultimately have led to the emergence of a more refined and species-specific internal representation of self, and an increased number of permutations of how this internal representation can interact with objects in extrapersonal space via the hands. It should be noted that this species-specific internal representation is not a static, enigmatic property that emerged in anthropoid primates alone but is a dynamic sensorimotor loop that all mammals possess in a derived form based on their morphological distinctions and distribution of sensory receptors. Studies of connections as well as electrophysiological recording data indicate that the motor system is a critical component for distinguishing self from nonself, an attribute traditionally delegated solely to association cortex. It follows then that any discussion of an internal representation of self and how an individual distinguishes itself from nonself should incorporate the motor system in this more than human phenomenon.

Glossary

choice A choice is required when an organism is confronted with alternatives for which an action is necessary to acquire or avoid one or more of the alternatives because of a desire, goal, or preference.

choice probability A trial-to-trial correlation between neuronal signals and the monkey's choice behavior.

detection The simplest perceptual experiences that is a prerequisite for any further sensory processing. In detection tasks repeated presentations of a near-threshold stimulus might unpredictably fail or succeed in producing sensory percept.

discrimination The capacity to determine the difference between two stimuli.

difference limen In flutter discrimination, the difference limen is a measure of how a small increase in the frequency of a vibrotactile stimulus can be detected when compared to a standard stimulus frequency. A smaller difference limen implies a higher discrimination capacity.

flutter A type of somatosensory stimulation that is felt when touching an object that vibrates at frequencies between ~10 and ~50 Hz.

functional magnetic resonance imaging (fMRI) The use of MRI to measure the hemodynamic response related to neural activity in the brain or spinal cord of humans or other animals. It is one of the most recently developed forms of neuroimaging.

intracortical microstimulation A neurophysiological technique that is used to activate a population of neurons within a restricted cortical locus. Pulses of electric current delivered through a microelectrode drive the activation.

memory An organism's ability to store, retain, and subsequently recall information.

neurometric curve A plot of the percentage of correct behavioral responses that an ideal observer would make on the basis of observing the neuronal responses that are elicited by a given test stimulus.

perception The process of acquiring, interpreting, selecting, and organizing sensory information. The word perception comes from the Latin *capere*, meaning to take, the prefix per meaning completely.

primary somatosensory cortex (S1) It is located in the poscentral gyrus and in the depths of the central sulcus. It consists of four functional areas: Brodmann's areas 1, 2, 3a, and 3b, each of which has a somewhat different role in somatic sensation.

Projections from the thalamus to S1 arise chiefly from the ventral posterior nucleus, are somatotopically organized, and transmit information from the contralateral body.

psychometric curve A plot of the percentage of correct behavioral responses as function of changes in the properties of the test stimulus.

psychophysics A subdiscipline of psychology dealing with the relationship between physical stimuli and their subjective correlates, or percepts.

receptive field The area of the sensory space in which stimulus presentation leads to the response of a particular sensory neuron.

receiver operating characteristic (ROC) ROC analysis is often used to evaluate the results of a detection task with weak signals. A ROC curve is generated by plotting the probability of true positives (hits) against the probability of false positives (false alarms) for a binary classifier system and its criterion is varied. In neurophysiology, it is used to test whether an ideal observer could reliably identify a given stimulus or a behavior based on a neural response.

sensory threshold A theoretical concept used in psychophysics. A stimulus that is less intense than the sensory threshold will not elicit any sensation. The concept can be applied to detection and perception in all senses. Several different sensory thresholds have been defined:

- *Absolute threshold.* The lowest level at which a stimulus can be detected.
- *Recognition threshold.* The level at which a stimulus can not only be detected but also recognized.
- *Differential threshold.* The level at which an increase in a detected stimulus can be perceived.
- *Terminal threshold.* The level beyond which a stimulus is no longer detected.

stimulus A detectable change in the internal or external environment.

top-down* and *bottom-up Strategies of information processing. The first is applied to cerebral signals that transmit information derived from past experience and the second is applied to cerebral signals that transmit sensory information.

vibrotactile stimulus A mechanical oscillation in time delivered on the skin.

Weber fraction Weber made the observation that, within a fairly large range, the increase in a stimulus that is just noticeable (ΔI) is a constant proportion of the initial stimulus (I) from any one sense. The proportion $\Delta I/I$ is the Weber fraction.

6.11.1 Introduction

A fundamental goal of neuroscience is to understand how sensory experiences arise from activity in the brain (Adrian, E. D., 1928). A major component of this problem involves understanding how the brain represents sensory features. Pioneering investigations in several sensory systems have shown how neural activity represents the physical parameters of the sensory stimuli both in the periphery and in the central areas of the brain (Mountcastle, V. B. *et al.*, 1967; Talbot, W. H. *et al.*, 1968; Hubel, D. H. and Wisel, T. N., 1998). These investigations have paved the way for new questions that are more closely related to cognitive processing. For example, where and how in the brain do the neuronal responses that encode the sensory stimuli translate into responses that encode a perceptual decision (Romo, R. and Salinas, E., 2001; Schall, J. D., 2001)? What components of the neuronal activity evoked by a sensory stimulus are directly related to perception (Newsome, W. T. *et al.*, 1989; Romo, R. *et al.*, 1998)? Where and how in the brain sensory information is stored in memory (Romo, R. *et al.*, 1999)? These questions have been investigated in behavioral tasks where the sensory stimuli are under precise quantitative control and the subject's psychophysical performances are quantitatively measured (Hernández, A. *et al.*, 1997; de Lafuente, V. and Romo, R., 2005). One of the main challenges of this approach is that even the simplest cognitive tasks engage a large number of cortical areas, and each one might render the sensory information in a different way (Romo, R. and Salinas, E., 2003; Romo, R. *et al.*, 2004). Also, the sensory information might be combined in these cortical areas with other types of stored signals representing, for example, past experience and future actions (Hernández, A. *et al.*, 2002; Romo, R. *et al.*, 2002; 2004). Thus, an important issue in neuroscience is to decode from the neuronal activity all these processes that might be related to perception.

In this chapter, we review results obtained using the somatic modalities and that are relevant for understanding the link between neural representations of sensory events in areas 3b and 1 of the

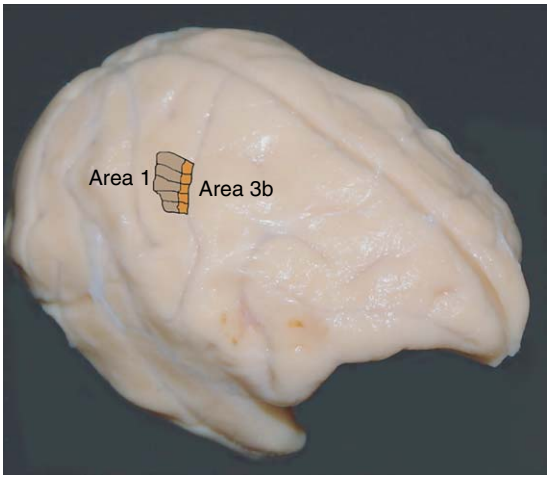

Figure 1 Picture of brain surface of one of the monkeys used to investigate the response properties of primary somatosensory cortex (S1) neurons during touch perception. Recordings were made in areas 3b and 1 of S1.

primary somatosensory cortex (S1; Figure 1) and psychophysically quantified behaviors during detection and discrimination tasks.

6.11.2 Sensory Detection

The detection of sensory stimuli is among the simplest perceptual experiences and is a prerequisite for any further sensory processing. A fundamental problem posed by the sensory detection tasks is that repeated presentation of a near-threshold stimulus might unpredictably fail or succeed in producing a sensory percept. Where in the brain are the neuronal correlates of these varying perceptual judgments? Pioneering studies on the neuronal correlates of sensory detection showed that in the case of vibrotactile stimuli the responses of S1 neurons account for the measured psychophysical accuracy (Mountcastle, V. B. *et al.*, 1969). However, direct comparisons between S1 responses and detection performance was not directly addressed and, therefore, it is not clear whether the activity of S1 accounts for the variability of the behavioral responses. Psychophysical performance was measured in human observers and S1 recordings were made in anesthetized monkeys.

6.11.3 Psychophysics of Sensory Detection

This problem has been recently addressed (de Lafuente, V. and Romo, R., 2005; 2006). These authors trained monkeys to perform a detection task. In each trial, the animal had to report whether the tip of a mechanical stimulator vibrated or not (Figure 2(a)). Stimuli were sinusoidal, had a fixed frequency of 20 Hz, and were delivered to the glabrous skin of one fingertip. Crucially, they varied in amplitude across trials. Stimulus-present trials were interleaved with an equal number of stimulus-absent trials in which no mechanical vibrations were delivered (Figure 2(a)). Depending of the monkeys' responses, trials could be classified into four types of responses: hits and misses in the stimulus-present condition, and correct rejections and false alarms in the stimulus-absent condition (Figure 2(b)). Stimulus detection thresholds were calculated from the behavioral responses (Figure 2(c)). Thus an important issue in this and similar tasks is to determine the neuronal correlates that account for these behavioral reports.

6.11.4 S1 Responses during Vibrotactile Detection

de Lafuente V. and Romo R. (2005) simultaneously characterized the activity of S1 neurons (areas 3b and 1) and the monkey's psychophysical performance by recording the extracellular spike potentials of single S1 neurons while the monkeys performed the detection task. Figures 2(c) and 3(a) show, respectively, the monkey's psychometric curve and the spike trains of an S1 neuron in the same trials. The firing rate of this example neuron varied smoothly as a function of stimulus amplitude, and no clear modulations in its firing rate could be appreciated during the stimulus-absent trials.

To test whether the responses of S1 neurons accounted for the monkey's psychophysical performance, de Lafuente V. and Romo R. (2005) calculated neurometric detection curves and compared them with the psychometric curves (Figures 3(b) and 3(c)). The proportion of yes responses for neurometric curves was defined, for a given amplitude, as the proportion of trials in which the neuron's firing rate reached or exceeded a criterion value (Green, D. M. and Swets, J. A., 1966;

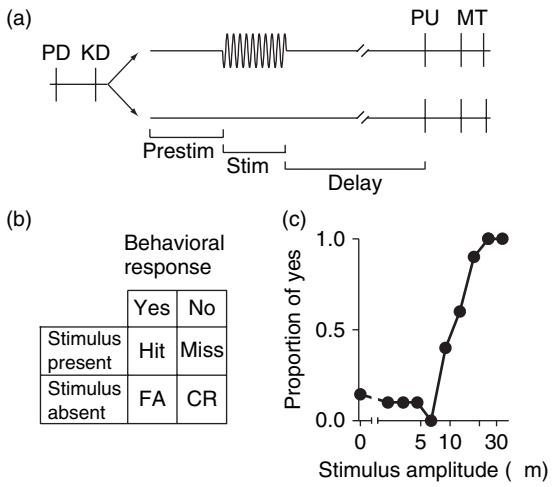

Figure 2 Detection task. (a) Trials began when the stimulator probe indented the skin of one fingertip of the right, restrained hand (probe down, PD). The monkey then placed its free left hand in an immovable key (key down, KD). On half of the randomly selected trials, after a variable prestimulus period (2.5–3.5 s), a vibratory stimulus (20 Hz, 0.5 s) was presented or not. Then, after a fixed delay period (3 s), the stimulator probe moved up (probe up, PU), indicating to the monkey that the response movement (MT) to one of the two push buttons could be made. The button pressed indicated whether the stimulus was felt or not (henceforth referred to as yes and no responses, respectively). (b) Depending on whether the stimulus was present or absent, and on the behavioral response, the trial outcome was classified as a hit, miss, false alarm, or correct rejection. Trials were pseudorandomly chosen; 90 trails were stimulus-absent (amplitude = 0) and 90 trials were stimulus-present with varying amplitudes (9 amplitudes with ten repetitions each). (c) Classical psychometric detection curve obtained by plotting the proportion of yes responses as a function of stimulus amplitude. Adapted from de Lafuente, V. and Romo, R. 2005. Neuronal correlates of subjective sensory experience. Nat. Neurosci. 12, 1698–1703.

de Lafuente, V. and Romo, R., 2005). For each neuron, this criterion was chosen to maximize the number of correct responses (Figure 3(b)). Pairwise comparisons of detection thresholds obtained from logistic fits to the simultaneously obtained neurometric and psychometric data showed that the detection thresholds of individual S1 neurons were not significantly different from the animals' psychophysical thresholds, and the two thresholds measures highly covaried. In addition, the shape of the mean neurometric curve resulting from the activity of the S1 neurons showed close correspondence with the shape of the mean psychometric curve (Figure 3(c)).

6.11.5 S1 Responses and Perceptual Reports

An important question addressed in this study is whether the activity of S1 neurons covaries with the perceptual yes–no judgments that the monkeys made on a trial-by-trial basis (de Lafuente, V. and Romo, R., 2005). To test this, these authors compared the activity during hit and miss trials for the near-threshold stimulus as well as for the corresponding activity in correct reject and false alarm trials in the stimulus-absent condition (Figure 4). They found no significant differences in the activity of S1 neurons between hits and misses (Figure 4, upper left panel) or between correct rejections and false alarms (Figure 4, upper right panel). This indicated that the activity of individual S1 neurons did not predict the monkey's behavior. To further quantify this, de Lafuente V. and Romo R. (2005) calculated a choice probability index, which estimates the probability with which the behavioral outcome can be predicted from the neuronal responses (Britten, K. H. *et al.*, 1996; Hernández, A. *et al.*, 2002). As shown in the lower panels of Figure 4, again they found no significant differences between hits and misses, or between correct rejections and false alarms trials.

6.11.6 Further Comments on the Functional Role of S1 in Sensory Detection

The low choice probability values are consistent with a detection model in which the activity of S1 serves as input to an additional processing stage(s) that determines whether a stimulus has occurred or not. Under this hypothesis, correlation between S1 activity and the final decision about the stimulus presence or absence is highly dependent on the amount of correlated noise among sensory neurons (Zohary, E. *et al.*, 1994). Indeed, de Lafuente V. and Romo R. (2005) found that the mean noise correlation coefficient across pairs of S1 neurons was 0.16 ± 0.02. This amount of correlated noise is similar to those reported in previous studies (Zohary, E. *et al.*, 1994; Bair, W. *et al.*, 2001; Romo, R. *et al.*, 2003), and is also consistent with the near chance choice probability values reported in the study of de Lafuente V. and Romo R. (2005). These results further support a detection model in which a central area(s) must be observing the activity of S1 neurons to judge about the stimulus

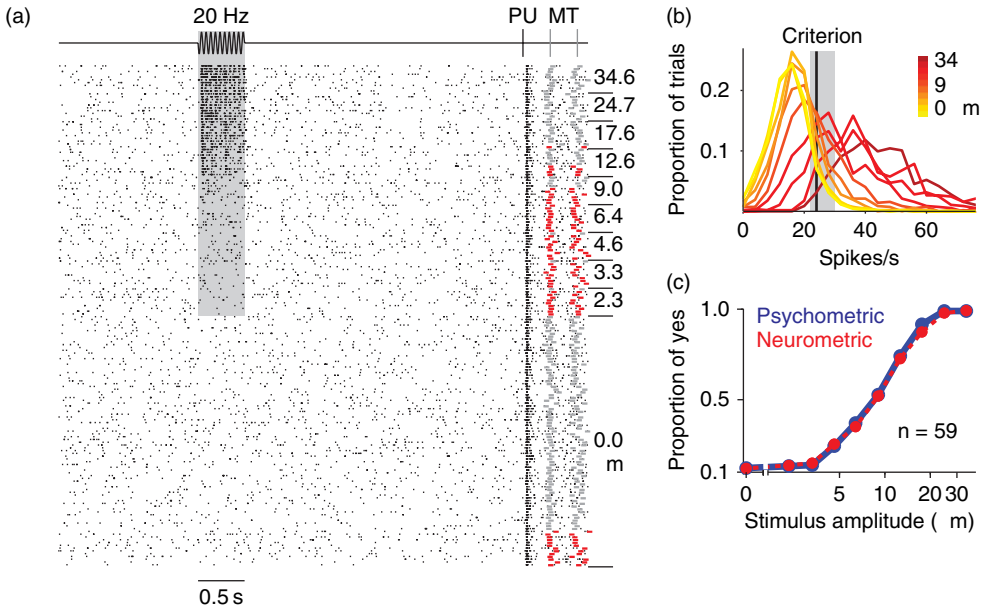

Figure 3 Activity of primary somatosensory cortex (S1) neurons during the detection task. (a) Raster plot of the spiking activity of an S1 neuron during the 180 trials of a typical detection experiment run. Each tick represents the time of spike occurrence and each row is a trial. Trials are arranged by stimulus amplitude, shown at right. Red markers at the end of the trial denote misses in stimulus-present trials, and false alarms in stimulus-absent trials. Gray box marks the time of stimulus presentation. (b) Activity distributions of the 59 neurons recorded in S1, grouped by stimulus amplitude (see calibration bar). Black vertical line marks the median criterion value (22 spikes per second) used to produce the neurometric proportion of yes for each neuron. Gray box indicates interquartile range. (c) Mean psychometric and neurometric detection curves (590 trials for each stimulus amplitude data point; 5310 trials for zero-amplitude data point). Adapted from de Lafuente, V. and Romo, R. 2005. Neuronal correlates of subjective sensory experience. Nat. Neurosci. 12, 1698–1703.

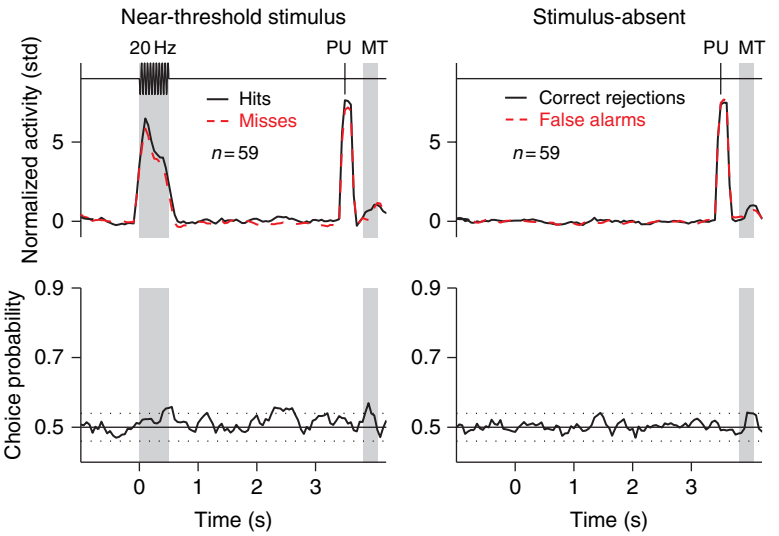

Figure 4 Correlation between psychophysical performance and neuronal responses during the detection task. Upper panels show the comparison of normalized neuronal population activity during hits and misses for near-threshold stimuli, and during correct rejections and false alarms in stimulus-absent trials. Lower panels show the choice probability index as a function of time. This index estimates the probability with which a trial's outcome can be predicted from the activity of neurons. Dotted lines mark significance levels (0.5 means chance levels) and *n* is the number of neurons. Adapted from de Lafuente, V. and Romo, R. 2005. Neuronal correlates of subjective sensory experience. Nat. Neurosci. 12, 1698–1703.

presence or absence. Therefore, the functional role of S1 in this and other perceptual tasks may be mainly to generate a neural representation of the sensory stimulus for further processing in areas central to it (Romo, R. *et al.*, 1999; Hernández, A. *et al.*, 2000; Salinas, E. *et al.*, 2000; Romo, R. *et al.*, 2002; 2003). However, a previous study found that functional magnetic resonance imaging (fMRI) signals in primary visual cortex (V1) reflected the percepts of human subjects rather than the encoded stimulus features (Ress, D. and Heeger, D. J., 2003). This result suggests that in V1 top-down signals (nonsensory inputs delivered to V1 via feedback projections) can be combined with bottom-up (sensory) information and this can contribute to sensory percepts (Ress, D. and Heeger, D. J., 2003). S1 data did not show evidence of this type of neural interaction; rather, they indicated that S1 represents the physical properties of stimuli and contributes little to near-threshold percepts (de Lafuente, V. and Romo, R., 2005). The discrepancy could be due to fundamentally different organizations across sensory cortices, or to differences between species. Another possibility to consider is that the modulation revealed through fMRI may have an effect that is invisible from the point of view of single neurons. This would happen if, for instance, such modulation acted only to synchronize the spikes of multiple target neurons (Fries, P. *et al.*, 2001a; 2001b).

6.11.7 Sensory Discrimination

The sensory detection task discussed above addressed the fundamental problem of whether the activity of S1 accounts for sensory detection. The results indicate that the S1 responses do not account for perceptual judgments in the detection task. However, there are reports suggesting a role for early sensory cortices in cognitive functions previously asigned to more central cortices. A more interesting cognitive task – sensory discrimination – was introduced by Mountcastle and colleagues several years ago (LaMotte, R. H. and Mountcastle, V. B., 1975; Mountcastle, V. B. *et al.*, 1990), and served to further explore the role of sensory cortices in perception. In the discrimination task they designed (LaMotte, R. H. and Mountcastle, V. B., 1975; Mountcastle, V. B. *et al.*, 1990), animals had to indicate whether the frequency of a comparison stimulus was lower or higher than the frequency of a base stimulus presented earlier (Figure 5). In principle, the task can be conceptualized as a chain of neural operations or cognitive steps: encoding the first stimulus frequency, maintaining it in working memory, encoding the second frequency and comparing it to the memory trace left by the first stimulus, and communicating the result of the comparison to the motor apparatus. Thus the flutter task offers a number of advantages as a model for sensory processing in the brain (Romo, R. and Salinas, E., 2001; 2003): not only do humans and monkeys perform similarly, but the items to be compared are spread out across time and always activate the same well-defined population of primary receptors (Mountcastle, V. B. *et al.*, 1967; Talbot, W. H. *et al.*, 1968; Ochoa, J. and Torebjörk, E., 1983; Macefield, G. *et al.*, 1990; Vallbo, A. B., 1995). So spatial variations are basically taken out of the picture. However, for the flutter task to be a useful model it is essential that it generate a reliable sequence of cognitive events like the one just mentioned. How do we know that this is so?

A crucial step is to scrutinize the psychophysics. Importantly, in the original paradigm the base frequency did not vary from trial to trial during a run (LaMotte, R. H. and Mountcastle, V. B., 1975; Mountcastle, V. B. *et al.*, 1990). When Romo and colleagues reexamined the flutter discrimination task, they found the paradigm to be ambiguous: when the base stimulus frequency is kept constant, the task can be solved either by comparing the two stimuli or by categorizing the second stimulus as high or low, ignoring the base stimulus (Hernández, A. *et al.*, 1997). What were the monkeys actually doing? When the base frequency was held constant during long blocks of trials, as done originally, the measured discrimination limens (DLs) and Weber fractions were similar to those reported before. If the monkeys had been discriminating the differences in frequency between the two stimuli, they would also have been able to do so when the frequency of the base stimulus changed from trial to trial. However, this was not the case: their performance dropped to chance levels. It seemed that the monkeys were paying attention only to the second stimulus, categorizing it as low or high with respect to an internal reference, perhaps the base frequency used during training. To test this possibility, in separate runs the base stimulus was removed and single stimuli were delivered in each trial. In this new condition the monkeys were rewarded for correctly categorizing stimulus frequency as lower or higher than an arbitrary reference (20, 30, or 40 Hz) kept constant during a block of trials; monkeys had to determine this reference by trial and error. The monkeys learned this task very quickly, and the

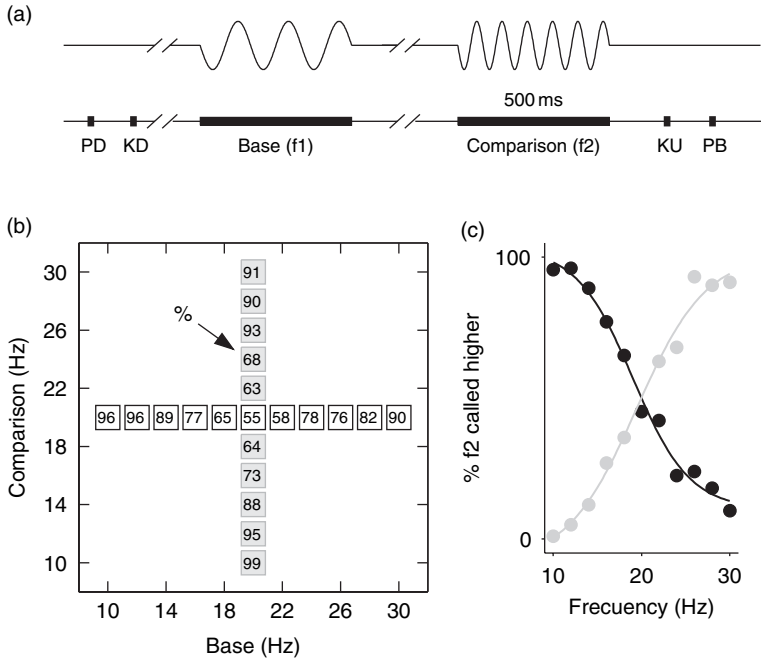

Figure 5 Discrimination task. (a) Sequence of events during discrimination trials. The mechanical probe is lowered, indenting the glabrous skin of one digit of the hand (PD); the monkey places his free hand on an immovable key (KD); the probe oscillates vertically, at the base frequency; after a delay, a second mechanical vibration is delivered at the comparison frequency; the monkey releases the key (KU) and presses one of two push buttons (PB) to indicate whether the comparison frequency was higher or lower than the base. (b) Stimulus set used to estimate psychometric thresholds. Each box indicates a base frequency/comparison frequency stimulus pair used; the number inside the box indicates overall percent correct trials for that base/comparison pair. (c) Psychometric curves computed from (b). Adapted from Romo, R., Hernández, A., Zainos, A., Brody, C. D., and Lemus, L. 2000. Sensing without touching: psychophysical performance based on cortical microstimulation. Neuron 26, 273–278 and Romo, R., Hernández, A., Zainos, A., and Salinas, E. 1998. Somatosensory discrimination based on cortical microstimulation. Nature 392, 387–390.

psychometric curves (Hernández, A. *et al.*, 1997) measured in this condition were practically identical to those measured during the classical discrimination task (Mountcastle, V. B. *et al.*, 1990).

For true discrimination, monkeys were retrained using multiple pairs of base and comparison frequencies. The key was to vary the base frequency in each trial but such that each frequency could be followed either by a higher or by a lower comparison; this forced the subjects to compare (Hernández, A. *et al.*, 1997). After retraining, which took a few months, performance in this situation was similar to that in the classical discrimination task. From these results it seems almost certain that the animals truly learned to discriminate between frequencies on a trial-by-trial basis.

The lesson is that although monkeys may indeed learn to discriminate they can also develop alternate strategies to solve a task, as suggested earlier based on theoretical arguments (Johnson, K. O., 1980). In particular, in the classical flutter discrimination paradigm, monkeys tend not to compare the two stimuli at every trial; instead they classify the second stimulus, possibly setting the limits of each category during the first few trials in a run. Whenever animals are assumed to discriminate, this problem should not be underestimated, regardless of sensory modality (Johnson, K. O., 1980; Vogel, R. and Orban, G., 1990; Vázquez, P. *et al.*, 2000).

This appears as a simple observation, but it may reflect fundamentally different mechanisms at work. Consider a task that involves variations in a single feature across trials. To identify or classify a current sensory stimulus, it must be compared to a reference stored in long-term memory, but it is not clear how the comparison process can be studied in this situation. How is information stored in long-term memory read out and made comparable to current sensory events? Where is this information stored and how does it differ from the original sensory-evoked activity? In contrast, in discrimination tasks in which two stimuli are presented sequentially in each trial, the

comparison is made against the short-term memory trace left by the first stimulus. This means that if we can identify the neural correlate of the working-memory component, it might be possible to study the comparison or decision-making mechanisms that underlie task performance. Indeed, such neural correlate has been reported recently (Hernández, A. *et al.*, 2002; Romo, R. *et al.*, 2002; 2004).

6.11.8 Neural Coding of Vibrotactile Stimuli in S1

Mountcastle and colleagues recorded S1 responses in behaving monkeys trained to detect and discriminate the frequencies of flutter stimuli (Mountcastle, V. B. *et al.*, 1990). The results support previous findings (Mountcastle, V. B. *et al.*, 1969). First, it was found that quickly adapting (QA) neurons of S1 (areas 3b and 1), like their afferent fibers, fire periodically, in phase with mechanical oscillations. Second, their firing rates seem to change little in the flutter range (this conclusion was based, however, on data from 17 neurons). Third, psychophysical performance matched the inferred performance based on the discriminability of the periodic interspike intervals (Mountcastle, V. B. *et al.*, 1990). It followed that, as proposed before, stimulus frequency could not be encoded by S1 firing rates; stimulus frequency had to be encoded temporally, in the serial order of evoked spikes (Talbot, W. H. *et al.*, 1968; Mountcastle, V. B. *et al.*, 1969; 1990).

In support of this proposal, using flutter stimuli, Merzenich and colleagues compared psychophysical data from monkeys to S1 recordings in separate experiments from the same animals (Recanzone, G. H. *et al.*, 1992). The comparison was consistent with a temporal coding mechanism, and firing rates were not seen to vary with stimulus frequency (however, the range of frequencies tested was quite narrow, and animals were anaesthetized). Merzenich and colleagues made another important observation: that spike timing associated with the sine wave was much more precise in trained animals than in untrained monkeys (Recanzone, G. H. *et al.*, 1992). Thus, based on these results, a psychophysical observer should exploit the periodic, spike timing evoked in the QA neurons of the S1 cortex for sensory discrimination.

Arguments in favor of the proposal reviewed above can be strengthened if a large number of neurons are studied and if neurons are studied in behaving animals during the flutter discrimination task. To this end, Romo and colleagues trained monkeys to discriminate between flutter stimulus frequencies and recorded many neurons with QA properties in areas 3b and 1 of S1 (Hernández, A. *et al.*, 2000; Salinas, E. *et al.*, 2000; Luna, R. *et al.*, 2005). Each recorded neuron with QA properties was studied during the discrimination task. There were three major results. First, the majority of neurons from S1 were phase-locked to the input stimulus frequency (Figures 6(a) and 6(b)); however, almost a third of QA neurons modulated their firing rates as a function of the stimulus frequency (Figures 7(a) and 7(b); Hernández, A. *et al.*, 2000; Salinas, E. *et al.*, 2000; Luna, R. *et al.*, 2005). Second, the QA neurons that modulate their firing rates were affected by the task condition; that is, they increased their transmitted information about the stimulus frequency during task performance (Salinas, E. *et al.*, 2000). Third, only those neurons that varied their firing rates as a function of the stimulus frequency were affected in error trials (Salinas, E. *et al.*, 2000).

These findings question a unique role of periodic, spike timing in discrimination of flutter stimuli, and suggest that a firing rate code cannot be discarded (Salinas, E. *et al.*, 2000). But, apart from this, what do these findings suggest? They suggest the presence of two subpopulations of QA neurons in S1 that behave differently in response to a periodic mechanical stimulus (Hernández, A. *et al.*, 2000; Salinas, E. *et al.*, 2000; Luna, R. *et al.*, 2005). These two subpopulations might be arranged in a hierarchical fashion: QA neurons that respond periodically might be closer to the input stimulus, and those that modulate their firing rates might integrate the responses of the periodic neurons and transform them into a rate code (Hernández, A. *et al.*, 2000). Such last-order neurons of the QA circuit could distribute the neural representation to those structures anatomically linked to S1, in order to solve the sensory discrimination task. However, further studies are needed to see whether this is so.

6.11.9 Neuronal Correlates of Flutter Discrimination in S1

A more direct test for the role of periodicity in flutter discrimination is measuring the discrimination capabilities of these subtypes of QA neurons associated with the psychophysical performance (Figures 6(c) and 6(d) and Figures 7(c) and 7(d)). A second test is to prove whether the evoked neural activity during discrimination in S1 cortex is sufficient for sensory performance. Finally, whether the temporal order of the spikes is important for sensory discrimination. These are

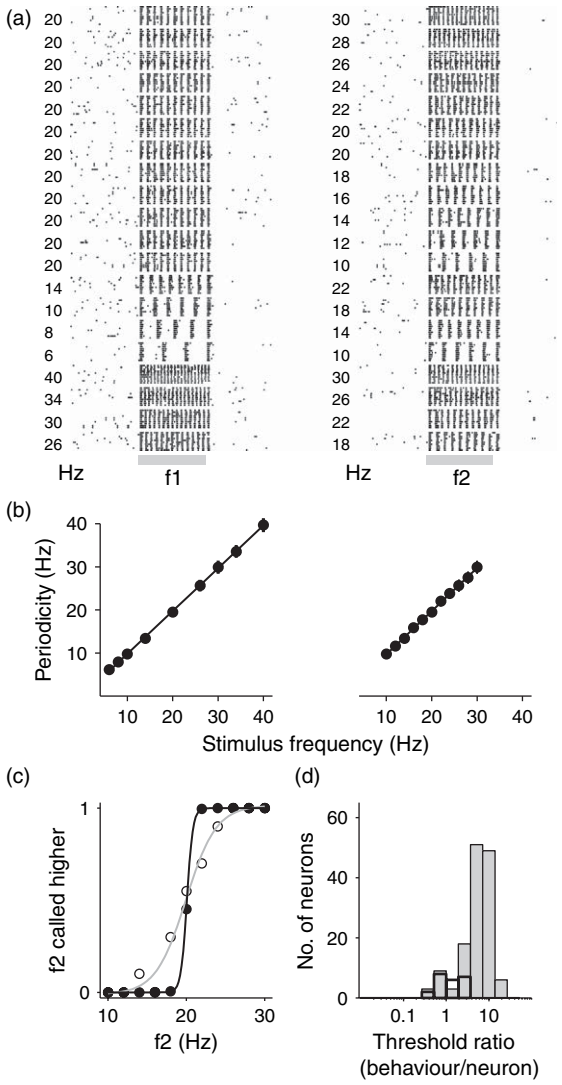

Figure 6 Periodic responses of a quickly adapting (QA) neuron of area 1 during the discrimination task. (a) Raster plots. Each row of ticks represents a trial, and each tick represents an action potential. Trials were randomly delivered. Gray horizontal lines indicate the first (f1) and the second (f2) stimulus. (b) Periodicity (±SD) as a function of the first (f1) and second stimulus (f2) frequencies. (c) Relationship between psychometric and neurometric discrimination functions. This is plotted as the probability that the second stimulus is judged higher than the first; data and sigmoidal fits (χ^2 test, $P < 0.001$) for 11 pairs of stimulus frequencies in which the base frequency was 20 Hz. Gray and black lines represent psychometric and neurometric functions, respectively. (d) Thresholds ratios (psychometric/neurometric thresholds) calculated from neurons with periodicity (gray bars). Open bars represent the threshold ratios between psychometric and neurometric thresholds calculated from a small number of neurons with modulations in their firing rate. incisive tests to validate the meaning of the neural encoding of the flutter stimuli in the S1 cortex.

The vibrotactile discrimination task requires the comparison of the second stimulus frequency against the first (Hernández, A. *et al.*, 1997). As indicated above, Romo and colleagues found two types of responses in QA neurons of the S1 cortex: one that is periodically entrained by the stimulus frequency, and a second that, although not periodically entrained, has average firing rates during the stimulus period that are modulated as a function of the stimulus frequency (Hernández, A. *et al.*, 2000; Salinas, E. *et al.*, 2000; Luna, R. *et al.*, 2005). To investigate which of these two representations is associated with the psychophysical performance, these authors determined the probability that an observer (a cortical region central to S1 cortex) could distinguish the difference between the two stimuli (Hernández, A. *et al.*, 2000; Salinas, E. *et al.*, 2000; Luna, R. *et al.*, 2005). This could be based on a comparison of the neuronal response distributions of the second stimulus frequency made against the neuronal response distributions of the first stimulus frequency. According to this, the observer could use a simple rule: if the number of spikes during the second stimulus is higher than during the first stimulus, then the second stimulus is higher than the first. The same rule can be used when considering the periodicity values: if the periodicity (estimated as the frequency with greatest power in a Fourier transform of the spiking responses) during the second stimulus period is higher than during the first stimulus period, then the second stimulus is higher than the first. The effect of this type of rule is equivalent to determining the area under the curve ROC (receiver operating characteristic; Green, D. M. and Swets, J. A., 1966) generated by the neuronal response distributions for each pair of stimulus frequencies, using both periodicity and firing rate values (Hernández, A. *et al.*, 2000; Luna, R. *et al.*, 2005). The areas under each of these two ROC curves are an estimate of the proportion of correct trials that an optimal observer would obtain by comparing the number of spikes or periodicity. In pairs of stimulus frequencies where the neuronal response distributions during the second stimulus are much higher than the neuronal distributions of the first stimulus, ROC values are close to 1; if the neuronal response distributions during the stimulus are much lower than the neuronal response distributions of the first stimulus, ROC values are close to 0; for overlapping distributions, intermediate ROC values are found. The ROC values were then used to compute neurometric functions. Psychophysical and neuronal discrimination thresholds are calculated as half the difference between the stimulus frequency identified as higher than the standard in 75% of trials and that frequency identified as higher in 25% of the trials. These are read directly from the logistic functions expressed in terms of hertz. Using this analysis, Romo and colleagues are in the position to address the question of which of the two representations is meaningful for frequency discrimination.

Neurometric functions based on periodicity (Figures 6(c) and 6(d)) or firing rate (Figures 7(c) and (d)) of single S1 neurons were directly compared to the psychometric thresholds (Hernández, A. *et al.*, 2000). The results of this analysis show that neurometric threshold values based on periodicity are far lower than the psychometric thresholds (Figure 6(d)). This is not the case when neurometric thresholds based on firing rate are compared to the psychometric thresholds (Figure 7(d)). They are very close to the psychometric thresholds. The goal of computing neurometric functions was not only to reveal the relationship between the neuronal responses of S1 to the mechanical stimulus, but also to discern whether these neural signals account for the psychometric behavior. However, what is then the functional meaning of the periodic neural signal in S1? One possible role is that they simply represent the temporal structure of the stimulus and that monkeys do not use this exquisite representation for frequency discrimination. This would be the case if, for example, discrimination were based on the mean number of spikes (or bursts) fired by the population of QA neurons as a function of the stimulus frequency. Consistent with this idea, Hernández A. *et al.* (2000) found that QA neurons in S1 whose firing rates are modulated by the stimulus frequencies and their neurometric thresholds based on firing rates are closely similar to the monkey's psychophysical thresholds. However, these correlations do not prove they are sufficient for discrimination (Romo, R. *et al.*, 1998; 2000).

One experiment that could give an insight about the functional meaning of the periodic spike structure of the evoked activity in S1 is testing whether monkeys could discriminate the difference between the two stimuli when periodicity is broken. If monkeys fail to discriminate the difference in mean frequency between the two stimuli, this would strengthen the proposal that discrimination of flutter stimuli depends on the periodic structure of the spike trains evoked in S1 (Figure 8). However, monkeys were able to extract the mean frequency from the nonperiodic signals and the psychophysical measures were almost identical with the periodic stimuli (Romo, R. *et al.*, 1998).

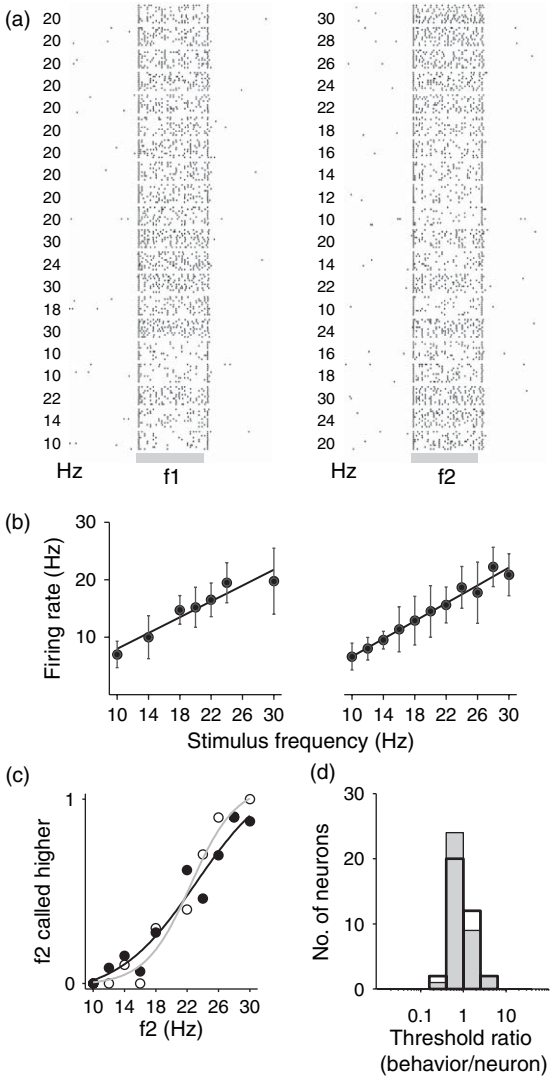

Figure 8 Firing rate modulation of a quickly adapting (QA) neuron of area 1 during the discrimination of aperiodic stimuli. Same format as in Figure 6, but both base (f1) and comparison (f2) frequencies (mean frequencies) lack periodicity. (a) Raster plots. (b) Mean firing rate (±SD) as a function of the stimulus frequency. (c) Relationship between psychometric and neurometric discrimination functions. (d) Threshold ratios calculated between psychometric and neurometric thresholds for each neuron during the discrimination of a periodic stimulus frequencies (open bars). Gray bars represent threshold ratios between psychometric and neurometric thresholds during the discrimination of aperiodic frequencies. Adapted from Hernández, A., Zainos, A., and Romo, R. 2000. Neuronal correlates of sensory discrimination in the somatosensory cortex. Proc. Natl. Acad. Sci. U. S. A. 97, 6091–6096.

Romo and colleagues then studied QA neurons in each of the two conditions: while monkeys discriminated between periodic stimuli and while monkeys discriminated between aperiodic stimuli (Hernández, A. *et al.*, 2000). Due to the aperiodic stimulus design, even highly stimulus-entrained neurons do not carry information about stimulus frequency in their periodicity. Clearly, neurometric thresholds based on the firing rate were again closely associated with the psychometric thresholds (Figures 8(c) and 8(d)). As in the periodic condition, a psychophysical observer could exploit firing rate for frequency discrimination of aperiodic stimuli. These results suggest that an observer could solve this task with a precision similar to that of the monkey, based only on the firing rate produced during the stimulus periods.

There are, however, some further unexplored possibilities. For example, QA neurons of S1 typically respond to each stimulus pulse with a discrete burst of spikes. Encoding of vibrotactile stimuli could therefore be based on the number or rate of events, where each event is defined as a burst instead of being defined as a single spike. An observer counting bursts would obtain a good estimate of the count of stimulus pulses, and this estimate would be independent of variability in the number of spikes fired in response to each pulse. Indeed, there is experimental evidence suggesting that bursting activity could efficiently encode the stimulus features (Reinagel, P. *et al.*, 1999; Martínez-Conde, S. *et al.*, 2000; Kepecs, A. *et al.*, 2002; Krahe, R. and Gabbiani, F., 2004). But whether bursting actually contributes directly to the psychophysical behavior is not known. Finally, the temporal window on which vibrotactile discrimination is based has not been determined. In previous experiments carried out by Romo and colleagues, stimulus periods were always 500 ms long. Under these conditions, the use of a code based on counting events and the use of a code based on the rate of events could not be distinguished.

To distinguish between all these alternatives, Romo and colleagues conducted new combined psychophysical and neurophysiological experiments in the vibrotactile discrimination task (Luna, R. *et al.*, 2005). They reasoned that if an observer uses a firing rate, a bursting rate, or a measure of periodicity, then increases or decreases in the duration of either of the two stimuli used in each trial of the task should not lead to a systematic bias in discrimination, in either of the two possible directions. (On the other hand, under this hypothesis, stimulus duration could affect the sensory signal-to-noise ratio and therefore affect the psychometric threshold.) Alternatively, if the observer uses a strategy based on the total number of spikes or bursts fired in response to each stimulus, then manipulation of

the stimulus duration should systematically bias performance, with longer stimuli being perceived as having been of higher frequencies than they actually were. Romo and colleagues found that when the duration of one of the two stimuli was changed by 50% relative to the other stimulus, monkeys indeed biased their discrimination performance (Luna, R. *et al.*, 2005). Monkeys treated shortened stimuli as if the applied stimulus frequency had been slightly but significantly lower than it actually was; conversely, monkeys treated lengthened stimuli as if the applied frequency had been slightly but significantly higher than it actually was. These effects were observed with both periodic and aperiodic stimuli. These investigators then sought an explanation for these psychophysical biases by recording QA neurons of S1 while the monkeys performed in variable-stimulus-length conditions (Luna, R. *et al.*, 2005). They found that the effects can be qualitatively explained if one assumes that the neural signal used by the observer to solve the task is an integral of either spikes or bursts over a time window that concentrates most of its mass within the first 250 ms of the stimulus, but also has a small tail into later parts of the stimulus. Finally, examining trial-by-trial covariations of weighted counts of spikes and weighted counts of bursts, they found that only the weighted count of spikes covaried with performance on a trial-by-trial basis.

In summary, firing rates that vary as functions of stimulus frequency are seen in multiple areas activated during the task, in particular in S1, and there is evidence that these rate variations have a significant impact on behavior. Clearly, the brain must be able to extract at least some information from the precise timing of S1 spikes evoked during the task; for instance, humans can easily distinguish periodic stimuli from aperiodic. However, Romo and colleagues found no indication that the high periodicity found in S1 contributes to frequency discrimination, although this possibility is hard to rule out entirely.

6.11.10 Artificial Induction of Activity in S1 Underlying Flutter Discrimination

How can we be sure that the activity recorded in S1 is actually related to perception and behavior? Intracortical microstimulation is a powerful technique capable of establishing a causal link – not just a correlation – between the activity of localized neuronal populations and specific cognitive functions (Salzman, D. *et al.*, 1990; Britten, K. H. and van Wezel, R. J., 1998; Romo, R. *et al.*, 1998; 2000). For flutter discrimination, this approach has provided the most compelling evidence that all the cognitive processes of the task may be triggered directly by the QA circuit in S1, and has also allowed us to explore questions about the neural code for flutter stimuli (Romo, R. *et al.*, 1998; 2000). Importantly, S1 is organized in modules of neurons sharing the same receptive field and mechanoreceptor submodality (Mountcastle, V. B., 1957; Powell, T. P. S. and Mountcastle, V. B., 1959; Sur, M. *et al.*, 1984). The experiments described below were aimed to drive a column(s) of S1 – mostly of the QA type – in a way that matched the dynamic responses recorded when mechanical stimuli were applied to a patch of skin of the fingertips.

Initially, the idea was to manipulate the comparison stimulus only (Romo, R. *et al.*, 1998). The monkeys first learned to discriminate the frequencies of two sinusoidal vibrations delivered successively to the fingertips. Once they mastered the task, neurophysiological recordings were made in area 3b of S1, which allowed the identification of clusters of QA neurons. An applied microstimulation current spreads around a certain cortical area, activating many neighboring units. Thus, a key for the success of microstimulation experiments is that the microelectrode must be located in the midst of a functionally homogeneous cluster of neurons. Fortunately, area 3b is indeed organized into modules of units with similar properties, or into columns (Sur, M. *et al.*, 1984). So, after the identificaton of a set of QA neurons, the comparison stimulus was substituted with microstimulation in one half of the trials. Artificial stimuli consisted of periodic current bursts delivered at the same comparison frequencies as mechanical stimuli. Microstimulation sites in S1 were selected to have QA neurons with receptive fields on the fingertip at the location of the mechanical stimulating probe. Remarkably, the monkeys discriminated the mechanical (base) and electrical (comparison) signals with performance profiles indistinguishable from those obtained with mechanical stimuli only (Figure 9(a)), so the artificially induced sensations probably resembled natural flutter quite closely (Romo, R. *et al.*, 1998).

Going back to the question of whether periodicity is crucial for frequency discrimination, Romo and colleagues applied aperiodic microstimulation patterns that mimicked the random trains of mechanical pulses discussed earlier (Figure 9(b)). The same mean frequencies were used in this condition – 20 Hz still corresponded to 10 current bursts delivered

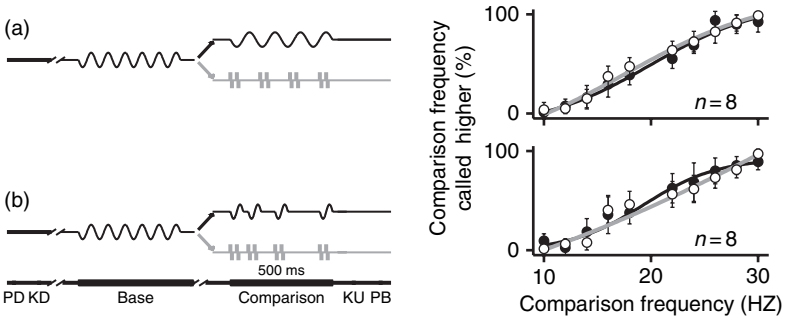

Figure 9 Psychophysical performance in frequency discrimination with natural mechanical stimuli and with artificial electrical stimuli injected into clusters of quickly adapting (QA) neurons of area 3b. The diagrams on the left show two types of trials that were interleaved during the experiments. In half of the trials, the monkeys compared two mechanical vibrations delivered on the skin. In the other half, one or both stimuli could be replaced by electrical frequencies microinjected into clusters of QA neurons of area 3b. The curves on the right show the animals' performance in the different situations, illustrated on the left. Filled and open circles indicate mechanical and electrical stimuli, respectively. In (a) and (b), the *y*-axis corresponds to the percentage of times the monkeys called the second stimulus frequency (*x*-axis) higher than the first (20 Hz). (a) Psychophysical performance using periodic stimuli; the comparison stimulus could be either mechanical or electrical frequencies. (b) Psychophysical performance when the comparison stimulus could be either aperiodic, mechanical or electrical stimulus frequencies. PD, indentation of the glabrous skin by the mechanical probe; KD, detection of indentation; KU, detection of the end of the comparison stimulus; PB, the monkeys presses one of two push buttons to indicate whether the second stimulus frequency was higher or lower than the first. in 500 ms – but the bursts were separated by random time intervals. Everything else proceeded as before, with mechanical and stimulation trials interleaved, as indicated in Figure 9(b). From the very first trials, the animals were able to discriminate both mechanical and electrical aperiodic signals (Figure 9(b)), with practically the same performance level reached with mechanical, periodic vibrations (Romo, R. *et al.*, 1998).

An interesting effect was observed as the intensity of the microstimulation current was varied. At very low intensities, artificial stimuli were not detected; the monkeys simply kept waiting. At intermediate intensities the monkeys detected the stimuli – they reacted and pushed a button – but their psychophysical behavior was at chance levels, as if they could determine the presence but not the frequency of the artificial stimuli. At higher intensities they discriminated normally (Romo, R. *et al.*, 1998). These transitions parallel those observed when the amplitude of mechanical vibrations is gradually increased; in particular, there is an atonal interval in which stimuli can be detected but their frequencies cannot be ascertained (LaMotte, R. H. and Mountcastle, V. B., 1975; Mountcastle, V. B. *et al.*, 1990). In an extra control experiment these authors investigated the effect of stimulus amplitude, which could potentially act as an alternate discrimination signal (Romo, R. *et al.*, 1998). Four frequency pairs and all stimuli were mechanical, and the other half of the comparison stimulus was electrical. In both cases, the amplitude of the comparison could take one of three values, a standard amplitude A, 0.6A, or 1.4A. The changes in amplitude were, in terms of percentage, of the same magnitude (40%) as the differences between base and comparison frequencies. The results showed that performance was not affected by the large variations in amplitude; had the monkeys been guided by the amplitudes changes, one of the three combinations for each frequency pair would have fallen to <25% correct, because performance was normally >75% correct. Amplitude corrections, like those mechanical stimuli, were also applied to electrical currents in ~60% of all runs; they had no marked impact on performance (Romo, R. *et al.*, 1998).

Because of the design of the paradigm, comparison of the second stimulus is made against a memory trace of the first one (Hernández, A. *et al.*, 1997). Having shown that the monkeys could use an artificial stimulus during the comparison, Romo and colleagues wondered whether they would be able to memorize and use an electrical stimulus delivered during the base period (Romo, R. *et al.*, 2000). In this case, in one half of the trials the base stimulus consisted of electrical microstimulation at a frequency equal to f1 (Figure 10), with the electric

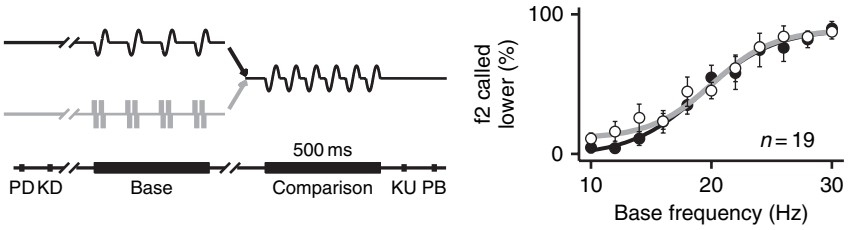

Figure 10 Psychophysical performance when the base stimulus could be either periodic, mechanical or electrical stimulus frequencies injected into clusters of quickly adapting (QA) neurons in area 3b. The same protocols and labels as in Figure 9, but here the base mechanical stimulus frequency was substituted by electrical stimulus frequencies. The *y*-axis corresponds to the percentage of times the monkeys called the comparison stimulus (20 Hz) lower than base stimuli at the frequency specified in the *x*-axis. Adapted from Romo, R., Hernández, A., Zainos, A., Brody, C.D., and Lemus, L. 2000. Sensing without touching: psychophysical performance based on cortical microstimulation. Neuron 26, 273–278.

current again being injected into QA neurons. The frequency pairs and event sequence during the task were the same as in previous experiments with natural stimuli; we stress this because careful design of the stimulus sets was particularly crucial here, in order to ensure that the monkeys paid attention to the base stimulus and stored it in working memory (Romo, R. *et al.*, 1999). The monkeys' psychophysical behavior was again indistinguishable from that observed with natural stimuli only (Figure 10), showing that the signals evoked by mechanical and artificial stimuli could be stored and recalled with approximately the same fidelity (Romo, R. *et al.*, 2000). Finally, they also investigated whether monkeys could perform the entire task on the basis of purely artificial stimuli. In most sessions in which the two mechanical stimuli were replaced by microstimulation patterns, monkeys were able to reach discrimination levels close to those measured with mechanical stimuli delivered to the fingertips. This demonstrates that activation of QA neurons is sufficient to drive all the cognitive processes involved in the task with little degradation in performance (Romo, R. *et al.*, 2000).

A couple of additional observations derived from these experiments are also noteworthy. First, early experiments with primary afferents had demonstrated that the flutter sensation is specifically mediated by QA fibers (Ochoa, J. and Torebjörk, E., 1983; Vallbo, A. B., 1995), but this was more difficult to test at the level of S1 (Romo, R. *et al.*, 1998). When microstimulation was applied to clusters of neurons identified as having slowly adapting (SA) properties (Figure 11(a)), the monkeys could barely discriminate, if at all (Romo, R. *et al.*, 2000). As the electrode was advanced to the border between SA and QA clusters, performance became somewhat better (Figure 11(b)), and it reached its usual degree of accuracy when QA properties became most evident in the recordings (Figure 11(c); Romo, R. *et al.*, 2000). Hence, QA and SA units are still functionally segregated in S1, consistent with previous observations (Sur, M. *et al.*, 1984).

In some sessions, Romo and colleagues were able to introduce three microelectrodes into a cluster of QA neurons of area 3b that shared the same receptive field (Romo, R. *et al.*, 2000). They knew that the most anterior microelectrode was placed in the superficial layers, because another microelectrode was placed in front of it and recorded units in primary motor cortex that were driven by spontaneous or passive movements of the fingers and lacked cutaneous receptive fields. The most posterior microelectrode was placed, they believe, in the lower layers, and the microelectrode between these two in the middle layers. In separate runs, the frequency pairs and event sequence were the same in both mechanical and microestimulation trials, except that in the microstimulation trials the first mechanical stimuli were substituted with train of current pulses delivered at the frequency of the mechanical stimulus they were substituting. Figure 12 shows that discrimination is triggered by microstimulating each of the three different clusters. Thus, activation of any part of the cluster of neurons (probably a QA column) with similar functional properties is sufficient to initiate discrimination in this task (Romo, R. *et al.*, 2000).

6.11.11 Further Comments on the Functional Role of S1 to Flutter Discrimination

The results obtained in these sets of experiments suggest that QA neurons from S1 represent the stimulus frequencies both in the periodic spike intervals and

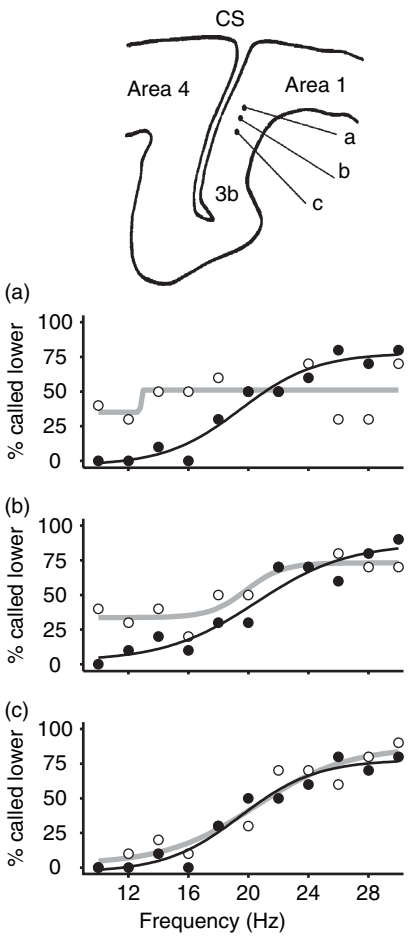

Figure 11 Psychophysical performance elicited by microstimulating at the base stimulus frequency in three different sites of area 3b. Same protocol and labels as in Figure 9. (a–c). in the firing rate (Hernández, A. *et al*., 2000; Salinas, E. *et al*., 2000), and that activation of the QA circuit is sufficient to activate the entire chain of discrimination processes of this task (Romo, R. *et al*., 1998; 2000).

The conclusion previously found in the literature – that frequency discrimination is based on periodicity – came from the observation that a small number of studied QA neurons from S1 reproduce in their activity the periodicity of the mechanical stimulus frequency, and also from the fact that these neurons did not have average firing rates that were modulated by the stimulus frequency (Mountcastle, V. B. *et al*., 1990). However, the study that reached this conclusion only determined the relationship between the

neuronal responses to the mechanical stimulus frequencies; no attempt was made to quantify the neurometric thresholds based on periodicity and to compare these to the psychophysical thresholds. Romo and colleagues observed that neurometric thresholds using the periodicity values are far lower than the psychometric thresholds (Hernández, A. *et al.*, 2000). What is then the functional meaning of this neural signal? One possible role is that this simply represents the temporal structure of the stimulus and that monkeys do not use this exquisite representation for frequency discrimination. Consistent with this interpretation, these authors found QA neurons in S1 whose firing rates are modulated by the stimulus frequencies (Salinas, E. *et al.*, 2000), and their neurometric thresholds based on this measure are similar to the monkey's psychophysical thresholds (Hernández, A. *et al.*, 2000).

These results also suggest that QA neurons of S1, which are classified according to their capacity to react to a slight mechanical indentation applied to the center of their receptive fields, may in fact be composed of two subpopulations, each of which behaves differently in response to a periodic mechanical stimulus. These two subpopulations might be organized in a hierarchical fashion: QA neurons that respond periodically might be closer to the input stimulus, and those that modulate their firing rate might integrate the responses of the periodic neurons and transform them into a rate code. Such last-order neurons of the QA circuit could distribute the neural representation of the stimulus to those structures anatomically linked to S1 (Burton, H. and Fabri, M., 1995; Burton, H. *et al.*, 1995), to solve the sensory discrimination task. Relevant to this interpretation is the fact that neurons in secondary somatosensory cortex (S2) respond by encoding the stimulus frequencies in their firing rates and this encoding correlates closely with the subject's discrimination performance (Salinas, E. *et al.*, 2000; Romo, R. *et al.*, 2002; 2003). Ascending the cortical hierarchy, neurons in the prefrontal cortex and in the premotor cortices respond, encoding the entire sequence of the discrimination task, and correlate closely with the decision motor report (Romo, R. *et al.*, 1999; Hernández, A. *et al.*, 2002; Brody. C. D. *et al.*, 2003; Romo, R. *et al.*, 2004).

The results obtained in the microstimulation experiments show that the relationship between the neuronal responses and the animal's behavior in the flutter discrimination task are not simple coincidences (Romo, R. *et al.*, 1998; 2000). Monkeys were able to discriminate the stimulus frequencies either delivered to the fingertips or artificially injected into a cluster of QA neurons. The specificity of QA stimulation for frequency discrimination is suggested by the fact that SA stimulation cannot produce discrimination (Romo, R. *et al.*, 2000). Interestingly, it has been shown that activity in a single cutaneous afferent fiber could produce localized somatic sensations (Ochoa, J. and Torebjörk, E., 1983; Macefield, G. *et al.*, 1990; Vallbo, A. B., 1995), and frequency microstimulation of QA afferents linked to Meissner's corpuscles produced the sensation of flutter (Vallbo, A. B., 1995). These observations strongly support the notion that the activity initiated in specific mechanoreceptors is read out by S1; this reading is then widely distributed to those anatomical structures that are linked to S1 (Romo, R. and Salinas, E., 2001). The whole sequence of events associated with this sensory discrimination task must depend on this distributed neural signal (Romo, R. *et al.*, 1999; Hernández, A. *et al.*, 2002; Romo, R. *et al.*, 2002; Brody, C. D. *et al.*, 2003; Romo, R. and Salinas, E., 2003; Romo, R. *et al.*, 2004).

6.11.12 Conclusion

The highly simplified sensory tasks used here require perception of the stimuli and producing a decision that is communicated to the motor apparatus. The most salient result obtained in the detection task is that the S1 activity does not account for the variability in the detection responses at near-threshold stimuli. However, the S1 neural representation of the stimulus is necessary for further central processing. Indeed, the activity of areas central to S1 did covary with trial-by-trial judgments in the detection task (not reviewed here). This suggests that perceptual judgments in this task arise in the activity of those areas linked to S1. Experiments not reviewed here show that covariations between neuronal activities and perceptual judgments increase gradually, from lower covariations in the somatosensory cortices of the parietal lobe to higher covariations in some areas of the frontal lobe. Experiments in the vibrotactile discrimination task suggest that S1 transforms the phase-locked responses into a firing rate code that accounts for the variability of the discrimination performance. Activation of the QA circuit of S1 appears sufficient for vibrotactile discrimination; however, similar to the detection task, perceptual judgments arise in the activity of more central areas linked to S1.

Glossary

haptics The study of touch and tactile sensations, especially as a means of communication. Haptic sensations are derived primarily from active touch, in which proprioceptive and cutaneous inputs are combined to define object properties.

intention Direction of the mind or attention to a particular action, goal, or effort. Intention also implies understanding the meaning, significance, import, purpose, design, or aim of an action. In its strongest usage, intention describes the volition or determination to carry out a particular action.

kinematics The science concerned with movements of the parts of the body.

kinaesthesia (kinesthesis) The sense of muscular effort and perception of movement that accompanies a voluntary motion of the body. This sense is mediated by end organs located in muscles, tendons, and joints stimulated by bodily movements and tensions.

prehension The action of taking possession of and grasping or holding something. The term is also applied to mental comprehension, the action of grasping with the mind.

proprioception The sense or perception, usually at a subconscious level, of the movements and posture of the body and especially its limbs, independent of vision. This sense is mediated by sensory nerve terminals in muscles and tendons (muscle spindles) and the fibrous capsule of joints combined with input from the vestibular apparatus.

stereognosis The appreciation and recognition of the form of solid objects by means of touch.

tactile agnosia The inability to recognize objects by touch, in the presence of intact cutaneous and proprioceptive hand sensation. This deficit is caused by a lesion in the contralateral parietal lobe, and is also termed astereognosis.

6.12.1 Introduction

One of the key concepts to illuminate our understanding of sensory processing in the cerebral cortex was set forth in a seminal paper by Ungerleider L. G. and Mishkin M. (1982). They proposed that visual information from the retina enters the cortex in the primary visual area, V1, is transmitted to V2 cortex, and then split into two parallel pathways directed to the temporal and parietal lobes. These pathways analyze the same sensory information in different ways that came to be known as the what and where streams.

The ventral stream – transmitted through the inferotemporal cortex – is the putative 'what' pathway. These cortical areas analyze the visual signals to derive cognitive information about the size, shape, and color of the stimulus. These intrinsic properties allow us to recognize such stimuli as distinct objects, persons, or places. The dorsal stream – transmitted through the parietal lobe – forms the where pathway. It analyzes the extrinsic properties of the image, defining the spatial and temporal properties of the stimulus with respect to the observer and the environment.

Later studies of these pathways by Milner A. D. and Goodale M. A. (1995) suggested a more sophisticated view, based on their clinical studies of patients with lesions localized to the parietal or temporal cortex. They proposed that the ventral stream forms a vision-for-cognition pathway that allows us to name objects, contributing to semantic memory. The dorsal stream forms a vision-for-action network that provides spatial information for guiding behavior. The parietal pathway creates a pragmatic representation of the world needed for immediate action, and for the formation of procedural memories underlying skilled behavior. The Milner–Goodale hypothesis can be summarized as what and how networks.

Mishkin M. (1979) also proposed a similar dual organization of the somatosensory pathways for touch and proprioception. In his formulation, the somatosensory ventral stream originates in the projections from the primary somatic sensory cortex (S-I) to the second somatic sensory area (S-II cortex), including the neighboring zones along the upper bank of the Sylvian (lateral) fissure and the parietal operculum. The ventral network has strong anatomical links through the insular cortex to the medial temporal lobe and hippocampus (Friedman, D. P. *et al.*, 1986; Felleman, D. J. and Van Essen, D. C., 1991), providing a cortico-limbic circuit for object memory acquired through touch.

The somatosensory dorsal stream is conveyed through the posterior parietal cortex (PPC), particularly the region bordering the intraparietal sulcus (IPS) in humans and monkeys. The dorsal stream represents the actions of the subject when interacting with the environment, as gleaned by touch and proprioception. The PPC projects primarily to the premotor areas of the frontal lobe, providing a pathway for initiating and controlling motor behavior. These frontal–parietal networks play a key role in voluntary movement, particularly the skilled behaviors of the hand and arm: reaching, grasping, and tool use.

In this chapter, I review the anatomical, physiological, and clinical evidence for a dorsal stream pathway in the sense of touch. The discussion is focused on actions of the hand and arm, as physiological studies have concentrated on the role of PPC in reach and grasp behaviors. The properties of the ventral stream network in the sense of touch are described in the chapters by Leah Krubitzer, Steven Hsiao, and Ranulfo Romo in this volume.

6.12.2 Anatomical Localization of the Posterior Parietal Cortex

The cortical areas surrounding the IPS in monkeys are referred to collectively as the posterior parietal cortex. PPC is normally subdivided anatomically into a rostral division – the superior parietal lobule (SPL) – and a caudal zone – the inferior parietal lobule (IPL). The SPL and IPL in monkeys were named areas 5 and 7 by Brodmann K. (1909). Vogt C. and Vogt O. (1919) subdivided the SPL into caudal and rostral regions (areas 5a and 5b), and the IPL into areas 7a and 7b. Later anatomists further subdivided the SPL into areas PE, PEc, and PEa, and the IPL convexity into areas PF, PFG, PG, and Opt (von Economo, C. and Koskinas, G. N., 1925; von Bonin, G. and Bailey, P., 1947; Pandya, D. N. and Selzer, B., 1982; Gregoriou, G. G. *et al.*, 2006) (Figure 1). Anatomical distinctions were also made for the regions buried within the wall of the IPS (areas MIP, LIP, AIP, and VIP) and those bordering the parietal operculum (PFop and PGop).

More recent physiological, cytoarchitectural, myeloarchitectural, and connectionist studies have resulted in further fractionation of this region into 17 distinct areas concerned primarily with vision and/or somatic sensation (Lewis, J. W. and Van Essen, D. C., 2000a; 2000b; Van Essen, D. C. *et al.*, 2001). Visual areas are situated primarily in the IPL, and along the midline at the parietal–occipital (PO) junction; these include areas 7a, LIPv, LIPd, VIPm, VIPl, PO (V6A), PIP, V3, V3A, MDP, and LOP. Somatosensory areas are situated primarily in the SPL, and in the rostral and lateral regions of the IPL (areas 5d, 5v, MIP, AIP, 7b, and 7t) (Figure 2). To add to the confusion of terminology, the regions of the SPL in the human brain called BA5 and BA7 do not coincide with their namesakes in the macaque cortex; their properties as revealed in functional imaging studies suggest instead that they correspond to areas PE, PEa, and PEc in the macaque (Galletti, C.

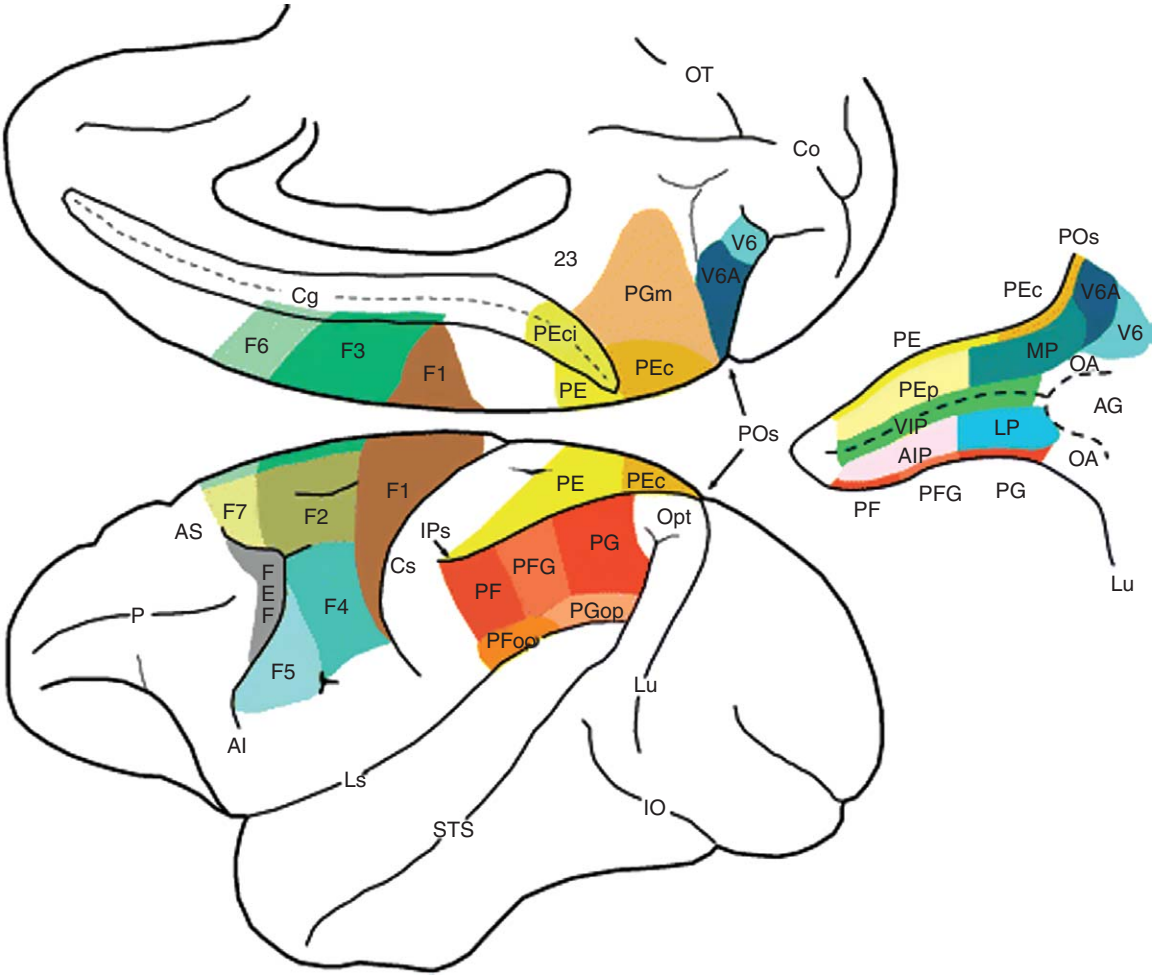

Figure 1 Lateral and medial views of the macaque cerebral cortex showing the anatomical locations of the posterior parietal cortex (areas PE, PEc, PO, PF, PFG, PG, Opt, PFop, and PGop) and frontal motor areas (areas F1, F2/F3, F7/F6, F4, F5, and FEF). The inset shows the areas lying within the intraparietal sulcus (IPS). Reproduced from Rizzolatti, G. and Matelli, M. 2003. Two different streams form the dorsal visual system: anatomy and functions. Exp. Brain Res. 153, 146–157; figure 1).

et al., 1997; Binkofski, F. *et al.*, 1999a). Similarly, the human BA39 and 40 are functionally related to the macaque areas 7a and 7b.

The anatomical connections of somatosensory areas of the PPC are schematized in Figure 3. The principal somatosensory input to area 5 originates from S-I cortex, particularly from area 2 (Jones, E. G. and Powell, T. P. S., 1969; 1970; Pearson, R. C. A. and Powell, T. P. S., 1985). These feed-forward projections are somatotopic. The hand representation in S-I projects to the lateral end of the IPS in areas 5d and 5v that is involved in grasping behaviors (Mountcastle, V. B. *et al.*, 1975; Gardner, E. P. *et al.*, 1999; 2002; 2007a). The arm and shoulder regions project to more medial and caudal regions in the SPL – designated the parietal reach region (PRR) – that are involved in reaching (reviewed in Caminiti, R. *et al.*, 1996; Andersen, R. A. *et al.*, 1997; Kalaska, J. F. *et al.*, 1997; Caminiti, R. *et al.*, 1998; Burnod, Y. *et al.*, 1999; Andersen, R. A. and Buneo, C. A., 2002). The face representation projects to area VIP, located at the fundus of the IPS at its rostral end; this region may be involved in hand–mouth coordination during feeding (Colby, C. L. *et al.*, 1993; Duhamel, J. R. *et al.*, 1998; Colby, C. L. and Goldberg, M. E., 1999).

Tracer injection studies reveal extensive interconnections between different subregions of the SPL and IPL. For example, the primary output targets of neurons in the hand region of area 5 are the more caudal regions of the SPL involved in reaching (Seltzer, B. and Pandya, D. N., 1980; Pandya, D. N. and Selzer, B., 1982; Lewis, J. W. and Van Essen, D.

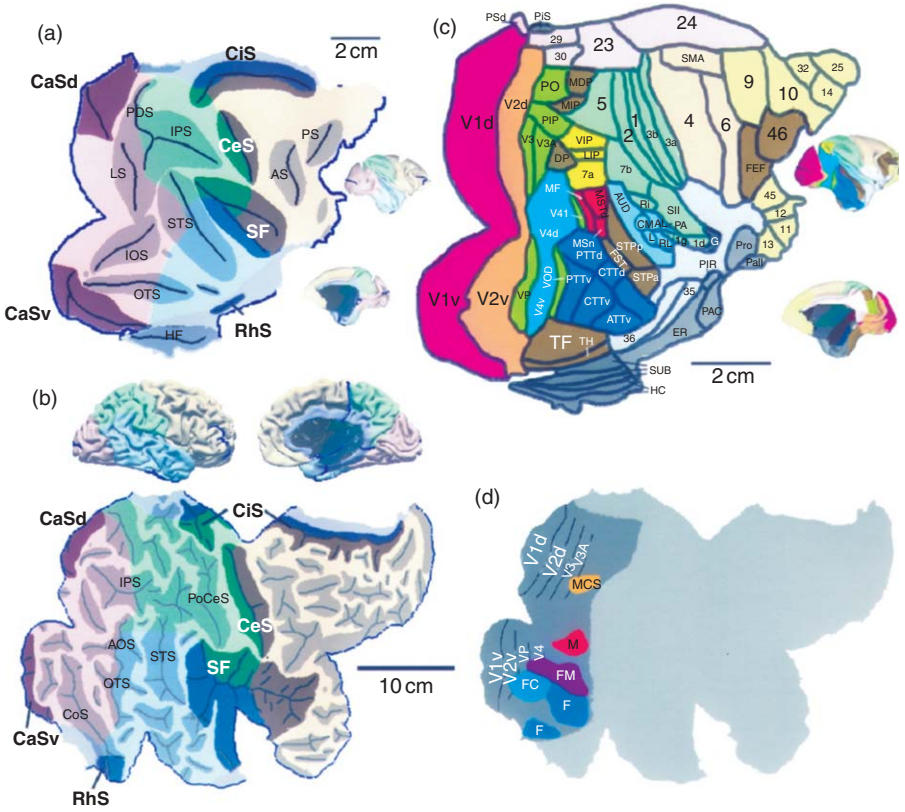

Figure 2 Flat maps showing the spatial relationship between somatosensory, visual, auditory, and motor areas of the cerebral cortex in macaques (a and c) and humans (b and d). The surface is colored to delineate the different cortical lobes. *Shaded regions* on the flat map indicate cortex buried within various sulci (AS, arcuate sulcus; CaS, calcarine sulcus (dorsal and ventral); CeS, central sulcus; CiS, cingulate sulcus; HF, hippocampal fissure; IOS, inferior occipital sulcus; IPS, intraparietal sulcus; LS, lunate sulcus; OTS, occipito-temporal sulcus; POS, parieto-occipital sulcus; PS, principal sulcus; RhS, rhinal sulcus; SF, Sylvian fissure; STS, superior temporal sulcus). Cortical areas in the macaque are labeled according to the partitioning scheme of Felleman D. J. and Van Essen D. C. (1991). Posterior parietal visual areas along the midline are colored chartreuse green (PO, PIP, V3, and V3A), and those buried in the IPS (AIP and VIP) and adjacent bank of the IPL (7a) are colored yellow. Somatosensory areas (3a, 3b, 1, 2, 5, 7b, SII, Ri, and Ig) are shown in pale green. Brown areas between the parietal visual and somatosensory regions (MDP, MIP, and DP) form portions of the parietal reach region (PRR). Dark blue regions in the temporal lobe indicate the ventral visual areas; no distinction is made in this figure between dorsal and ventral somatosensory areas. Reproduced from Van Essen, D. C. and Drury, H. A. 1997. Structural and functional analyses of human cerebral cortex using a surface-based atlas. J. Neurosci. 17, 7079–7107; figure 13).

C., 2000b), providing anatomical pathways to coordinate reach and grasp during goal-directed hand behaviors. Neurons in the hand representation of area 5 project to mirror-image sites in the contralateral hemisphere, providing circuitry for bilateral coordination of the left and right hands (Jones, E. G. *et al.*, 1978; Padberg, J. *et al.*, 2005). This is the first site of bilateral hand interactions in the dorsal pathway, as the hand representation in S-I is apparently acallosal (Jones, E. G. *et al.*, 1978; 1979; Caminiti, R. and Sbriccoli, A., 1985; Shanks, M. F. *et al.*, 1985; Padberg, J. *et al.*, 2005).

Neurons in the hand representation of area 5 also provide prominent somatosensory inputs to areas AIP and 7b in the IPL (Neal, J. W. *et al.*, 1986; 1987; Cavada, C. and Goldman-Rakic, P., 1989a), thereby linking tactile and visual information needed for grasping. The connections between SPL and IPL neurons are reciprocal, allowing exchange of tactile and visual information between cortical areas. Area 7b also receives somatosensory inputs from S-II cortex (Disbrow, E. *et al.*, 2003).

Area 5 also has strong projections to motor areas of the frontal lobe, particularly to the premotor cortex. Medial regions of area 5 that represent the arm project primarily to the dorsal premotor cortex (PMd or F2), while the lateral regions representing the hand and face project to ventral premotor cortex

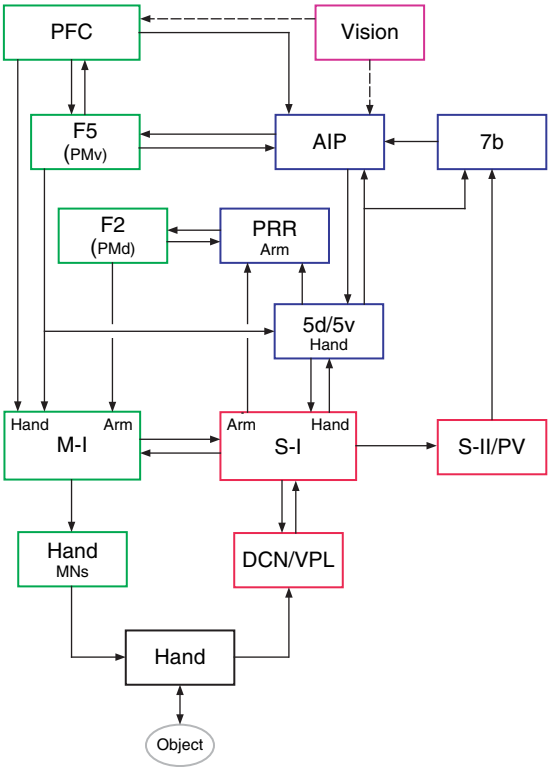

Figure 3 Simplified block diagram of the input–output circuits for grasping. Somatosensory areas (red): DCN/VPL (dorsal column nuclei and ventral posterolateral nucleus of the thalamus), S-I (primary somatosensory cortex, areas 3a, 3b, 1, and 2), S-II/PV (secondary somatosensory and parietal ventral cortex). Posterior parietal areas (blue): 5d/5v (rostral end of superior parietal lobule), PRR (parietal reach region, caudal end of superior parietal lobule), AIP (anterior intraparietal area of inferior parietal lobule), and 7b (lateral convexity of the inferior parietal lobule). Frontal motor areas (green): PFC (prefrontal cortex), F5 (ventral premotor cortex), F2 (dorsal premotor cortex), and M-I (primary motor cortex). Other important frontal motor areas that project to M-I, such as the supplementary motor area (SMA) and cingulate motor area (CMA), are not shown, nor are the corticomotor pathways to spinal interneurons from M-I and F5. Visual areas (violet): For simplicity, the visual pathways from the retina to areas AIP, PRR, and PFC have been compressed into a single box that includes important visuomotor centers of PPC such as areas LIP, CIP, 7a, and V6A; the dashed arrows denote polysynaptic pathways. Reproduced from Gardner, E. P., Ro, J. Y., Babu, K. S., and Ghosh, S. 2007b. Neurophysiology of prehension: II. Response diversity in primary somatosensory (S-I) and motor (M-I) cortices. J. Neurophysiol. 97, 1656–1670; figure 10).

(PMv or F5/F4) (Petrides, M. and Pandya, D. N., 1984; Matelli, M. *et al.*, 1986; Cavada, C. and Goldman-Rakic, P., 1989b; Kurata, K., 1991; Ghosh, S. and Gattera, R., 1995; Johnson, P. B. *et al.*, 1996; Wise, S. P. *et al.*, 1997; Matelli, M. *et al.*, 1998; Luppino, G. *et al.*, 1999; Matelli, M. and Luppino, G., 2001; Tanne-Gariepy, J. T. *et al.*, 2002; Rizzolatti, G. and Matelli, M., 2003).

Neurons in the IPL also receive somatosensory information, but it arrives not from the primary somatic sensory cortex, but from area 5 and S-II cortex. Actions of the arm are represented primarily in area 7a, and those of the hand in more lateral zones, particularly areas AIP and 7b. However, visual inputs exert a stronger influence on these neurons than the somatosensory modality (reviewed in Felleman, D. J. and Van Essen, D. C., 1991; Fogassi, L. and Luppino, G., 2005; Jeannerod, M. *et al.*, 1995; Andersen, R. A. *et al.*, 1997; Rizzolatti, G. *et al.*, 1997; Sakata, H. *et al.*, 1997; Colby, C. L. and Goldberg, M. E., 1999; Van Essen, D. C. *et al.*, 2001; Andersen, R. A. and Buneo, C. A., 2002; Buneo, C. A. and Andersen, R. A., 2006). Hand manipulation neurons in areas AIP and 7b receive visual inputs from area LIP (Lewis, J. W. and Van Essen, D. C., 2000b; Nakamura, H. *et al.*, 2001), project to ventral premotor cortex (PMv or F5), and receive reciprocal connections from these frontal motor areas (Matelli, M. *et al.*, 1986; Rizzolatti, G. *et al.*, 1987; Matelli, M. *et al.*, 1988; Cavada, C. and Goldman-Rakic, P., 1989b; Preuss, T. M. and Goldman-Rakic, P. S., 1991; Fogassi, L. and Luppino,G., 1995; Rizzolatti, G. *et al.*, 1997; Ghosh, S. and Gattera, R., 1995; Luppino, G. *et al.*, 1999; Matelli, M. and Luppino, G., 2001; Rizzolatti, G. and Luppino, G., 2001).

6.12.3 Physiological Studies of Posterior Parietal Cortex

The anatomical connections of PPC suggest that this region is a higher-order somatosensory and visual area important for feature detection for one or both modalities (Gardner, E. P., 1988; Felleman, D. J. and Van Essen, D. C., 1991; Van Essen, D. C. *et al.*, 2001). Its connections to the frontal motor areas also provide sensory feedback networks for guiding movements. Early physiological studies seemed to support the notion of serial hierarchical processing of tactile input in PPC for the purpose of exteroception and object recognition (Iwamura, Y. and Tanaka, M., 1978; Darian-Smith, I. *et al.*, 1984; Koch, K. W. and Fuster, J. M., 1989; Felleman, D. J. and Van Essen, D. C., 1991; Ageranioti-Bélanger, S. A. and Chapman, C. E., 1992; Iwamura, Y. *et al.*, 1993, 1995). Neurons recorded along the rostral bank of the IPS were shown to have complex tactile receptive fields that distinguish the roughness of textures (Ageranioti-Bélanger, S. A. and Chapman, C.

E., 1992), the spatial frequency and/or orientation of gratings scanned by the fingers (Darian-Smith, I. *et al.*, 1984), and the shape of objects touched by the hand (Iwamura, Y. and Tanaka, M., 1978; Iwamura, Y. *et al.*, 1995), or aid recognition of the surface features of objects previously grasped in the hand (Koch, K. W. and Fuster, J. M., 1989). Other neurons recorded in this region receive proprioceptive signals from multiple joints that aid perception of integrated body postures (Duffy, F. H. and Burchfiel, J. L., 1971; Sakata, H. *et al.*, 1973). Although many of these physiological studies attributed recording sites in the superior bank of the IPS to area 2, anatomists such as Pandya D. N. and Selzer B. (1982), Pons T. P. *et al.* (1985), and Lewis, J. W. *et al.* (1999) have included this region in Brodmann's area 5, calling it area PEa or 5v. Interestingly, most of the complex tactile responses reported in the physiological studies cited above were evoked by active hand movements that were rewarded, such as grasping objects or palpating surfaces.

Our view of PPC was changed dramatically by the pioneering studies of Vernon Mountcastle and Juhani Hyvärinen and their collaborators (Hyvärinen, J. and Poranen, A., 1974; Mountcastle, V. B. *et al.*, 1975; Leinonen, L. *et al.*, 1979; Hyvärinen, J., 1981; 1982a; 1982b). They found that neurons in areas 5 and 7 in the macaque cortex did not respond to the traditional types of tactile stimuli used to study S-I, such as pressure pulses or vibration. In a later historical review, Mountcastle V. B. (1995) described these cells as "neurons that were active if and only if the animal 'had a mind' to deal with the stimulus in a behaviorally meaningful way!" They responded to goal-directed actions of the hand and arm "aimed at securing for the animal an object he desires, such as food when he is hungry; or, as in our experimental paradigm, contacting a switch or pulling a lever that provides fluid when he is thirsty" (Mountcastle, V. B. *et al.*, 1975). Mountcastle and coworkers distinguished two classes of neurons in PPC: arm projection neurons involved in reaching to targets in immediate extrapersonal space and hand manipulation neurons engaged in hand movements such as grasping or foraging for objects with the fingers. Both types were influenced by visual information, particularly neurons recorded in area 7. Reaching and grasping behaviors activated neurons in different portions of PPC, as arm projection neurons were recorded at more medial sites in areas 5 and 7 than hand manipulation neurons. These actions are also segregated anatomically into medial and lateral zones in human parietal cortex, as revealed in functional imaging studies (Chieffi, S. and Gentilucci, M., 1993; Grafton, S. T. *et al.*, 1996; Binkofski, F. *et al.*, 1998; 1999a; Ehrsson, H. H. *et al.*, 2000; 2001; Culham, J. C. *et al.*, 2003; Connolly, J. D. *et al.*, 2003; Ehrsson, H. H. *et al.*, 2003; Shikata, E. *et al.*, 2003; Culham, J. C., 2004; Frey, S. H. *et al.*, 2005; Culham, J. C. and Valyear, K. F., 2006).

The studies by Mountcastle, Hyvärinen, and their collaborators played a seminal role in subsequent investigations of PPC that have focused on reaching movements of the arm, grasping actions of the hand, and goal-directed eye movements to salient targets. They led to the development of new behavioral tasks that tested not only sensory discrimination and motor behaviors, but also the role of memory, intention, and planning of such actions. The correlation of neuronal firing patterns with hand actions also provided an impetus for detailed analyses of the kinematics of reach and grasp behaviors. Collectively, these studies implicate PPC in sensorimotor transformations that couple perceptions to actions needed to direct the hand to objects of behavioral interest such as food and acquire them for consumption.

6.12.3.1 Reaching as a Model System for Analyzing Sensorimotor Integration

Neurons in the SPL appear to play an important role in perception of the body, and its relation to external space during reaching, pointing, and grasping. Reaching is primarily a visuomotor action in which the subject projects the arm toward a target object to touch or grasp it (reviewed in Jeannerod, M., 1994; Jeannerod, M. *et al.*, 1995; Paulignan, Y. and Jeannerod, M., 1996). Reaching occurs in a smooth trajectory in which the peak velocity of the wrist occurs at 40% of the movement time in humans (Jeannerod, M., 1984) and 50% in monkeys (Georgopoulos, A. P. *et al.*, 1982; Roy, A. C. *et al.*, 2000). Ipsilateral reaches take proportionately less time than those to contralateral sites at the same distance. Reaches toward small objects take longer than those toward large ones (Wing, A. M. *et al.*, 1986; Marteniuk, R. G. *et al.*, 1990; Paulignan, Y. and Jeannerod, M., 1996; Roy, A. C. *et al.*, 2000; Roy, A. *et al.*, 2002), presumably because a small object requires more precise aim and finger placement for accurate grip.

Reach and grasp are temporally synchronized but controlled by distinct networks of neurons in parietal cortex (Chieffi, S. and Gentilucci, M., 1993; Grafton, S. T. *et al.*, 1996; Binkofski, F. *et al.*, 1998; 1999; Ehrsson, H. H. *et al.*, 2000; 2001; 2003; Astafiev, S. V. *et al.*, 2003; Culham, J. C. *et al.*, 2003; Rizzolatti, G. and Matelli, M., 2003; Shikata, E. *et al.*, 2003; Frey, S. H. *et al.*, 2005; Hu,

Y. *et al.*, 2005; Tunik, E. *et al.*, 2005). Reach targets are encoded by neurons in the shoulder representation of area 5, the PRR including areas MIP, 7a, PEc, and the PO zone (areas V6, V6A, and 7m) on the medial surface of the hemisphere. These regions have been studied using a variety of reaching tasks (Kalaska, J. F. *et al.*, 1983; Crammond, D. J. and Kalaska, J. F., 1989; Snyder, L. H. *et al.*, 1998a; 1998b; Kalaska, J. F. *et al.*, 1990; Galletti, C. *et al.*, 1993; Kalaska, J. F. and Crammond, D. J., 1995; Lacquaniti, F. *et al.*, 1995; Caminiti, R. *et al.*, 1996; Ferraina, S. *et al.*, 1997; Kalaska, J. F. *et al.*, 1997; Rizzolatti, G. *et al.*, 1997; Caminiti, R. *et al.*, 1998; Batista, A. P. *et al.*, 1999; Battaglia-Mayer, A. *et al.*, 2000; Batista, A. P. and Andersen, R. H., 2001; Ferraina, S. *et al.*, 2001; Andersen, R. A. and Buneo, C. A., 2002; Galletti, C. *et al.*, 2003; Fattori, P. *et al.*, 2004; Fogassi, L. and Luppino, G., 2005; Buneo, C. A. and Andersen, R. A., 2006).

The notion that goal-directed reaches are mediated through area 5 was first analyzed by Kalaska J. F. *et al.* (1983) and Georgopoulos, *et al.* (1884). They developed a behavioral paradigm – called the center-out task – that has been widely used to study reaching and other goal-directed behaviors such as eye movements (Georgopoulos, A. P. *et al.*, 1982). In this task, monkeys are trained to grasp a handle, place it at a central start point, and then displace it to one of eight targets surrounding the origin (Figure 4, *upper panels*). Each trial requires the animal to reach in a specific direction to a visually defined endpoint. They found that most neurons in area 5 respond to a broad range of reach directions, with maximum firing in one preferred direction, and minimum rates along the opposite path. The directional tuning curves of firing rates for the eight different directions can be approximated by a sine wave (Figure 4, *lower panel*), allowing them to derive preferred reach directions for each cell studied. Although the individual neurons do not by themselves provide a strong directional signal, collectively the population of neurons precisely specifies the reach direction on each trial. This notion was further extended to three dimensions in later studies (Georgopoulos, A. P. *et al.*, 1988; Schwartz, A. B. *et al.*, 1988; Lacquiniti *et al.*, 1995). Kalaska and colleagues (1990) later discovered that the tuning of area 5 neurons to particular reach directions reflects the movement kinematics, that is, the particular muscle groups needed to direct the arm in specific directions. Area 5 firing rates are independent of the amount of muscle force needed to pull or push the handle toward the specified target.

The time course of neural responses during reaches also has important implications concerning the sensorimotor role of PPC. The onset of neuronal responses in area 5 coincides with the start of reach and overlaps motor activity in primary motor cortex (M-I) and in the dorsal premotor cortex (PMd) (Kalaska, J. F. *et al.*, 1983; Crammond, D. J. and Kalaska, J. F., 1989; Kalaska, J. F. *et al.*, 1990; Burbaud, P. *et al.*, 1991; Kalaska, J. F. and Crammond, D. J., 1995). In addition, Seal J. *et al.* (1982) and Seal J. and Commenges D. (1985) found that area 5 neurons in deafferented monkeys respond to reaching movements in the absence of somatosensory feedback, suggesting that an efference copy of motor commands from the frontal lobe is also transmitted to PPC (Mountcastle, V. B. *et al.*, 1975). These findings led to the proposal that area 5 receives convergent central and peripheral signals that allow it to compare central motor commands with peripheral sensory feedback during task performance. These circuits provide a network for planning intended movements and updating ongoing actions as they proceed. Kalaska and colleagues (1997) described this role as a "sequence of sensorimotor coordinate transformations between a signal of spatial location and a pattern of muscle activity."

6.12.3.2 Role of Posterior Parietal Cortex in Motor Planning and the Neural Representation of Space

Further clues about the sensorimotor function of PPC have been derived from instructed delay tasks when the animal was able to plan reaches or saccades to cued spatial targets. In these studies, the motor plans or intentions of the animal are distinguished from subsequent actions during motor performance of the task. During delayed reaching tasks, neurons in areas 5 and PRR show strongly enhanced firing rates prior to the onset of movement that are tuned to the location of the visual target and that specify potential actions that can be performed there (Crammond, D. J. and Kalaska, J. F., 1989; Andersen, R. A., 1995; Kalaska, J. F. and Crammond, D. J., 1995; Kalaska, J. F., 1996; Batista, A. P. and Andersen, R. H., 2001). The initial hand position modifies the strength of responses of neurons in area 5 (Crammond, D. J. and Kalaska, J. F., 1989; Kalaska, J. F. and Crammond, D. J., 1995), but not those in PRR (Andersen, R. A. *et al.*, 1997; Batista, A. P. and Andersen, R. H., 2001; Buneo, C. A. and Andersen, R. A., 2006), suggesting that these regions respond to different aspects of the sensory cue. These studies support the notion that PPC activity reflects the intention to execute a specific motor program.

Premovement activity during the instructed delay period has been variously described as motor intentions (Andersen, R. A. *et al.*, 1997; Andersen, R. A. and

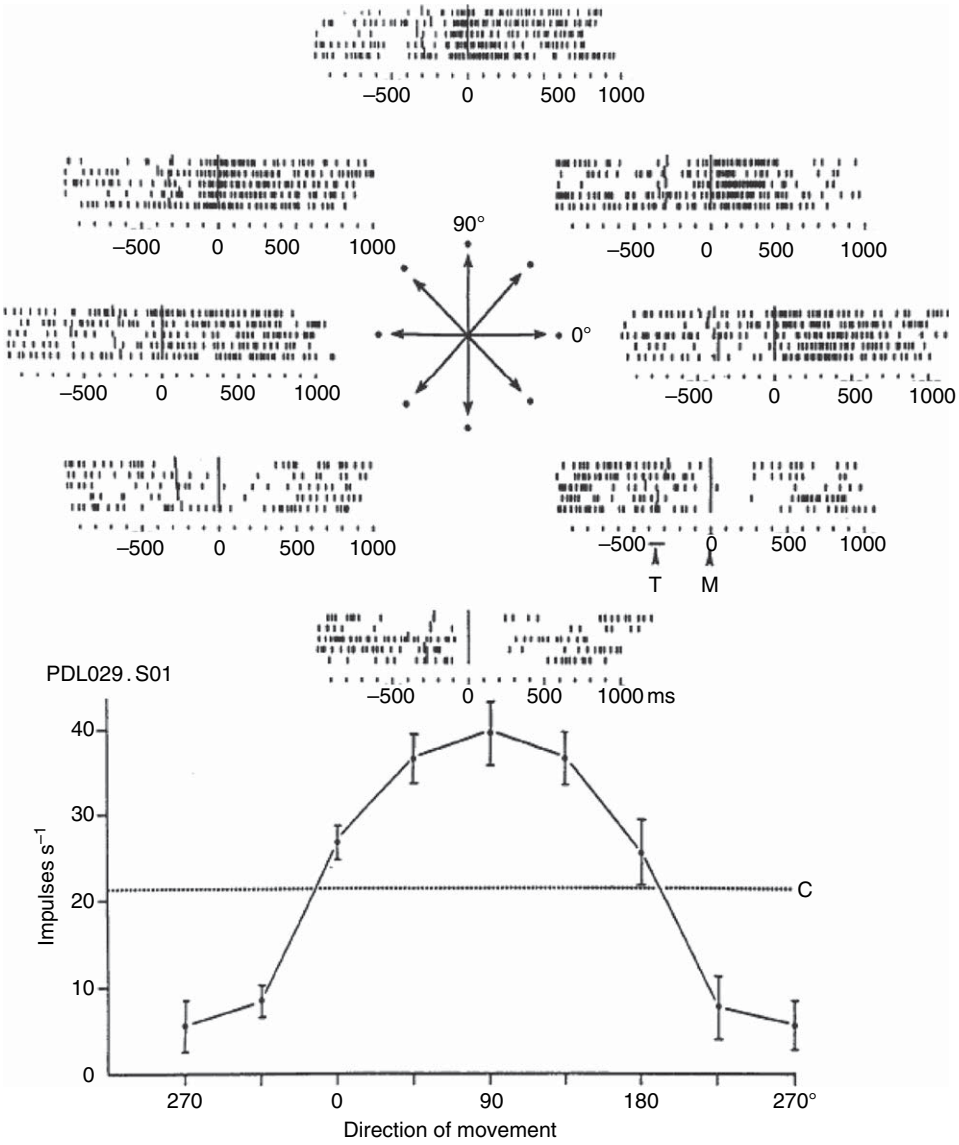

Figure 4 Tuning of responses of an area 5 neuron to the direction of reach in the center-out task. Upper panels: Rasters illustrating five trials in the stated directions aligned to the start of reach (M); the neuron responded most vigorously to upward movements (90°) and was inhibited by movement in the opposite direction (270°). Note that neural responses precede the start of movement, and continue until the hand reaches the specified target. Lower panel: Mean firing rate during the movement time; the neuron responded to movement over most of the range tested. *C*, mean firing rate during the control period before the target cue light was illuminated. Reproduced from Kalaska, J. F., Caminiti, R., and Georgopoulos, A. P. 1983. Cortical mechanisms related to the direction of two-dimensional arm movements: relations in parietal area 5 and comparison with motor cortex. Exp. Brain Res. 51, 247–260; figure 3).

Buneo, C. A., 2002; Buneo, C. A. and Andersen, R. A., 2006), spatial attention (Colby, C. L., 1998; Duhamel, J. R. *et al.*, 1998; Colby, C. L. and Goldberg, M. E., 1999; Bisley, J. W. and Goldberg, M. E., 2003), or perceptual decision-making (Platt, M. L. and Glimcher, P. W., 1999; Shadlen, M. N. and Newsome, W. T., 2001; Glimcher, P. W., 2003; Dorris, M. C. and Glimcher, P. W., 2004; Sugrue, L. P. *et al.*, 2004; 2005). We refer to this early activity as motor planning, because it reflects high-level cognitive plans for movement without the implication of emotional commitment to such behaviors.

Motor plans for reaching require transformation of a visual signal concerning the target position in the

workspace into a motor signal that selects the appropriate muscle groups needed to transport the hand to the specified place. The intended goal of the reach is often described as a motor error signal, that is, the difference between the starting hand and arm position, and the desired goal (reviewed in Buneo, C. A. and Andersen, R. A., 2006). Actions of the arm are represented in a variety of coordinate systems along the SPL including eye-centered (Figure 5), head-centered, arm-centered, and hand-centered reference frames, or combinations of these expressed as gain fields (Crammond, D. J. and Kalaska, J. F., 1989; Pause, M. and Freund, H.-J., 1989; Galletti, C. *et al.*, 1993; Kalaska, J. F. and Crammond, D. J., 1995; Lacquaniti, F. *et al.*, 1995; Caminiti, R. *et al.*, 1996; Andersen, R. A. *et al.*, 1997; Ferraina, S. *et al.*, 1997; Kalaska, J. F. *et al.*, 1997; Caminiti, R. *et al.*, 1998; Colby, C. L., 1998; Snyder, L. H. *et al.*, 1998a; 1998b; Batista, A. P. *et al.*, 1999; Burnod, Y. *et al.*, 1999; Ferraina, S. *et al.*, 2001; Battaglia-Mayer, A. *et al.*, 2003; 2006; Buneo, C. A. and Andersen, R. A., 2006). This is a hotly debated and somewhat controversial subject. In a recent review, Buneo C. A. and Andersen R. A. (2006) proposed that PPC contains both a "representation of target and hand position in eye coordinates, and a representation of motor error in hand-centered coordinates." They seem to recognize that different coordinate systems are arrayed along the IPS but that their relative importance may depend on the specific task requirements. Multiple coordinate frames are useful for achieving flexibility when reaching is the prelude to subsequent hand actions such as grasping, pointing, pulling, pushing, or turning that require a variety of motor synergies.

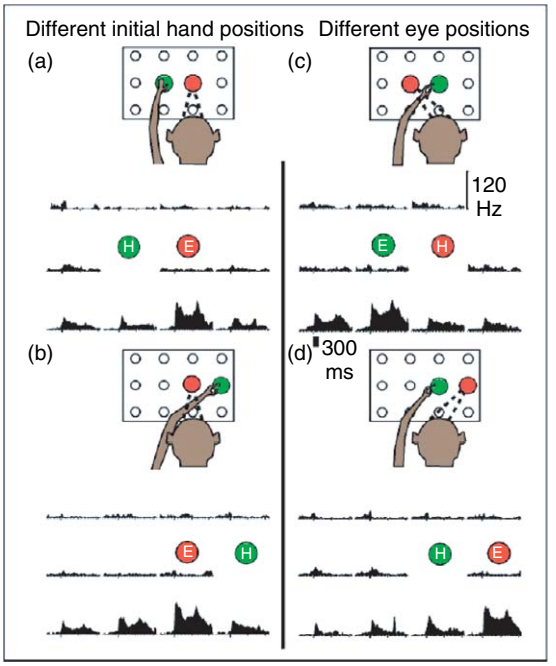

Figure 5 Sensitivity of a neuron in the parietal reach region (PRR) to eye and hand position during the instructed delay period of a reach task. The initial hand position and the point of visual fixation are represented by green and red circles, respectively, in the behavioral cartoons. The animal is instructed to reach to one of the other 11 positions when the GO signal occurs while maintaining fixation of gaze on the red circle. The spike density histograms below the cartoons illustrate the averaged response to the cue; in each case the strongest response occurred when the animal was instructed to reach to the location below the center of gaze, regardless of the starting point of the hand or the direction of reach. The authors conclude that the neuron encodes the required movement in terms of the target location on the retina. Modified from Andersen, R. A. and Buneo, C. A. 2002. Intentional maps in posterior parietal cortex. Annu. Rev. Neurosci. 25, 189–220; figure 5).

Spatial maps may play a critical role in the dysmetrias and neglect syndromes characteristic of damage to PPC (reviewed in Hyvärinen, J., 1982b; Pause, M. *et al.*, 1989; Milner, A. D. and Goodale, M. A., 1995; Ghika, J. *et al.*, 1998; Pouget, A. and Driver, J., 2000; Freund, H.-J., 2001; Goodale, M. A. and Westwood, D. A., 2004; Battaglia-Mayer, A. *et al.*, 2006). Ben-Hamed and Duhamel reported that the population of neurons in area VIP of each hemisphere responded to stimulation of the entire visual field, both ipsilateral and contralateral, but the relative distribution of neurons responding at each eccentricity was skewed, with peak numbers ~15° contralateral to the recording side (Figure 1 in Pouget, A. and Driver, J., 2000). This coincides with the location of the fingertips when the arm is extended forward of the body. From a bilateral perspective, the greatest number of neurons represents the workspace between the shoulders, with equal representation at the midline for left and right sides, and a gradual bias toward the contralateral side that accelerates lateral to the shoulder. The large population monitoring the intramanual space endows it as the preferred site of skilled bimanual actions. If one hemisphere is disabled, the skewed representation of visual space biases reaches and attention toward the contralateral side. This model predicts hypometric reaches toward ipsilateral targets, because fewer than 10% of cells in the intact hemisphere represent eccentricities >20° in that space. Similarly, modulation of visual gain fields by eye and head position could further skew neuronal responses to contralaterally displaced reach targets (Andersen, R. A. *et al.*, 1985; Snyder, L. H. *et al.*, 1998a; 1998b).

6.12.3.3 Grasping and Hand Manipulation Neurons in Posterior Parietal Cortex

Prehension is an object-oriented behavior that is fundamental to skilled actions of the hand. As Lederman S. J. (1994) notes, "the grasp would appear to be a privileged movement pattern of the human hand, inasmuch as it provides varied somatosensory inputs that may be used to guide both motoric and perceptual functions." Skilled grasping behaviors are strongly influenced by both visual and somatosensory information. Visual information about the object's size, shape, and orientation is required during reaching for proper orientation of the hand and for preshaping of the fingers prior to acquisition (Jeannerod, M., 1984; 1994; Milner, A. D. and Goodale, M. A., 1995; Paulignan, Y. and Jeannerod, M., 1996; Connolly, J. D. and Goodale, M. A., 1999; Castiello, U., 2005). The grip aperture of the fingers is proportional to object size and is maximum at 75% of the movement time as the hand decelerates near the target (Jeannerod, M., 1986; Chieffi, S. and Gentillucci, M., 1993; Jeannerod, M., 1994; Jeannerod, M. *et al.*, 1995; Lemon, R. N. *et al.*, 1995; Roy, A. *et al.*, 2002; Hu, Y. *et al.*, 2005). Hand preshaping to object size and shape is characteristic of normal primate hand function and is disrupted by lesions of PPC (LaMotte, R. H. and Acuña, C., 1978; Gallese, V. *et al.*, 1994; Jeannerod, M. *et al.*, 1994; Milner, A. D. and Goodale, M. A., 1995; Fogassi, L. *et al.*, 2001; Tunik, E. *et al.*, 2005). Johansson and coworkers (Jenmalm, P. and Johansson, R. S., 1997; Jenmalm, P. *et al.*, 2000; Johansson, R. S. *et al.*, 2001) demonstrated that visual information helps guide the choice of grasp points on an object to promote stability and efficient manipulation. The development of grasp forces is determined initially by visual identification of the object and retrieval of implicit memory information concerning its physical properties (Johansson, R. S. and Westling, G., 1984; Gordon, A. M. *et al.*, 1993).

Grasping is also influenced by somatosensory information from previous encounters with objects. Through experience we learn how and where to grasp objects, and the rate and amount of force required to lift and manipulate them. Roland Johansson and Göran Westling have shown that when we grasp objects, we do so delicately applying just enough force to secure it in the hand without slippage (reviewed in Johansson, R. S., 1996). The tactile information transmitted by receptors in the hand as objects are handled allows us to develop skills and learn new behaviors that can be used as templates for future action.

Johansson R. S. (1996) proposed that prehension is governed by two control mechanisms operating in parallel: anticipatory parameter control and sensory-driven event control (see chapter by Johansson and Flanagan, this volume). Anticipatory parameter control is used for motor planning of prehension. Subjects anticipate what an object should feel like in the hand when it is viewed and formulate a grasp program. Visual and somatosensory inputs are combined with sensorimotor memories to construct an internal model of the hand shape and grip forces needed for prehension and manipulation of the object. These modalities set a context in which ascending tactile information is interpreted after the object is touched. Anticipatory parameter control also involves the conjoint application of grip and load forces to the object in order to execute a smooth lift without the application of excessive grip force. Discrete event, sensory-driven control describes the sensory information that signals completion of one action such as grasping to allow rapid transition to another behavior such as manipulation. It also includes error signals when a mismatch occurs between expectation and execution of the task, requiring corrective responses. For example, tactile afferents in the hand can detect slippage due to unexpected contours, textures, or weight that require adjustment in hand position or force. Anticipatory parameter control provides an efficient mechanism of sensorimotor control, because long-loop feedback to the cortex is not needed for the initiation of sequential actions. It allows rapid movement execution by relying on experience to control the timing of muscle activation in the hand. Sensory feedback monitors how the task proceeds; this information strengthens grasp motor programs when implemented properly and initiates corrective actions if errors such as slippage occur.

Studies of the neurophysiology of prehension using single unit recordings in monkeys indicate that PPC responses are predictive rather than reactive to touch receptor stimulation during prehension (Mountcastle, V. B. *et al.*, 1975; Leinonen, L. *et al.*, 1979; Taira, M. *et al.*, 1990; Sakata, H. *et al.*, 1995; Murata, A. *et al.*, 1996; Sakata, H. *et al.*, 1997; Gardner, E. P. *et al.*, 1999; Murata, A. *et al.*, 2000; Ro, J. Y. *et al.*, 2000; Debowy, D. J. *et al.*, 2001; Gardner, E. P. *et al.*, 2002; Fogassi, L. and Luppino, G., 2005; Gardner, E. P. *et al.*, 2007a). Other studies demonstrate that sensory-driven control is mediated primarily by neurons in S-I (Iwamura, Y. and Tanaka, M., 1978; Hikosaka, O. *et al.*, 1985; Wannier, T. M. *et al.*, 1986; Wannier, T. M. *et al.*, 1991; Iwamura, Y. *et al.*, 1995; Iwamura, Y. and Tanaka, M., 1996; Brochier, T. *et al.*, 1999; Gardner, E.

P. *et al.*, 1999; Salimi, I. *et al.*, 1999; Ro, J. Y. *et al.*, 2000; Debowy, D. J. *et al.*, 2001; Gardner, E. P. *et al.*, 2002; 2007b; Jenmalm, P. *et al.*, 2006).

Mountcastle V. B. *et al.* (1975) described neurons in areas 5 and 7 activated during exploratory hand movements such as foraging for raisins in small containers. They named these cells 'hand manipulation' neurons but did not document their firing patterns beyond a textual description. They noted that hand manipulation neurons in area 7 responded to both visual and tactile modalities when the stimuli occupied the same spatial location. These cells fired during visual fixation or tracking of desired objects such as food but responded at highest rates during projection of the arm toward the object or manipulation of it in the hand. The eye–hand coordination neurons were situated in the posterior bank of the IPS in the most anterior portion of area 7, a region that is now called the anterior intraparietal (AIP) area. Leinonen L. *et al.* (1979) described similar hand manipulation neurons in the adjacent convexity of the IPL (area 7b) that were active as monkeys tried to acquire raisins or other food morsels from the experimenter and ceased firing as the food was grasped and brought to the mouth.

The first systematic studies of hand manipulation neurons in monkeys were performed by Hideo Sakata and coworkers, who developed a prehension task to study neural responses in area AIP (Taira, M. *et al.*, 1990; Sakata, H. *et al.*, 1995; Murata, A. *et al.*, 1996; Sakata, H. *et al.*, 1997; 1999; Murata, A. *et al.*, 2000). They trained the animals to grasp and pull handles of different shapes located on a turntable in the middle of the workspace. In order to test the visual sensitivity of these neurons, and to measure its effect on hand movements, the task included an instructed delay period in which the animal viewed an object (FIX, Figure 6) before a GO cue signaled the start of the movement period. Some of the task trials were also conducted in the dark where only tactile and proprioceptive signals were available to aid task performance. Sakata and colleagues subdivided the population of hand manipulation neurons into five classes according to their relative sensitivity to vision and somatosensory modalities. The most common class was visuomotor 'object-type' neurons (28%) that were similar to the eye–hand coordination neurons originally reported by Mountcastle V. B. *et al.* (1975). These neurons combined visual and tactile inputs, displaying higher overall firing rates during manipulation in light – in which the animal viewed the object and the hand grasping it – than in the dark when neither hand nor object was visible (Figure 6a). It is unclear whether the enhanced responses resulted from somatosensory input from the hand, efference copy of the motor commands for hand preshaping and grasping, or visual stimulation as the hand entered foveal receptive fields. Responses during the visuomotor and motor tasks were higher than during object fixation, when the object was displayed and viewed but not grasped. Fourteen percent of the neurons tested responded only to the conjunction of vision and hand actions during manipulation in the light (visual nonobject, Figure 6d), showing no response to object presentation during fixation, nor during manipulation in the dark. Another 16% had purely visual inputs, responding only when the object was visible, without increasing their firing rates during reach or grasping actions (visual object, Figure 6c). The remaining 42% of cells did not have overt visual responses; they responded only during the reach and grasp stages of the task (visuomotor nonobject or motor, Figure 6b and e).

The firing rates of hand manipulation neurons were also tuned to broad categories of object shapes tested in this task (Murata, A. *et al.*, 2000). Visuomotor neurons displayed the same preferences during viewing and grasping objects, suggesting that they might provide relevant information about the size, shape, and composition of objects needed to grasp them. However, Murata and coworkers concluded that AIP neurons signaled the type of manipulatory action performed by the hand, rather than object properties, because the neurons did not distinguish between objects of different shape that were grasped using the same or similar hand postures.

Likewise, neurons in areas F5 and F2vr (the primary projection targets of area AIP) responded primarily to the grasp posture of the hand rather than the object form (Murata, A. *et al.*, 1997; Raos, V. *et al.*, 2004; 2006). Raos V. and coworkers (2006) noted that "although the object-related visual responses of AIP neurons reflect the objects' common geometrical features, the object-related visual responses of F5 neurons reflect the chosen grip." These circuits create 'pragmatic representations' of objects in which their intrinsic properties are encoded in terms of the hand postures normally used to grasp them. Since neurons in area AIP respond both to direct view of an object to be grasped and to the actual performance of grasp, they are postulated to be involved in the sensorimotor transformation of the visual representation of object features into the hand posture needed for grasping (Jeannerod, M. *et al.*, 1995; Sakata, H. *et al.*, 1997; Fagg, A. H. and Arbib, M. A., 1998; Rizzolatti, G. and Luppino, G., 2001; Fogassi, L. and Luppino, G., 2005).

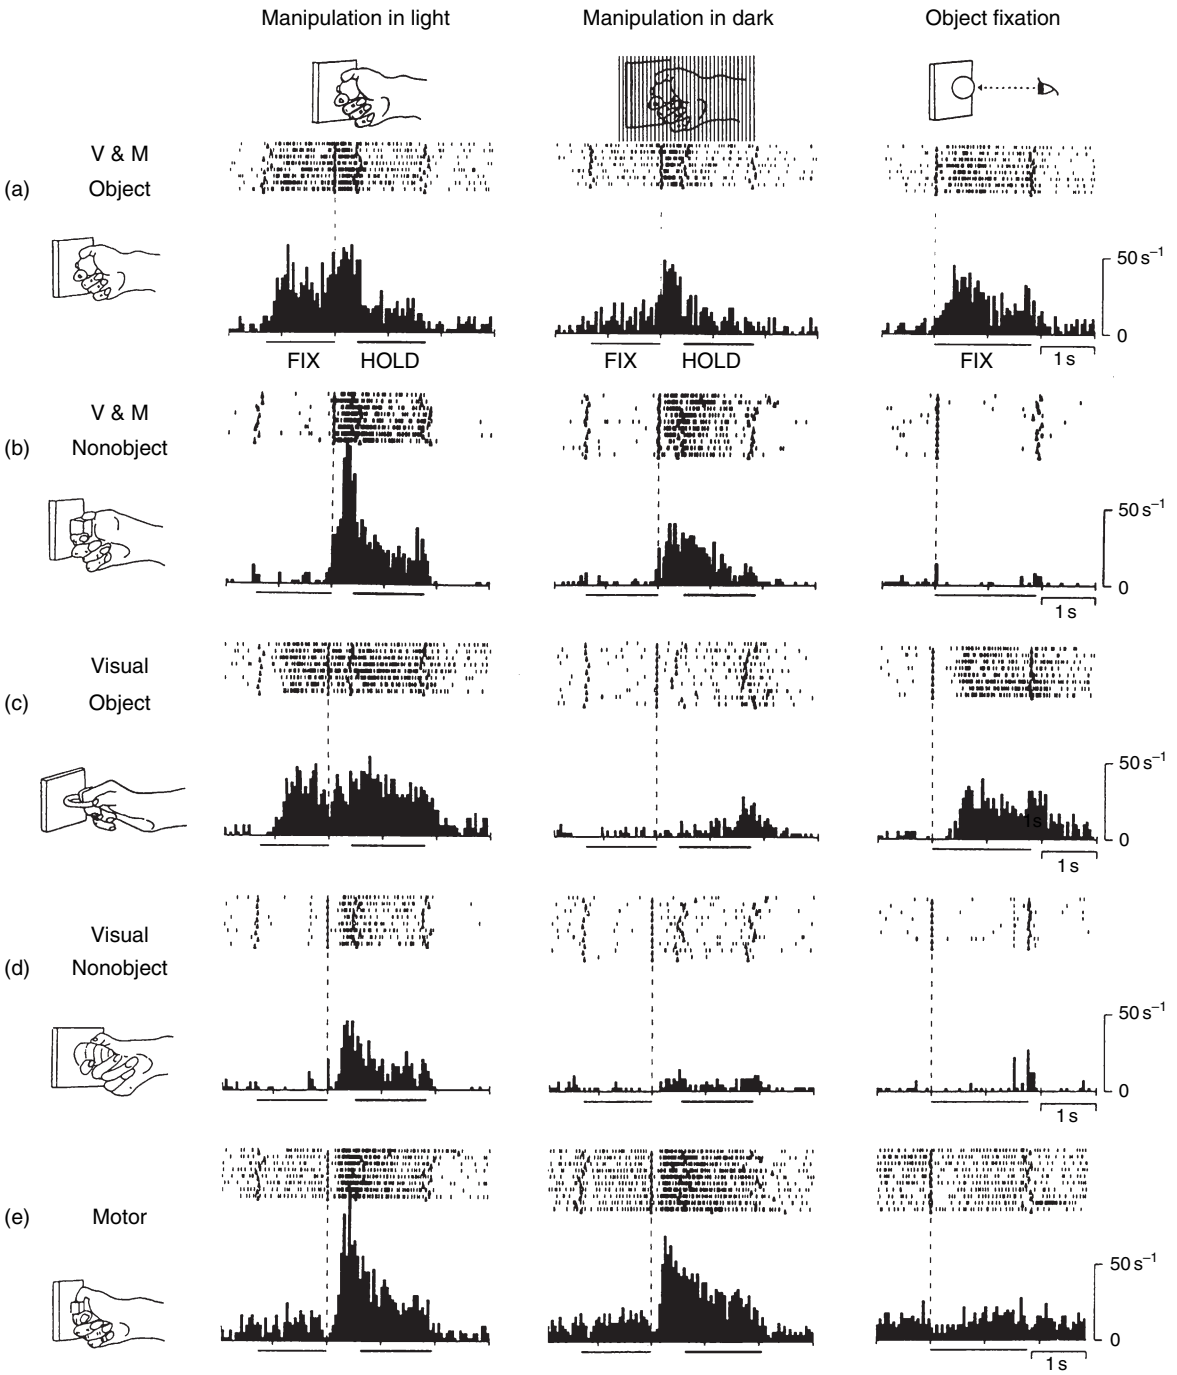

Figure 6 Classes of hand manipulation neurons recorded in area AIP during a prehension task. Responses illustrated in the rasters and peristimulus–time histograms (PSTHs) are aligned to the onset of reach; different neurons are illustrated in each row. At the start of each trial, the animal had to maintain gaze on the test object for ~2 s while pressing a button with the test hand (FIX). The animal was trained to reach toward the test object after a GO signal, grasp and pull it, and maintain the pull posture during the HOLD period. All of these neurons fired at highest rates during reach and grasp actions, and most continued to respond during holding, although at lower rates. Object-type neurons responded to viewing the object during the FIX period; nonobject-type responded only to hand actions but not to visual stimulation. Motor type neurons responded equally well to manipulation in light and in darkness. Reproduced from Murata, A., Gallese, V., Luppino, G., Kaseda, M., and Sakata, H. 2000. Selectivity for the shape, size and orientation of objects for grasping in neurons of monkey parietal area AIP. J. Neurophysiol. 83, 2580–2601; figure 2).

Hand manipulation neurons in area 5 also signal how an object is grasped. Using digital video methods to quantify hand kinematics, Esther Gardner and colleagues found that area 5 neurons responded to the actions of the hand during object acquisition and manipulation (Ro, J. Y. *et al.*, 1998; Gardner, E. P. *et al.*, 1999; Ro, J. Y. *et al.*, 2000; Debowy, D. J. *et al.*, 2001; 2002; Gardner, E. P. *et al.*, 2002; 2007a). Activity in area 5 spanned the period from the start of reach through object manipulation (Figures 7b and 8). Responses began before the hand was stimulated directly by the object when approach was initiated. Firing rates peaked during hand preshaping or at contact and declined after the object was securely grasped in the hand. Neural activity during lifting and holding was weaker than during acquisition and concluded when the object was released from the hand.

Selectivity of neuronal firing rates for particular objects occurred most often after contact and during grasping and lifting actions. For example, the neuron in Figure 9e responded most vigorously to grasp and lift of a large round object (stages 3 and 4) but showed little distinction in firing rates between the test objects during approach or at contact. Most neurons

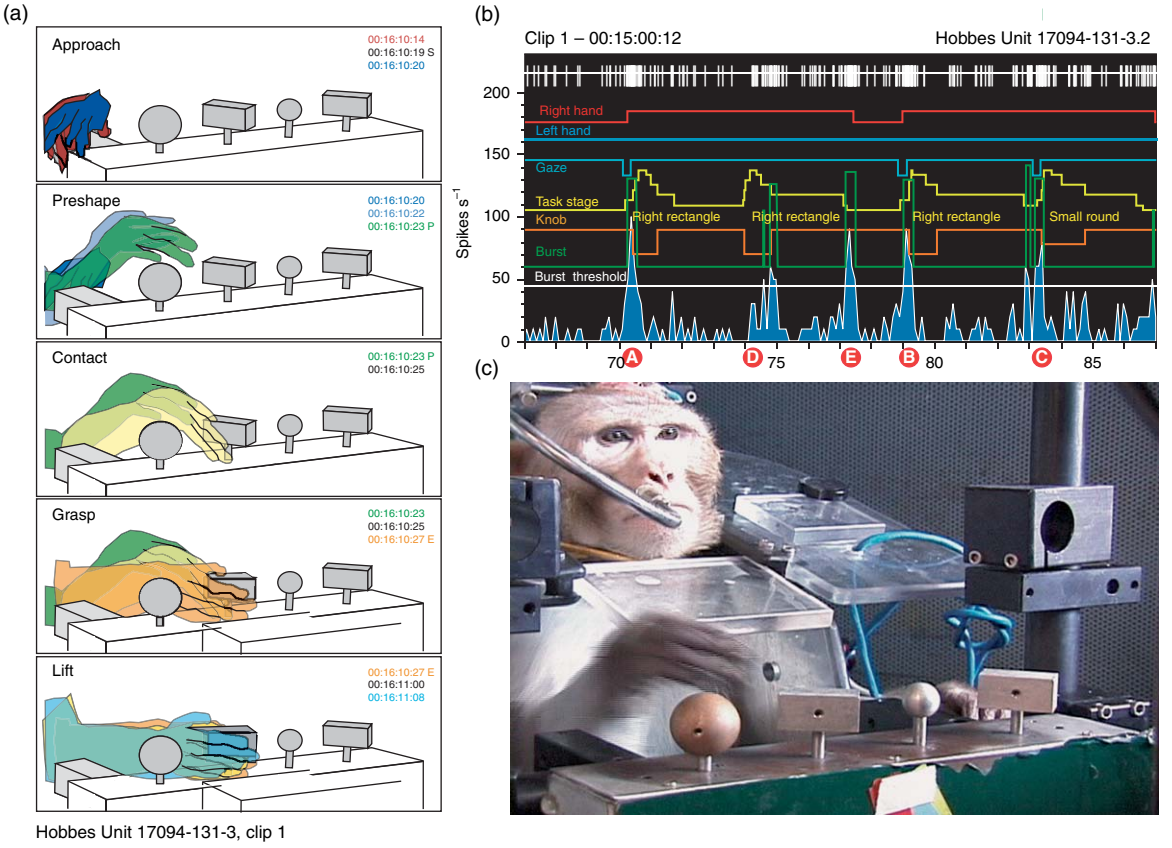

Figure 7 Hand kinematics and neural responses in area 5 during a prehension task. The animal was trained to grasp and lift one of four knobs designated by icons on a video monitor. (a) Kinematic actions of the hand during sequential stages of the task traced from digital video images of a single trial. Labels describe the action performed in the top image of each set. (b) Burst analysis graphs of continuous neural and behavioral activity recorded during the task. Neural responses evoked during the trial in Panel (a) are marked by the red A below the graph. Each burst in this 20 s record coincides with the initiation of a task trial (A–D), or grasp of the chair frame (E). Green burst trace: Periods of firing 1 SD above the mean rate for the entire analysis period. *Yellow task stage trace*: Each stepped pyramid marks a single trial. Upward deflections denote the start of stages 1–4 (approach, contact, grasp, and lift); downward deflections mark the onset of stages 5–8 (hold, lower, relax, and release). *Orange knob trace:* Downward pulses indicate knob location in the workspace and duration of hand contact. Other traces illustrate spontaneous actions of the two hands (red and blue) and gaze fixation on the target object (cyan, downward deflection). (c) Video image captured at the peak of burst A; maximum activity occurred during hand preshaping prior to contact. Modified from Gardner, E. P., Babu, K. S., Reitzen, S. D., Ghosh, S., Brown, A. M., Chen, J., Hall, A. L., Herzlinger, M. D., Kohlenstein, J. B., and Ro, J. Y. 2007a. Neurophysiology of prehension: I. Posterior parietal cortex and object-oriented hand behaviors. J. Neurophysiol. 97, 387–406; figures 4 and 5).

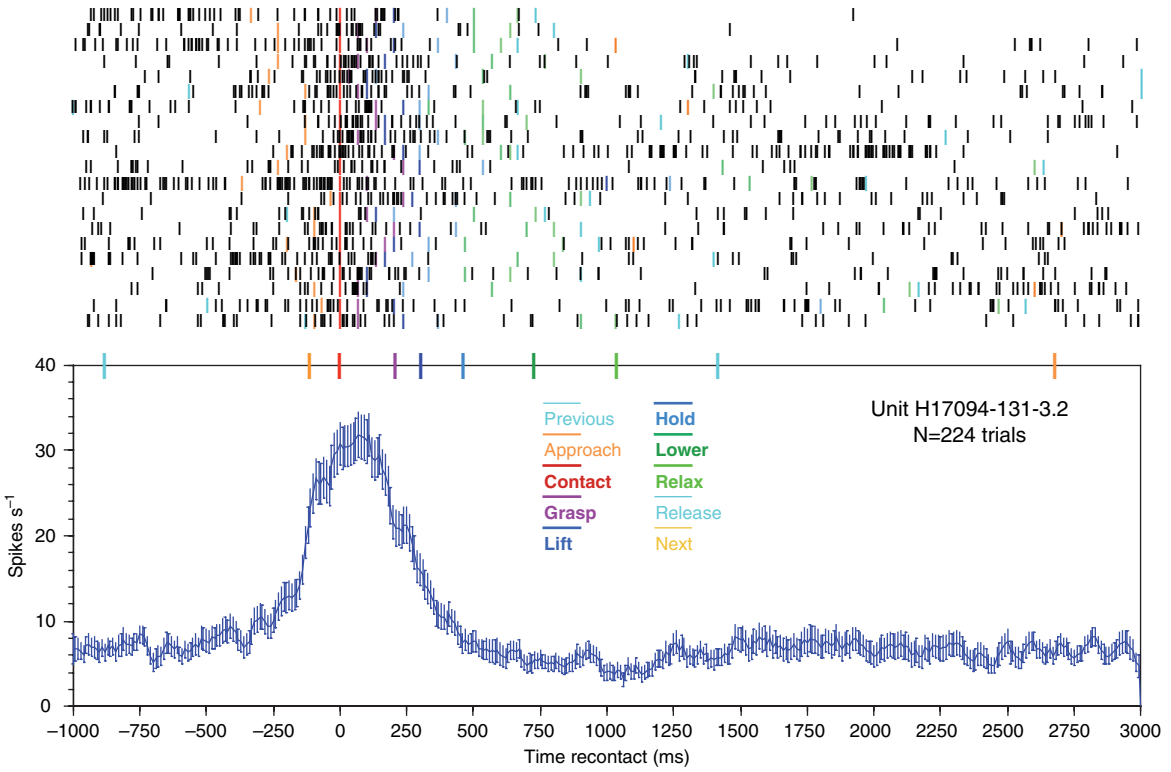

Figure 8 Raster and spike density plot of neural responses during the prehension task aligned to hand contact with the objects; error bars show SEM during each time epoch. Same neuron as in Figure 7. Colored lines on rasters and markers above the spike density graph indicate the onset times of the task stages relative to contact. Responses began ~250 ms before contact at the start of approach and peaked at contact. Modified from Gardner, E. P., Babu, K. S., Reitzen, S. D., Ghosh, S., Brown, A. M., Chen, J., Hall, A. L., Herzlinger, M. D., Kohlenstein, J. B., and Ro, J. Y. 2007a. Neurophysiology of prehension: I. Posterior parietal cortex and object-oriented hand behaviors. J. Neurophysiol. 97, 387–406; figure 7).

in area 5 displayed weak and subtle distinctions between objects as in Figure 9f. The slight preference of this neuron for the smallest object during grasping appears to reflect the tightly flexed posture of the fingers (Figure 9a–d).

The similarity of the hand postures used to grasp these objects and the overlap in evoked firing patterns throughout most of the task suggest that neurons in area 5, like those in area AIP, represent grasp actions of the hand rather than the particular shape of the grasped object. The persistence of neural activity after contact indicates that neurons in area 5 also monitor the success or failure of object acquisition. Dynamic error correction occurred when an incorrect object was touched, and it was reflected in immediate alteration of responses of area 5 neurons (Gardner, E. P. *et al.*, 2007a).

The strong responses observed during approach suggest that the motor commands for hand preshaping and grasping may originate in area 5 and as well as in AIP. Alternatively, area 5 neurons may receive an efference copy of motor commands from the ventral premotor cortex (area F5) that is itself activated from visuomotor signals originating in area AIP. Like reach neurons in the more medial regions of area 5, hand manipulation neurons in the SPL may provide a body schema of hand actions that allow them to compare the predictions of feed-forward grasping plans with feedback sensory information from the hand.

We were somewhat surprised by the weak selectivity for object shape in the area 5 population, as Iwamura and coworkers had reported shape-specific responses in the anterior bank of the IPS during spontaneous grasp of objects such as fruits, rulers, or blocks (Iwamura, Y. and Tanaka, M., 1978; Iwamura, Y. *et al.*, 1985; 1995; Iwamura, Y. and Tanaka, M., 1996). However, it is possible that the selectivity for shape described in their studies may actually reflect the animal's intentions or interest in the test objects. It is clear from Mountcastle's original observations that the intentions motivating grasp of food are different from those directed toward inedible wooden objects. Alternatively, the

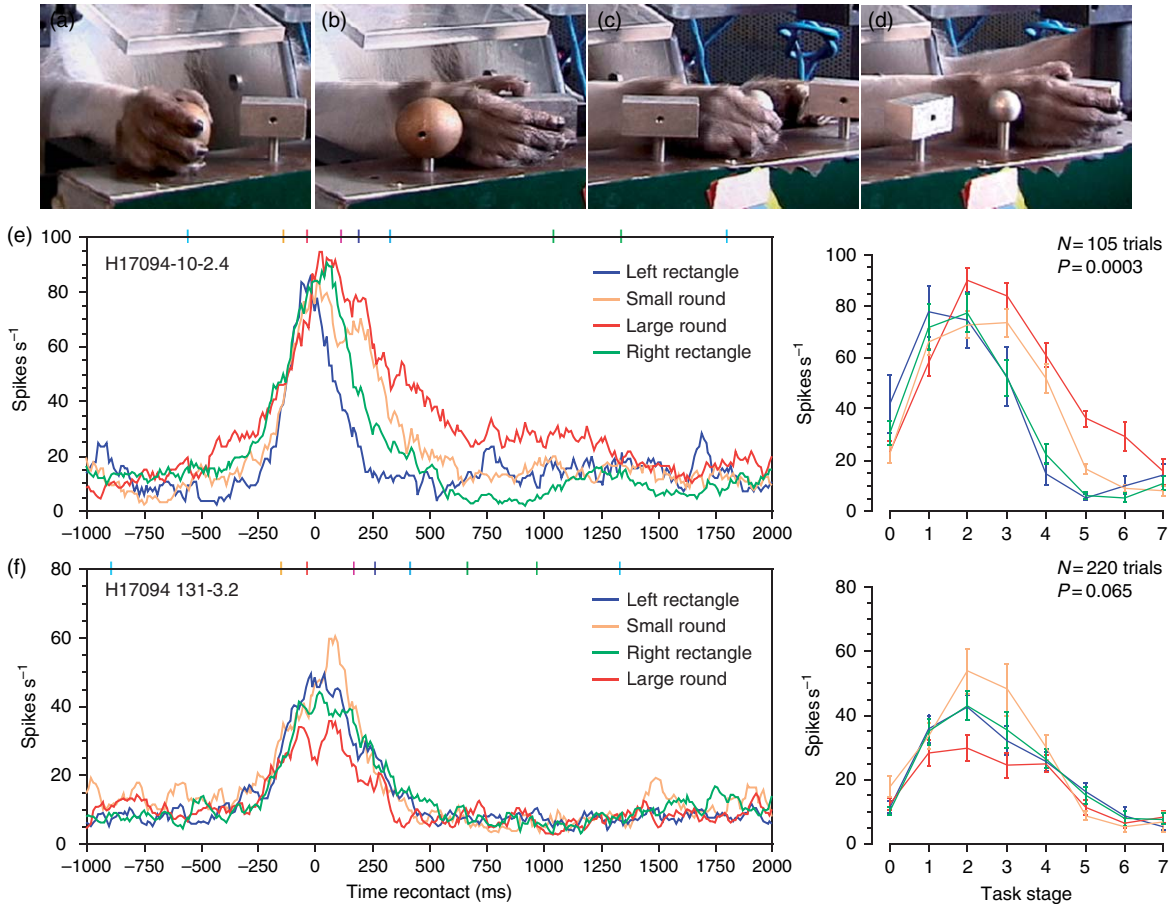

Figure 9 Shape selectivity of two different area 5 neurons during performance of the prehension task. (a–d) Video images of the grasp posture used for each knob captured during recordings from Unit H17094-131-3. (e–f) *Left panels*: Superimposed spike density plots evoked by the four test objects. Right panels: Average firing rates per task stage evoked by each object. The neuron in (e) responded most vigorously to grasp of the large round knob, particularly during lift and hold. The neuron in (f) preferred the small round knob and had the weakest response to the large one; responses to the two rectangles were similar, as these objects were grasped with the same posture.

apparent shape selectivity reported in the Iwamura and Tanaka studies may reflect the diverse hand postures and distinctive muscle activation patterns used to grasp their test objects (Brochier, T. *et al.*, 2004).

Hand manipulation neurons in areas 5 and 7 differ in their sensitivity to visual inputs. As noted above, 58% of the neurons recorded in area AIP responded to viewing as well as grasping objects, and most responded more vigorously during the task when both the hand and objects were visible. Mirror neurons recorded more caudally in area 7b responded to observation as well as performance of grasping, suggesting that they signal action recognition as well as motor planning (Rizzolatti, G. *et al.*, 2001; Rizzolatti, G. and Craighero, L., 2004; Fogassi, L. *et al.*, 2005).

Visual receptive fields in area 5 are rare and, when present, seem linked to view of the animal's own hand rather than to view of the object. Iriki A. and coworkers (1996; 2001) reported that such neurons respond to salient objects (such as food morsels) approaching the hand and fire at peak rates when the object is in range for grasp regardless of where the gaze is directed. These fields may extend beyond the hand when the animal uses a tool to rake in distant food morsels. Maravita A. and Iriki A. (2004) proposed that area 5 neurons may contribute to the animal's own body schema, the conscious perception of one's own actions.

Functional magnetic resonance imaging (fMRI) studies in humans have revealed similar areas for grasping in the human cerebral cortex (Figure 10). The first of these studies by Binkofski, F. *et al.* (1998) demonstrated that patients with lesions that included the anterior intraparietal sulcus had impairments of grasping behaviors whereas patients with PPC lesions sparing this

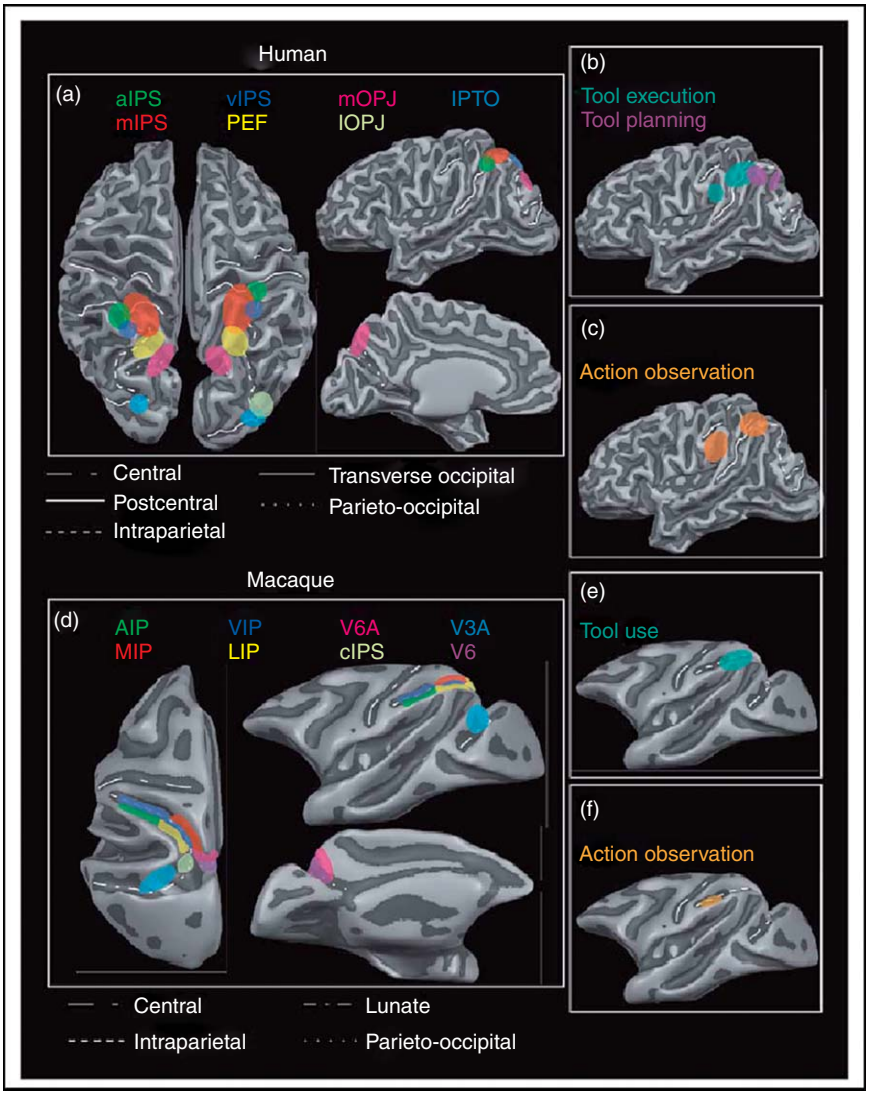

Figure 10 Inflated brain maps of the macaque and human brain showing regions of posterior parietal cortex (PPC) involved in various skilled tasks. Reproduced from Culham, J. C. and Valyear, K. F. 2006. Human parietal cortex in action. Curr. Opin. Neurobiol. 16, 205–212; figure 1).

region did not. The deficits in hand preshaping included slower hand opening during reach, and unusually large apertures betweeen the thumb and index finger of the contralesional hand before contact, compared to age-matched control subjects, and to their own ipsilesional hand. fMRI scans of neurologically normal adults in this same study revealed a focus of activation in the lateral bank of the anterior intraparietal sulcus (aIPS) when they grasped and manipulated rectangular blocks. The activation sites in the aIPS during grasping have been confirmed in subsequent studies comparing grasping and reaching behaviors (Culham, J. C., *et al.*, 2003; Frey, S. H., *et al.*, 2005). These same brain areas are also activated by viewing grasping actions performed by other individuals (Buccino, G., *et al.*, 2001; Fogassi, L., *et al.*, 2005; Shmuelof, L. and Zohary, E., 2005, 2006). More detailed descriptions of areas in the human brain involved in grasping are provided in several excellent reviews recently published (Culham, J. C., and Valyear, K. F., 2006; Culham, J. C., *et al.*, 2006; Grefkes, C., and Fink, G. R., 2005; Tunik, E., *et al.*, 2007).

In summary, hand manipulation neurons in areas 5 and 7 participate in sensorimotor networks involved in grasp planning, prediction of sensory stimulation, and monitoring of appropriate execution of the desired actions. Firing patterns of these neurons appear to

reflect the internal motor commands needed to accomplish task goals, as well as the sensory events resulting from self-generated movement. The onset of firing seems best correlated with the preparation of specific actions. The external tactile stimulation of the hand by the grasped object appears to reinforce the motor plans by signaling the accomplishment of the desired action when successful or provides an error signal for corrective maneuvers when it fails.

6.12.4 Bilateral Coordination of the Hands

Neurons in both the dorsal and ventral stream pathways for touch respond to tactile stimulation of both the contralateral and ipsilateral hands. Anatomical studies indicate that callosal connections within the hand representation do not occur in S-I but first appear in S-II (reviewed in Disbrow, E. *et al.*, 2003) and in PPC (Jones, E. G. *et al.*, 1978; Padberg, J. *et al.*, 2005). Bilateral receptive fields on the hands of monkeys have been found in S-II cortex (Whitsel, B. L. *et al.*, 1969; Robinson, C. J. and Burton, H., 1980a; 1980b; Burton, H., 1986; Disbrow, E. *et al.*, 2003; Fitzgerald, P. J. *et al.*, 2004; 2006) and in PPC (Mountcastle, V. B. *et al.*, 1975; Leinonen, L. *et al.*, 1979; Koch, K. W. and Fuster, J. M., 1989; Iwamura, Y. *et al.*, 1994; Iwamura, Y., 2000; Iwamura, Y. *et al.*, 2002; Padberg, J. *et al.*, 2005), and on midline structures in S-I (Taoka, M. *et al.*, 1998; Iwamura, Y., 2000).

The functional role of distal bilateral receptive fields is unclear and has not been tested rigorously in monkeys. Using digital video, we analyzed how hand kinematics are related to neuronal spike trains recorded in area 5 as monkeys performed trained prehension tasks and spontaneous behaviors engaging both hands (Gardner, E. P. *et al.*, 2001). Many of the cells analyzed responded equally to grasp by either hand. These bimanual neurons represented equivalent actions of the right and the left hand in a common cell population. For example, the neurons shown in Figure 11 responded equally to grasp of a raisin with the ipsilateral left hand (burst D) and the contralateral right hand (burst E). The responses to precision grip were similar to those evoked in the same neurons during the trained task (Figure 7). Like the hand manipulation neurons described by

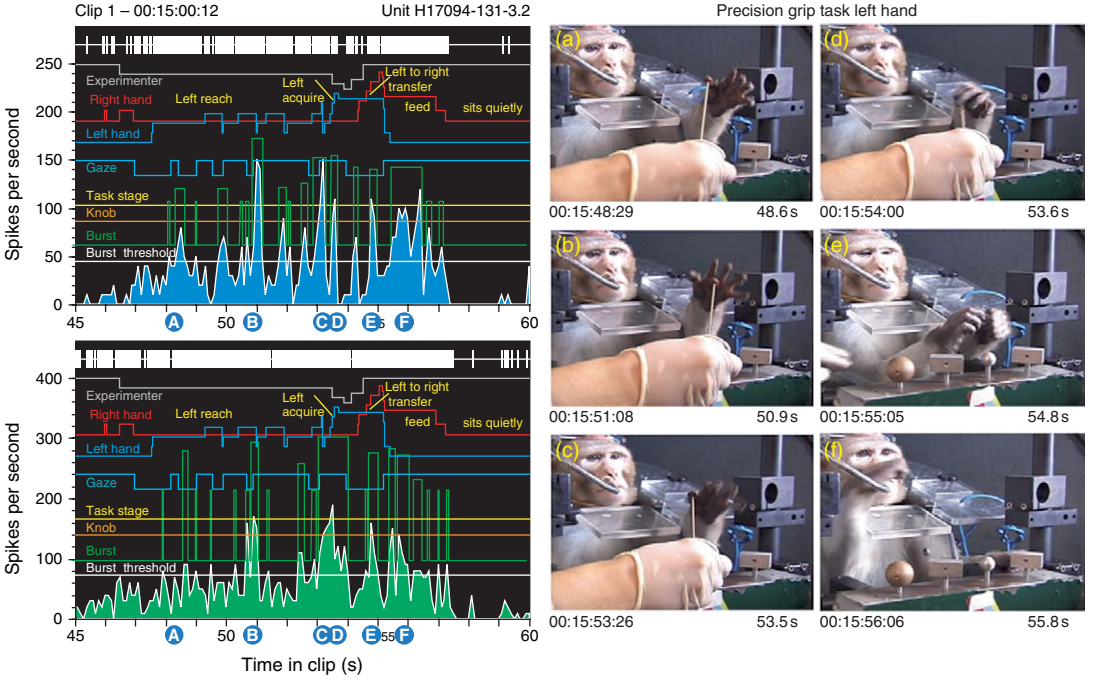

Figure 11 Responses of two simultaneously recorded area 5 neurons to acquisition of a raisin with the ipsilateral (left) hand. Natural grasping actions of the right and left hands (red and blue traces) are represented in the burst analysis records using the same format as the task stages in Figure 7. Each attempt to grasp the raisin was accompanied by a burst of impulses (A–D). Video images captured at the times marked by letters below the burst analysis graphs; note that when reaching toward a moving target, the animal opened the fingers using a baseball glove-like posture to maximize contact area on the hand. Once the stick was immobilized, the animal plucked the raisin using a precision grip between the thumb and digits 2 and 3.

Leinonen L. *et al.* (1979) in area 7b, these area 5 neurons fired at high rates as the hand tracked movements of the raisin by the experimenter (bursts A, B, and C). Activity declined once the raisin was acquired in the hand (burst D), or when the animal withdrew the hand as the target moved beyond reach. These neurons also responded strongly as the hand brought the raisin to the mouth to eat it (burst F).

Other neurons in area 5 fired most intensely when bilateral actions were coordinated between the left and the right hand, as when food morsels were transferred between them (Figure 12). These

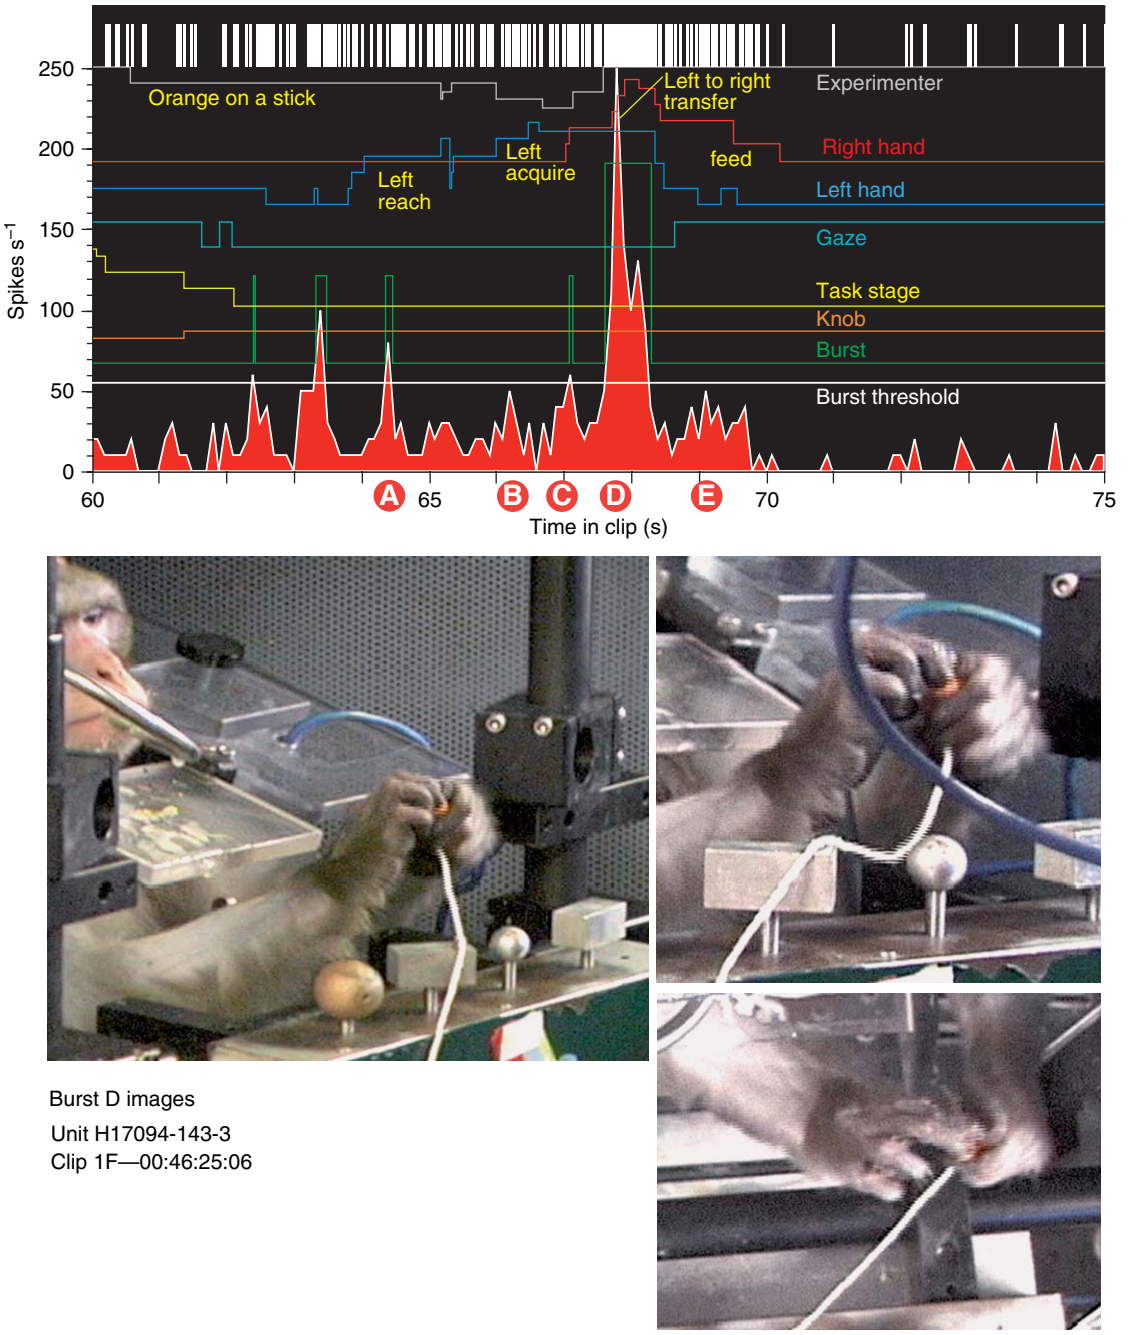

Figure 12 Responses of an intrapersonal-coordinated neuron in area 5 to precision grasp of an orange segment; the strongest responses were obtained when the orange was transferred from the left to the right hand (burst D). Images captured at the time of peak firing on three different cameras.

intrapersonal-coordinated neurons did not just encode equivalent tactile information from either side but preferentially signaled coincident somatosensory data shared between hemispheres during synergistic hand actions. They responded more vigorously to manipulatory actions of the two hands during bimanual transfer than to acquisition or release of food by either hand alone. Kinematic analyses of the hand actions indicated that hand-to-hand transfer integrated two prehensile actions: one hand slowly released grip as the other acquired the object. Bimanual and intrapersonal coordination neurons thus provide somesthetic feedback from both limbs, encoding whether the hands act independently or in concert. Consequently, frontal motor areas receive information, allowing them to coordinate the actions of both hands.

Two complementary mechanisms have been envisaged for bilateral coordination of the left and right hands. Temporal coordination involves a bilateral schema in which each hand is controlled separately in the contralateral hemisphere. Coordinated actions between the hands would need to be synchronized temporally by simultaneous activity in homologous regions on both sides of the brain (Gerloff, C. and Andres, F. G., 2002; Serrien, D. J. and Brown, P., 2002; Swinner, S. P., 2002; Serrien, D. J. *et al.*, 2006). Spatial specialization is a unilateral mechanism in which each hemisphere has neurons activated by bimanual actions (Kermadi, I. *et al.*, 2000; Donchin, *et al.*, 1998, 2002). Specific classes of these bilateral neurons would be engaged when coordinated bimanual activity is required. Although the temporal coordination hypothesis is the traditional view, the spatial specialization hypothesis provides an attractive mechanism for bilateral control for various reasons. In addition to the obvious advantage of providing redundant circuits for recovery from cortical damage, autonomous bilateral control is a prerequisite for hemispheric specialization and unilateral dominance. It also could explain some bilateral interactions observed between the hands during skilled tasks. Grasp forces exerted by each hand are interdependent regardless of whether the hands manipulate the same or different objects (Marteniuk, R. G. *et al.*, 1984; Paulignan, Y. *et al.*, 1989; Geffen, G. M. *et al.*, 1994; Wiesendanger, M. *et al.*, 1996; Ohki, Y. and Johansson, R. S., 1999; Birznieks, I. *et al.*, 2001; Serrien, D. J. and Wiesendanger, M., 2001; Serrien, D. J. *et al.*, 2006); a common output pathway would provide a simple circuit for coordinating grip force during bimanual grasp. PPC is a likely source of such bilateral control, as lesions to the posterior corpus callosum have been associated with losses of coordinated actions between the hands (Eliassen, J. C. *et al.*, 1999; Serrien, D. J. *et al.*, 2001).

6.12.5 Posterior Parietal Cortex and Active Touch

In their original study, Mountcastle V. B. *et al.* (1975) emphasized the difficulty of evoking responses in areas 5 and 7 to light tactile stimuli applied to the hand. However, these neurons were successfully activated when the animal's attention was directed toward the stimuli as a mechanism for reward or during active palpation of surfaces during tactile discrimination tasks. Like the studies of reach and grasp described above, the active touch studies involved goal-directed hand movements. However, the hand actions were directed not toward acquiring objects, but rather to acquiring sensory information needed for reward. Although many of these studies attributed recording sites in the rostral bank of the IPS to area 2, this region is now properly included in area 5 (Pandya D. N. and Selzer B., 1982; Pons, T. P. *et al.*, 1985; Lewis, J. W. *et al.* 1999).

Darian-Smith I. and colleagues (1984) trained monkeys to scan their fingers over gratings using a back-and-forth sinusoidal pattern. About one-third of the cells recorded in their area 5 population responded to the direction of hand movement but failed to signal the spatial properties of the grating surface. Indeed these authors expressed disappointment at the failure to find a greater population of neurons sensitive to the properties of the textured surface. Similarly, Ageranioti-Bélanger S. A. and Chapman C. E. (1992) classified area 5 responses to scans of gratings and smooth surfaces as either texture-related (25%) or movement-related (26%). These neurons were presumed to underlie the analysis of surface texture and the representation of the physical parameters of movement, respectively. Their movement-related cells showed monotonic increases in firing rates precisely timed to the onset and end of hand movement and were independent of whether the surface texture was rough or smooth. In addition, 35% of the texture-related units responded more vigorously during active performance of the scanning movement than to passive stimulation of the fingers with the same surfaces (texture- and movement-related cells); no such units were found in area 3b, and only one was encountered in area 1.

Lastly, they described neurons that were silent during the scanning movement but subsequently fired a burst that was stronger for rough surfaces, suggesting that they signaled the perceptual decision made by the animal.

Studies using procedural memory tasks – in which the animal had to retain visual information about a target's shape or location during a delay period – are consistent with the notion that PPC activity may express the intention to execute a specific motor program. Fifty percent of neurons tested in areas 2, 5, and 7 by Joaquin Fuster and colleagues showed sustained activity during a delayed visual–haptic match-to-sample task related to the surface texture of a viewed object (Koch, K. W. and Fuster, J. M., 1989; Zhou, Y. D. and Fuster, J. M., 1996; 1997; 2000); tactile responses to palpation of the object were of matching sign. These authors proposed that alterations of firing prior to hand contact with an object may represent long-term tactile memory associations with objects previously perceived by touch or by vision. Zhou Y. D. and Fuster J. M. (2000) suggested that, by association, the visual cue might activate the internal representation of the object's tactile features to enable the correct choice. Alternatively, the firing patterns could represent the upcoming exploratory procedures used during palpation by the hand to distinguish the object properties (Klatzky, R. A. *et al.*, 1985; Bodegård, A. *et al.*, 2001).

Object manipulation activates similar regions in the human brain (Binkofski, F., *et al.*, 1999; Bodegård, A. *et al.*, 2001; Grefkes, C., *et al.*, 2002; Stoeckel, M. C., *et al.*, 2004), including area aIPS and the anterior portion of the superior parietal cortex (aSPL) that corresponds to the macaque area 5 hand representation. Activation of aSPL was particularly strong when subjects had to palpate the surfaces to discriminate object dimensions or form, while area aIPS was preferentially activated in cross-modal visual–tactile matching tasks. Neurological tests of stereognosis in humans and psychophysical tests of complex tactile discrimination in humans and animals can be considered goal-directed actions in which the aim is to acquire information about objects, rather than to gain possession of objects as in prehension tasks. The common neurological substrate of both types of behaviors supports hypotheses that the principal function of the dorsal stream involves both the planning of such behaviors and on-line control and adjustment of hand actions to achieve the intended goal.

6.12.6 Conclusions

We have shown in this chapter that goal-directed hand and arm movements seem to play a key role in the responses of neurons in PPC. Although most of the current research has analyzed reaching, pointing, and grasping behaviors, studies of active touch should also be included in analyses of PPC function. The common feature of all of these studies has been the importance of directing actions of the hand to internally generated task goals such as acquiring objects or information about them that are beneficial or desirable to the subject. Repeated experience and practice allows the subject, whether human or monkey, to plan the action efficiently and to monitor successful execution. The feedback circuits between parietal and frontal cortex allow dynamic error correction and updating of existing motor programs. They help guide hand movements to salient targets on an object, whether for efficient grasp or for exploratory palpation. The sensory feedback provided to S-I cortex from the hand may in turn call forth more information by redirecting the hand elsewhere on the object. As such, these circuits enable acquisition of new skills and the maintenance of a repertoire of learned adaptive behaviors of the hand.

Lesions of the hand representation of PPC result in paucity of exploratory and skilled movements of the hand in humans and deficits in stereognosis and other complex tactile recognition tasks (reviewed in Pause, M. *et al.*, 1989; Ghika, J. *et al.*, 1998; Binkofski, F. *et al.*, 2001; Freund, H.-J., 2001; Jäncke, L. *et al.*, 2001). The importance of PPC in monitoring and guiding sensorimotor functions of the hand may explain the neurophysiological basis of such disorders.

Acknowledgments

Major funding for studies from my laboratory described in this chapter has been provided by Research Grant R01 NS11862 from the National Institute of Neurological Diseases and Stroke (NINDS) and from Human Brain Project Research Grant R01 NS44820 funded jointly by the National Institute of Neurological Diseases and Stroke (NINDS), National Institute of Mental Health (NIMH), and the National Institute of Aging (NIA). I thank my colleagues Drs. Daniel J. Debowy,

Soumya Ghosh, Jin Y. Ro, K. Srinivasa Babu, Jessie Chen, and Shari D. Reitzen for their many contributions to these studies, and Dr. Daniel Gardner for insightful comments and criticisms of this chapter.

Glossary

ablation For example, cortical ablation. Removal or excision of a region of cortex.

afferent For example, afferent nerve, of primary afferent neuron. Nerve or neuron that carries impulses toward the central nervous system. The opposite of an afferent nerve is an efferent nerve that carries impulses away from the CNS. To deafferent, is to cut or block afferent input.

brachial plexus A network or plexus of spinal nerves that originate in the back of the neck, extend through the axilla (armpit), and innervate the hand and upper limb. Nerve fibers of the brachial plexus enter or leave the spinal cord from cervical segment 5 (C5) to thoracic segment 1 (T1).

CNS Central nervous system.

D1, D2,. . .,D5 Digits 1–5 where D1 is the thumb and D5 is the little finger.
dermatome A region of skin that is innervated by the sensory fibers of a single dorsal root
contralateral Opposite side of body, ipsilateral refers to the same side of the body
dystonia For example, focal hand dystonia. Disabling movement disorder characterized by sustained contraction of muscles, or muscle spasms that cause abnormal postures or uncontrolled twisting.
fractionated digit movements Independent voluntary control of individual fingers.
Fasciculu Nerve fiber tract
glial scarring Following an injury that causes neuronal cell death in the CNS, glial cells infiltrate the region to phagocytose degenerating neurons. This gradually results in the formation of a glial scar. Astrocytes and oligodendrocytes in the glial scar have been shown to release inhibitory factors that prevent the growth or invasion of axons into or through the glial scar.
hemiparesis Weakness or paralysis affecting one side of the body.
hemorrhagic cyst A cyst containing blood or resulting from the encapsulation of a hematoma.
infarct An area of tissue that undergoes necrosis (cell death) due to the obstruction of the local blood supply.
ischemia A decrease of the blood flow to a part of the brain (or other body part) which is caused by the constriction or obstruction of the blood vessels.
neuraxis The axial unpaired part of the central nervous system, comprising the spinal cord, brainstem, thalamus, and cerebral cortex.
nociceptors Sensory receptors that respond to pain produced by noxious, chemical, or mechanical stimuli.
parvocellular: parvo = small Refers to the small cell component of a neuronal structure. For example, the parvocellular red nucleus refers to that component that comprises small neurons. Large celled = magnocellular
phantom limb A term used to describe abnormal sensations (painful or nonpainful) perceived on a previously amputated limb.
spinal contusion injury An injury caused by the application of a weight of set force to the dorsal surface of the spinal cord. Frequently used to create a rodent model of clinical spinal cord injury.
somatotopy Orderly topographic relationship of receptors in the body from periphery to subsequent levels of the pathway (e.g., brainstem nuclei, thalamic projection nuclei) to functional areas of the cerebral cortex (e.g., primary somatosensory cortical areas 3a, 3b, 1, and 2) in the CNS.
rhizotomy Surgical cutting or severance of spinal nerve roots. A dorsal rhizotomy refers to the transection of just the dorsal nerve roots or rootlets that make up the root.
thalamotomy A stereotaxic surgical technique that destroys a part of the thalamus (typically for therapeutic purposes)
thenar eminence Fleshy region of the palm at the base of the thumb.
transneuronal degeneration Degeneration across synapses from one neuron to the next affecting multiple steps of a pathway.

6.13.1 Introduction

The field of somatosensory plasticity has come a long way in the last two decades. It is now generally accepted that after an especially malleable period during development and early life, the mammalian brain retains a surprising plasticity into adulthood. We still have much to learn about the details of this plasticity; details of where and under what circumstances it occurs, its cellular and molecular bases, functional relevance, and so forth. What is clear, however, is that the brain, from the cortical or subcortical representational map to the underlying synaptic connectivity, continues to respond to ever-changing peripheral and central inputs, or extrinsic and intrinsic environmental circumstances. Inputs can be manipulated in a great variety of ways. Injury, disease, and alterations in behavior brought about by learning, have all been shown to alter the activation and wiring of the somatosensory, as well as the visual, auditory, and motor pathways. System level plasticity has been studied intensively in these

systems for over two decades and the purpose of this chapter is to bring the reader up-to-date with much of the current knowledge and concepts relating to plasticity in the somatosensory system. A good deal of the research being done is broadly directed toward a clinical application, in which reorganizing principles might be used to manipulate and alter neural circuitry to benefit or improve behavioral outcome in the patient. For this and reasons of personal bias, much of the work reviewed in this chapter focuses on primate research, both human and nonhuman. Much excellent work has also been accomplished in the somatosensory system in other mammalian species, most notably the rodent. It has not been possible to address this work in depth in this chapter, and the reader is referred to reviews where possible. However, a section (further in the chapter) has been included that describes some of the most important differences between the rodent and the primate in the organization of the sensorimotor pathways, particularly in the spinal cord. My hope is that some readers will find this summary useful for the interpretation of data in the literature and when comparing specifics of rodent and primate lesion models.

The term plasticity is used in this chapter to refer to the capacity of the brain to reorganize itself in response to changes in input, be it the removal of input following injury, or a change in the activity (amplitude, synchrony, tuning) of inputs to a specific cortical or subcortical region. Neural plasticity can be demonstrated in many ways, and is generally defined according to the technique being used to measure it – an altered behavior, representational map, cellular response, neuronal activity, protein expression, and so forth.

The definition of somatosensory also deserves comment from the outset. In the context of even a simple voluntary task, such as the exploration of an object with the hand, there is a complex interplay between somatosensory feedback and motor control (Jeannerod, M., 1999). Somatosensory plasticity is therefore inherently sensorimotor in nature. For this reason, motor pathways directly associated with changes in the somatosensory system are mentioned throughout this chapter.

Another goal in this chapter has been to address changes that occur at multiple levels of the pathway. Though the early emphasis of study was to look at cortical responses and cortical reorganization, it is now broadly accepted, particularly in work in the somatosensory system, where there is a spinal cord and spatially distributed connectivity from periphery to cortex, that modifications at one level of the neuraxis seldom, if ever, occur independently of other levels. Data is therefore presented for multiple levels of the CNS (see Wall, J. T. *et al.*, 2002 for review of subcortical involvement).

6.13.2 The Functional Anatomy of the Somatosensory System

The primary somatosensory pathway comprises the afferent projections of the sensorimotor system, from peripheral receptors (mechanoceptors, thermoreceptors, nociceptors, etc.) to the spinal cord, brainstem, thalamus, and cortex (Darian-Smith, I. *et al.*, 1996; Darian-Smith, I. and Darian-Smith, C., 2005; Mountcastle, V. B., 2005). If we take hand function as an example, information received by mechanoreceptors of the skin, muscles, tendons, and joints of the hand surface is transmitted via the dorsal roots to the dorsal horn of the spinal cord (see Figure 1). Fibers in the dorsal column project to the ipsilateral cuneate nucleus of the brainstem, and cross the midline in the medial lemniscus before terminating in the contralateral ventral posterolateral nucleus (VPLc) of the thalamus. The cell bodies of the spinothalamic neurons originate in the cervical dorsal horn and cross the midline within 1–2 spinal segments before terminating primarily in the same thalamic VPLc nucleus. In the monkey and human, spinothalamic fibers also terminate more caudally in the anterior pulvinar (Pul.o) of the thalamus, and more rostrally in the posterior nucleus of the ventral lateral complex (VLp). Rodents (and even the cat) do not have an anterior somatosensory component to their thalamic pulvinar, which evolved exclusively in primates with a greater sophistication of hand function. In primates, thalamocortical projections from the thalamic VPLc nucleus terminate within the primary somatosensory cortex (Brodmann's areas 3a, 3b, 1, and 2). Projections from the Pul.o also terminate within these regions, the posterior parietal cortex, and even the caudal primary motor cortex. Figure 1 shows these pathways at their simplest level of organization in the macaque monkey. In rodents, that have only one body map representation in the primary somatosensory cortex (primates have up to 4), and an additional representation in somatosensory area II (SII), thalamocortical projections are far simpler, with projections from the thalamic ventrobasal complex terminating within just the primary somatosensory cortex.

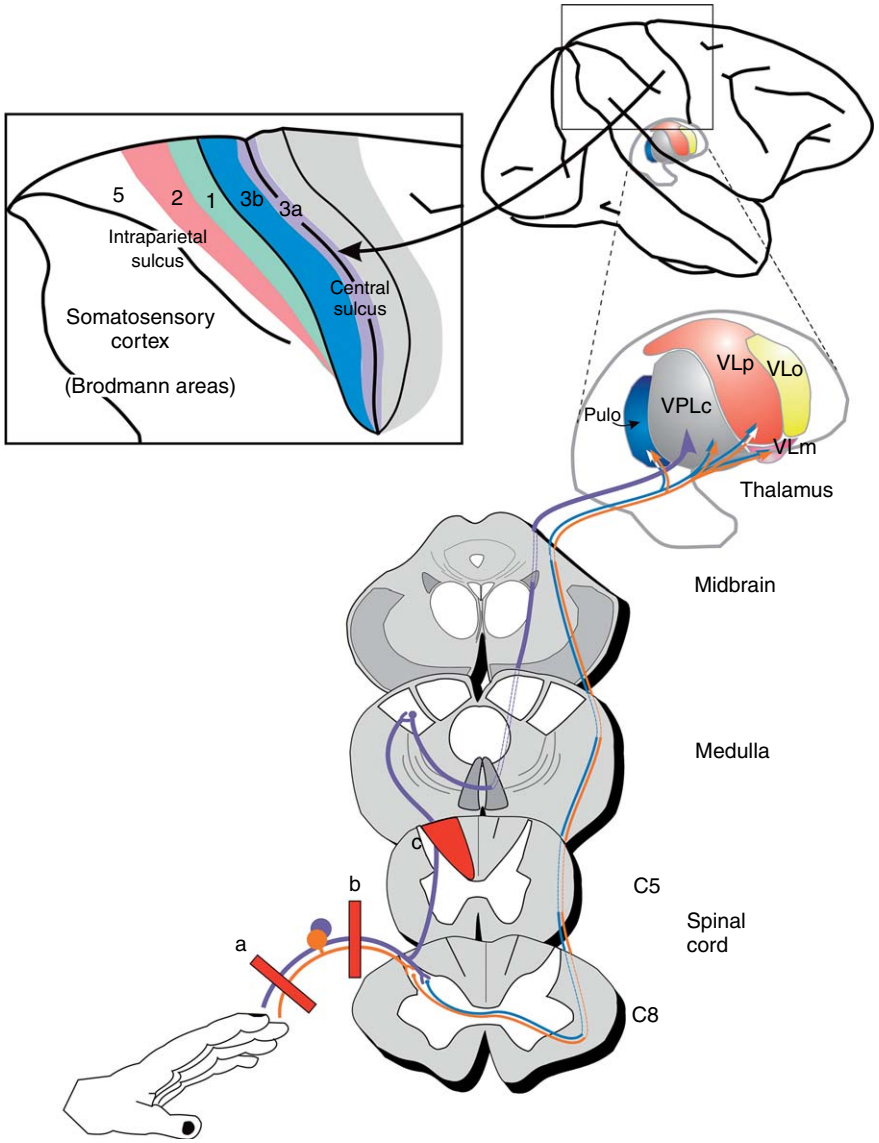

Figure 1 The primary somatosensory pathway showing the two major afferent projections, and the different levels at which reorganization can occur in the primary afferent following injury. a–c mark the three levels at which primary afferent neuronal populations can be blocked following a peripheral nerve (a), dorsal root (b), or central dorsal column (c) injury. In the macaque monkey and human, the primary somatosensory cortex (S1) comprises four functional subdivisions, areas 3a, 3b, 1, and 2, each named according to Brodmann K. (1908). Each area receives input from the full body surface, though there is greater representation of the digits and mouth, or those parts of the body having greater somatosensory receptor density and somesthetic importance. Reproduced from Darian-Smith, I. and Darian-Smith, C. 2005. Touch, Tangible Surfaces and Their Neuronal Representation. In: Encyclopedia of Neuroscience, 3rd edn. (*eds*. G. Adelman and B. Smith). Elsevier, with permission from Elsevier.

In both primates and rodents, additional afferent projections also transmit sensory information to higher levels (e.g., spinoreticular, spinocerebellar, spinocervical), and feedback loops from higher levels of the pathway can be found at every step (Figure 1). For example, the somatosensory cortex (e.g., the hand region in monkeys) projects directly to the cuneate nucleus and to the dorsal horn of the cervical spinal cord, as part of the corticospinal tract. In the execution of fine manipulative tasks that involve ongoing

tactile and proprioceptive feedback from the monkey or human hand, many of these pathways and feedback loops are continuously involved.

6.13.2.1 Functional Circuitry of the Spinal Cord – Comparing Primates and Rodents

The somatosensory and motor circuitry of the spinal cord has been described elsewhere in great detail (Snow, P. J. and Wilson, P., 1991; Willis, W. D. and Coggeshall, R. E., 2004 for reviews), and is only briefly addressed here to help guide the reader through various spinal injury models in different species. Some of the important differences between the primate (including humans) and rodent spinal cord organization are not easily found in a brief overview of the literature and are important to keep in mind when assessing studies that correlate the rodent with the human condition. Figure 2 shows the general layout of the major afferent and efferent pathways of the spinal cord in the primate and rodent, as they relate to the left hand or forepaw and the cervical spinal cord. Primary afferent pathways are shown in color. In addition to the major somatosensory pathways, smaller pathways including the spinoreticular, spinomesencephalic, and spinocerebellar tracts are indicated. The spinoreticular and spinomesencephalic tracts are mainly ipsilateral, terminate in the reticular complex and periaqueductal gray in the midbrain, respectively, and respond to noxious stimuli. Neither pathway transmits cutaneous information. The spinocerebellar pathways transmit signals from muscle spindles and Golgi tendon organs as well as cutaneous information (mainly of the lower body) to the cerebellar nuclei. Cutaneous information also reaches the cerebellum via the cuneocerebellar pathway that receives input directly from dorsal column fibers.

More than 65 million years of evolution divide the early rodent-like mammals and the modern primates. It is therefore unsurprising that there are some notable differences between rodent and primate neuroanatomy. In rats, somatosensory input arising from the forelimb and coursing through the nerves of the brachial plexus, terminates bilaterally in the dorsal horn, from cervical segments C1–C5 (Webster, K. E. and Kemplay, S. K., 1987) (Figure 3). This bilateral projection does not occur in the monkey or human. Rats have an ipsilateral projection (~5%) from the dorsal column nuclei to the thalamus (Wree, A. *et al.*, 2005) which is also not observed in primates. This suggests a greater bilaterality of afferent projections at multiple levels of the somatosensory pathway in the rodent, and such differences may play a role in the adaptive plastic changes observed following peripheral or central injuries. In addition, while the spinocervical tract has been described in the rodent and some primate species, and is particularly prominent in the cat (Willis, W. D. and Coggeshall, R. E., 2004), it is generally associated with the hindlimb and does not appear to play a significant role in primate forelimb circuitry.

Peripheral nerves are also organized somewhat differently in the rat compared with the monkey, and this is important to keep in mind when comparing peripheral nerve and dorsal root injuries in rats and monkeys. As an example, the mechanosensory median nerve innervates a large part of the medial glabrous hand in the monkey and human and projects via dorsal roots to terminate in the dorsal horn through segments C5–C8. In rodents, the median nerve also innervates part of the forepaw, but terminates in the dorsal horn over a greater rostrocaudal distance, from C3 to T2 (LaMotte, C. *et al.*, 1991).

There are also important differences in the organization of descending pathways (Figures 2(c) and 2(d)). The corticospinal tract (CST) has been the subject of numerous investigations over the decades, since it plays a critical role in fine directed movements of the hand and digits in monkeys and humans (Galea M. P. and Darian-Smith, I., 1997a; 1997b). In primates, the corticospinal tract originates from multiple regions of the somatosensory and motor cortex, and is the most functionally important control pathway in voluntary manual dexterity. In the primate, 90% of fibers that project to the cervical cord are contralateral and descend in the dorsolateral CST. An additional 8% of fibers course in the ipsilateral dorsolateral tract and there is a further bilateral component in the ventral tract (~2%). The rubrospinal tract is relatively insignificant in monkeys, and almost nonexistent in the human, and projections from the magnocellular red nucleus of the midbrain have diminished as the parvocellular component has evolved into a more prominent feedback loop to the cortex via the inferior olive and lateral cerebellar hemispheres (Burman, K. *et al.*, 2000a; 2000b). In contrast in the rat, the CST relays mainly in the medial columns (see Figure 2(d)) ventral to the dorsal columns (Brosamle, C. and Schwab, M. E., 1997). A small number of fibers (between 5% and 15%) descend within the contralateral dorsolateral CST and within the ipsilateral ventral CST (<5%). The medial positioning of the CST in the rat is important when

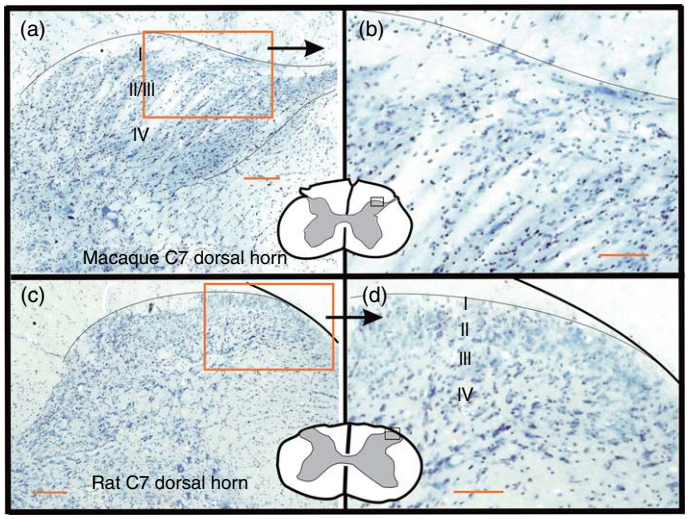

Figure 3 The cytoarchitecture of the cervical (C7) dorsal horn in the macaque monkey and rat, stained with the Nissl stain cresyl violet, showing some of the species differences. (a) In the monkey, large diameter myelinated primary afferents course through the superficial layers, evident as streaks of white matter. Laminae II–III are also difficult to differentiate, and have mostly small diameter (8–10 μm diameter) neurons, with large nuclei and little cytoplasm. (b) Shows the characteristic layering and uniform soma packing density in laminae, which is typical of rodent dorsal horn. Scale bars = 50 μm (a, c), 25 μm (b, d).

considering the effects of a dorsal transection or spinal contusion. In the monkey, sectioning the dorsomedial cord blocks the major cutaneous mechanoreceptor pathway. In the rodent, both the dorsal column and CST pathways are cut. In contusion injuries in the rat, the corticospinal pathway is likely to be involved by the lesion, but this is not the case in a similar injury in the monkey or human. The rubrospinal tract plays a more prominent role in voluntary movements of the limbs than it does in primates, and courses in the contralateral dorsolateral tract.

At a behavioral level, the quadrupedal rodent mainly uses its limbs to locomote efficiently through its external environment. Though their forelimbs and forepaws are used to reach and grasp, in locomotion they are moved in a bilaterally synchronous gate with the hindlimbs. Even with a total transection of the thoracic cord, the hindlimbs can be trained to step when the appropriate sensory feedback is applied to the hindpaws and the body weight-supported. This demonstrates a local spinal circuitry that is capable of orchestrating coordinated limb movement, independent of cortical or brainstem control. Studies that demonstrate the recovery of walking in rodents following cord transection should therefore be interpreted in the context of the rodent.

In humans, a very rudimentary stepping behavior can be learned in patients with a technically complete spinal cord transection. However, while the therapies that simulate synchronous walking in such

Figure 2 (a, b) Shows terminal distributions for the different primary afferent subpopulations into the cervical dorsal horn (left side), and the major ascending (color), and descending (grayscale) tracts involved in the transmission of somatosensory and motor information relevant to sensorimotor control (right). (a, b) The general pattern of input to the different laminae of the dorsal horn is similar in the rodent and macaque monkey, though details and fine circuitry differ. Though the local circuitry and neurochemical composition are complex, and primary afferent inputs less segregated than originally thought, dominant primary afferent inputs have been broadly characterized. In both species, the predominant primary afferent input into lamina I is from Aδ and C fibers. Lamina II is the main recipient layer for collaterals from fine, mainly unmyelinated, sensory fibers, including Aδ and C fibers, but at least in monkeys, this layer also receives some coarse primary afferent input. Large diameter mechanosensory afferents terminate in laminae II (medially) III and IV, but input from large myelinated fibers is dominant in III–IV. Lamina V in both monkeys and rats receives input from heterogeneous sources including collaterals from deeper tissues. (c, d) Shows the major ascending and descending tracts at the level of C6 in both the monkey and rat as they relate to the left forelimb. See text. patients can lead to important collateral health benefits, these patients are not able to step without complete assistance. This is because the circuitry required for walking is particularly complex, and complicated further by the weight-bearing needs of the large human biped.

Forelimbs in the human are no longer used for weight-bearing synchronous locomotion, and have not been for 3–4 million years, when our ancestral bipedal *Australopithecines* lived. Along with an expanding forebrain, primates have evolved pathways that uniquely serve precision manual dexterity and hand–eye coordination. With such an emphasis on hand function, it is perhaps not surprising that primates are the only mammals with corticospinal pathways that directly synapse with motor neurons innervating the hand and forelimb (corticomotoneuronal projections). In the cat and rodent, all corticospinal input to the cord synapses first on interneurons or networks of interneurons within the intermediate zone (Porter, R and Lemon, R. N., 1993). Rodents do not perform fractionated digit movements, have no opposing digits, and can perform only rudimentary sensorimotor tasks of grasping and holding with the forepaws. Paw behavior is not easily compared with primate hand use.

Another neuronal pathway worth mentioning is that of the short and long propriospinal neurons (PSNs). Long PSNs link forelimb and hindlimb activity during locomotion (e.g., walking or running). They originate in C3–C5, travel in the ventral and lateral columns and terminate in the ventral horn of the lumbosacral enlargement. They are spared in midthoracic dorsal hemisection and are able to bridge spinal segments above and below such a lesion. Long ascending PSNs have also recently been reported to project from lumbosacral segments to the contra- and ipsilateral (to a lesser extent) upper cervical cord in the rat (Dutton, R. M. *et al.*, 2006), though the presence of this contralateral projection in the primate is unclear. Primates, including humans, also have long propriospinal neurons that connect fore- and hindlimbs and play a role in coordinating arm with leg swing during locomotion. However, there is no evidence in humans with midthoracic spinal cord injury (SCI) that long PSNs can contribute significantly to the recovery of locomotion postinjury (Dietz, V., 2002). Short PSNs only connect the rostral and caudal cervical cord (C3–C4 and C6–T1) (Bareyre, F. M. *et al.*, 2004).

In the rodent and the cat, which have no direct corticomotoneuronal connections (CM), a substantial amount of corticospinal (CST) excitation reaches the forelimb motor neurons via cervical propriospinal projections. In contrast, in the macaque monkey and particularly in the human, where CST neurons innervate motor neurons directly, the propriospinal pathway plays little part in the transmission of cortical commands to motor neurons innervating the forelimb (Nakajima, K., *et al.*, 2000).

6.13.2.2 Representational Maps

The skin and fascia of the body surface are represented at each level of the somatosensory pathway, in much the same way as the retina of the visual pathway and cochlea of the auditory system. These representations are topographic in their organization or, in the case of the somatosensory system, somatotopic (Merzenich, M. M., *et al.*, 1978; Kaas, J. H. *et al*, 1979). This means that the inputs from adjacent body parts are always located adjacent to each other at subsequent levels of the neuraxis (e.g., within the cuneate nucleus, the VPL nucleus, and the primary somatosensory cortex). The primate hand is also like the retinal fovea in providing the sharpest somatosensory image of the world within reach. As such, the digits of the primate hand have a greater mechanoreceptor density than elsewhere (Darian-Smith, I., 1984), and the skin of the digit pads occupies a disproportionately large region of S1, and subcortical nuclei. Somatotopic body representations can be mapped at any level of the pathway by recording the unitary activity of the component neurons, and receptive fields can be plotted while stimulating the skin surface or deeper fascia. Such maps have been used extensively over the last two decades to explore the mutability of the adult brain following injury, disease, and other manipulations (e.g., learning paradigms).

In adult mammals, map somatotopy remains stable over time, and maps obtained months and even years apart will be largely indistinguishable at the population level. However, when the activity of the constituent neuron populations is modified significantly with, for example, the instigation of a training regiment (Fox, K. and Wong, R., 2005) or following an injury of the peripheral or central pathways, then these central maps alter and adapt to the new circumstances. Cortical reorganization has been demonstrated extensively across species and systems since the early seminal studies of Merzenich and colleagues (Merzenich, M. M. *et al.*, 1983a; 1983b; 1984) who reported significant alterations in the cortical map following a median nerve cut and digit amputation.

Reorganization also occurs at subcortical levels, and has been fully appreciated only in the last decade (see Wall, J. T. *et al.*, 2002 for review). Earlier studies generally focused on the cortical map, because it represents the processing center for all primary pathway inputs, and is easily accessed for electrophysiological recordings. A corticocentricity may also reflect real differences in the organization of visual and somatosensory pathways. In the visual pathway, which has long led sensory system neuroscience research, the receptor sheet in the form of the retina is physically small, and afferent projections to the lateral geniculate nucleus (of the thalamus) and cortex are spatially tightly organized. As such, the most dramatic plastic changes occur in the cortex (Darian-Smith, C. and Gilbert, C. D., 1995). In contrast, the receptor sheet for the somatosensory pathway is comparatively vast and multilayered (skin, muscles, joints) and there is a spinal cord, with its complex spatially distributed parallel circuitry, which is unique to the somatosensory system. This provides more opportunity for subcortical circuit reorganization.

The primate somatosensory cortex is unique amongst mammals in having multiple representations of the body map. The prosimian galago brain has at least three representations of the body surface, divided into the functional subdivisions denoted as Brodmann areas 3a, 3b, and 1.

6.13.3 Somatosensory Plasticity Following Injury

6.13.3.1 Reorganization Following Injury to the Primary Afferent

The somatosensory pathways respond differently to injury, depending on whether the primary afferent neuron is cut or damaged peripherally, centrally to the dorsal root ganglion, or centrally within the CNS (e.g., in the dorsal column; see Figure 1). The extent to which fibers are spared by the lesion, the size of the injury, and the postlesion time period at which changes are examined, will also affect outcome.

The postlesion time period can be divided into several stages of postinjury reorganization. These generally include an acute phase (minutes to hours), a chronic phase (days, weeks, early months), and an extended chronic phase (years). For example, immediately following a digit amputation or median nerve cut, a silent region is produced within the corresponding contralateral cortical hand map, and there is a rapid expansion of the representation of parts of the hand lying adjacent to the silenced or deafferented region. This expansion can occur within minutes to hours, and may persist for weeks to months. During the chronic second stage (weeks to months), there is opportunity for the establishment of new connections from spared inputs and there is a consolidation of the cortical and subcortical body maps. A final stage (years) involves the eventual atrophy of chronically deafferented neuronal populations. This was shown more than a decade after monkeys received a dorsal rhizotomy that deafferented the forelimb (see Jones, E. G., 2000). The cuneate nucleus of the brainstem and the VPLc nucleus of the thalamus reduced substantially in volume over this period (Woods, T. M. *et al.*, 2000), and the face representation expanded proportionately within the somatosensory cortex. This suggests that when the deafferentation is complete and extensive, consolidation involving cell shrinkage and death can continue slowly over many years and even decades.

The patterns of deafferentation that result from injuries to primary afferent neuron populations relaying sensory information from the hand to the cortex, have been studied extensively (Buonomano, D. V. and Merzenich, M. M., 1998; Belyantseva, I. A. and Lewin, G. R., 1999; Bradbury, E. J. *et al.*, 2000; Jones, E. G., 2000; Wall, J. T. *et al.*, 2002; Kaas, J. H., 2002; Ding, Y. *et al.*, 2005, for reviews). They include investigations into peripheral nerve injury (Xu, J. and Wall, J. T., 1999), amputations (Florence, S. L. and Kaas, J. H., 1995), dorsal rhizotomies (Darian-Smith, C. and Brown, S., 2000), and more central injuries to the spinal cord and dorsal column (Jain, N. *et al.*, 1997; 2000; Weng, H. R. *et al.*, 2003).

The following sections briefly summarize what happens when injuries involve different components of the primary afferent pathway, as shown in Figures 1(a)–1(c).

6.13.3.1.1 Peripheral nerve injuries and amputation

Peripheral nerves retain the capacity to regenerate following injury, and will do so unless blocked by a physical or chemical barrier (Sunderland, S., 1991), so the central map changes that result following nerve cut are often relatively minor. Even so, studies in the macaque monkey have shown that if a nerve is cut and then rejoined to enable regeneration, the cortical somatotopic map does not completely recover. Many neurons in the reorganized cortex

develop abnormal multiple receptive fields on non-adjacent skin regions, and the map becomes disorganized (Florence, S. L. *et al.*, 1994). This mislocalization is avoided following nerve crush, presumably because individual fibers are able to regenerate to innervate their original peripheral target.

When nerves are prevented from reaching their original target (e.g., following nerve ligation), cortical reorganization is far more substantial. Following peripheral nerve transection, for example, a silent zone is initially observed within the corresponding somatosensory map, where the digits and/or skin surface have been deafferented. Within minutes to hours the silent zone is surrounded by an expanded representation of the adjacent body parts, and over a period of weeks to months, there is a gradual filling in or expansion of the representation of the adjacent skin surface until the new organization stabilizes. In an early example of this, median and ulnar nerves were sectioned in squirrel monkeys (Garraghty, P. E. and Kaas, J. H., 1991). This resulted in a corresponding deprived region of cortex, which responded over many months to inputs originating from the back of the hand.

Following the amputation of the hand or digits, where afferent and efferent nerves are both cut, the pattern of cortical reorganization mimics that seen following the permanent section of both sensory and motor nerves supplying the hand. Thus, following digit amputation, the representation of the stump region (or adjacent hand) expands into the deprived region of the cortical map. This again takes weeks to months to occur, and parts of the cortex may remain chronically silent if the injury is sufficiently large.

When the whole of the forelimb is amputated in monkeys, there is some expansion of the face representation (which lies adjacent to hand representation) into the hand cortex. Imaging studies in humans with hand or forearm amputations, similarly report face responses within the deprived hand cortex months or even years following the amputation. Though the neural substrate for these observations remains unclear, the longer timeframe suggests that local neuronal growth, synapse formation and modification, and perhaps even some transneuronal atrophy (where years have elapsed since the injury) may contribute (see Section 6.13.6.2.3).

In studies of nerve section or amputation, changes observed within the cortex reflect subcortical reorganization. Cutting nerves supplying the hand in the squirrel monkey, for example, results in the reorganization of the hand map in both the brainstem cuneate nucleus, and the thalamic ventroposterior lateral nucleus (Churchill, J. *et al.*, 2001). Reorganization within the brainstem and thalamus was found to be similar in extent to that observed in the cortex of these monkeys.

6.13.3.1.2 Dorsal rhizotomy – root cut

Mott and Sherrington (Mott, F. W. and Sherrington, C. S., 1895) demonstrated over a century ago that cutting dorsal roots C4–T2 causes an extensive deafferentation of the macaque's hand and forearm, and a profound and lasting impairment of voluntary manipulative movements. In humans, the loss of sensory feedback from the hand (e.g., following brachial plexus injury) also results in a severe impairment in dexterity (Nagano, A., 1998).

When dorsal roots that innervate the digits of the hand are sectioned, the central axons of the primary afferents that are cut degenerate, while their cell bodies within the dorsal root ganglion and peripheral axons remain alive. Thirty years ago, Basbaum A. I. and Wall P. D. (1976) showed that when dorsal roots supplying the hindlimb were cut in the cat, initially deafferented dorsal horn neurons developed novel cutaneous receptive field. Though this work indicated central neuronal plasticity in response to dorsal rhizotomy, the mechanisms were not determined.

Early studies that looked at dorsal root injury in nonhuman primates, focused on a unique group of macaque monkeys, the so-called Silver Spring Monkeys, that received massive dorsal root sections (C2–T4), for an unrelated series of studies, some 12–20 years earlier (Pons, T. P. *et al.*, 1991). These lesions completely deafferented the forelimb, and in some cases part of the trunk, and the arm was rendered completely nonfunctional. The data from these studies demonstrated several things. First, it was shown that chronic deafferentation of such a large magnitude results in significant transneuronal degeneration over many years (Jones, E. G. and Pons, T. P., 1998). Not surprisingly, there was an extensive reorganization of the body map within the thalamic somatosensory nucleus VPLc, and within the primary somatosensory cortex (S1) cortex. In the cortex, no unresponsive zones were detected, but the face was represented over a larger region and abutted the trunk representation in the absence of any input from the deafferented limb. There was also significant atrophy within the cuneate fasciculus of the spinal cord, the cuneate nucleus of the brainstem (37–48%

shrinkage by volume; Woods, T. M. *et al.*, 2000), the thalamic VPLc nucleus and possibly even the somatosensory cortex, though the latter was not determined. Perhaps surprisingly, only 5–15% of neurons were lost within the cuneate nucleus even up to 20 years postinjury. This indicated that shrinkage by volume was associated with a loss of neuropil, axons, and possibly dendrites, rather than a loss of neurons.

In recent investigations in the macaque monkey, we investigated acute, chronic, and long-term changes (>8 months) that accompany substantially smaller dorsal rhizotomies. In these experiments, only dorsal rootlets innervating the first 2–3 digits of one hand were cut (Figure 4). Immediately following one of these lesions, there is no detectable input from the experimentally deafferented digits, and a silent region is present in the corresponding spinal dermatomal map, and in somatotopic maps at the level of the brainstem (Figure 5; Darian-Smith, C. and Ciferri, M., 2006), and somatosensory cortex (Darian-Smith, C. and Brown, S., 2000). These silent zones persist for many weeks at all levels of the pathway and correspond to what can be a severe behavioral deficit initially (see further, Figures 4 and 6). Gradually, over the course of many weeks, and with constant hand use, there is some recovery of digit use (see Figures 4(c), 6(b), and 6(c)), and as this occurs, there is a corresponding reorganization within the cuneate nucleus of the brainstem (Figure 5) and cortex (Figures 4 and 6). Within dorsal root fascicles immediately adjacent to the lesion, cutaneous responses can also be elicited where this was not previously possible.

To examine the neural basis of these changes, a series of anatomical experiments were conducted in monkeys with a similar lesion (Darian-Smith, C., 2004). These indicated that a small population of spared afferent fibers continued to innervate the deafferented digits. These entered the cord adjacent to the lesion site, and for many weeks following the lesion, were presumably too weak in response to drive the somatotopic map at any level of the pathway. The axon terminals of these spared fibers were shown to sprout locally within the spinal dorsal horn and cuneate nucleus over several postlesion months. It was proposed that these sprouts form additional connections with input-deprived postsynaptic target neurons to play a role in driving reorganization at the spinal and higher levels of the neuraxis.

Importantly, these studies also demonstrated a limit to the amount of reorganization and recovery that can occur. Quite extensive postlesion reorganization can occur in the spinal dorsal horn (and at higher levels) as long as a small population (<5%) of uninjured primary afferents remain intact, and continue to transmit information from the impaired digits. For example, in monkeys with lesions that removed most input from the thumb and index finger, there was a complete re-emergence of the cortical map over the first 3–4 postlesion months (Figure 4(b)). However, in macaques with a slightly larger lesion (2–3 segments; Figure 6(a)), the hand map never completely re-emerged. This was true for the cuneate nucleus (Figure 5) and cortex (Figures 4(b) and 6(a)) (Darian-Smith, C. and Ciferri, M., 2005, for additional examples).

6.13.3.1.3 Deafferentation of the dorsal column nuclei

Studies that have investigated the effects of partial or complete deafferentation of the cuneate or gracile nuclei, have shown that deafferented neurons can immediately enlarge or express new peripheral receptive fields from the same or surrounding regions of the body surface, depending on the extent of deafferentation (Millar, J. *et al.*, 1976; Pettit, M. J. and Schwark, H. D., 1993; Kalaska, J. and Pomeranz, B., 1982; Wang, X. and Wall, J. T., 2005). Longer-term changes, such as those described in the previous section and following dorsal rhizotomy (Darian-Smith, C. and Ciferri, M., 2006), also demonstrate substantial reorganization within these nuclei following partial deafferentation. These changes reflect much of the reorganization seen in the somatosensory cortex, and clearly demonstrate that the dorsal column/medial lemniscal pathway plays a role in cortical reorganization.

But what happens when the afferent input to the dorsal column nuclei is completely blocked following a dorsal column section? Some insight into how the somatosensory system can respond is provided in a study of owl monkeys (Jain, N. *et al.*, 1997) in which a high cervical dorsal column lesion (at C3–C4) removed input from the entire extent of the dorsal column nuclei (Figure 7). Though the spinothalamic pathway remained intact, these neurons could not independently transmit sufficient afferent information from the forelimb to reactivate the cortical map. When even a small afferent population was spared, this input was able to reactivate the corresponding cortex and expand its representation into the cortical map. When no afferents were spared within the dorsal columns, face inputs expanded to utilize the adjacent silent forelimb cortex. A subsequent anatomical study showed that preserved inputs from the face had

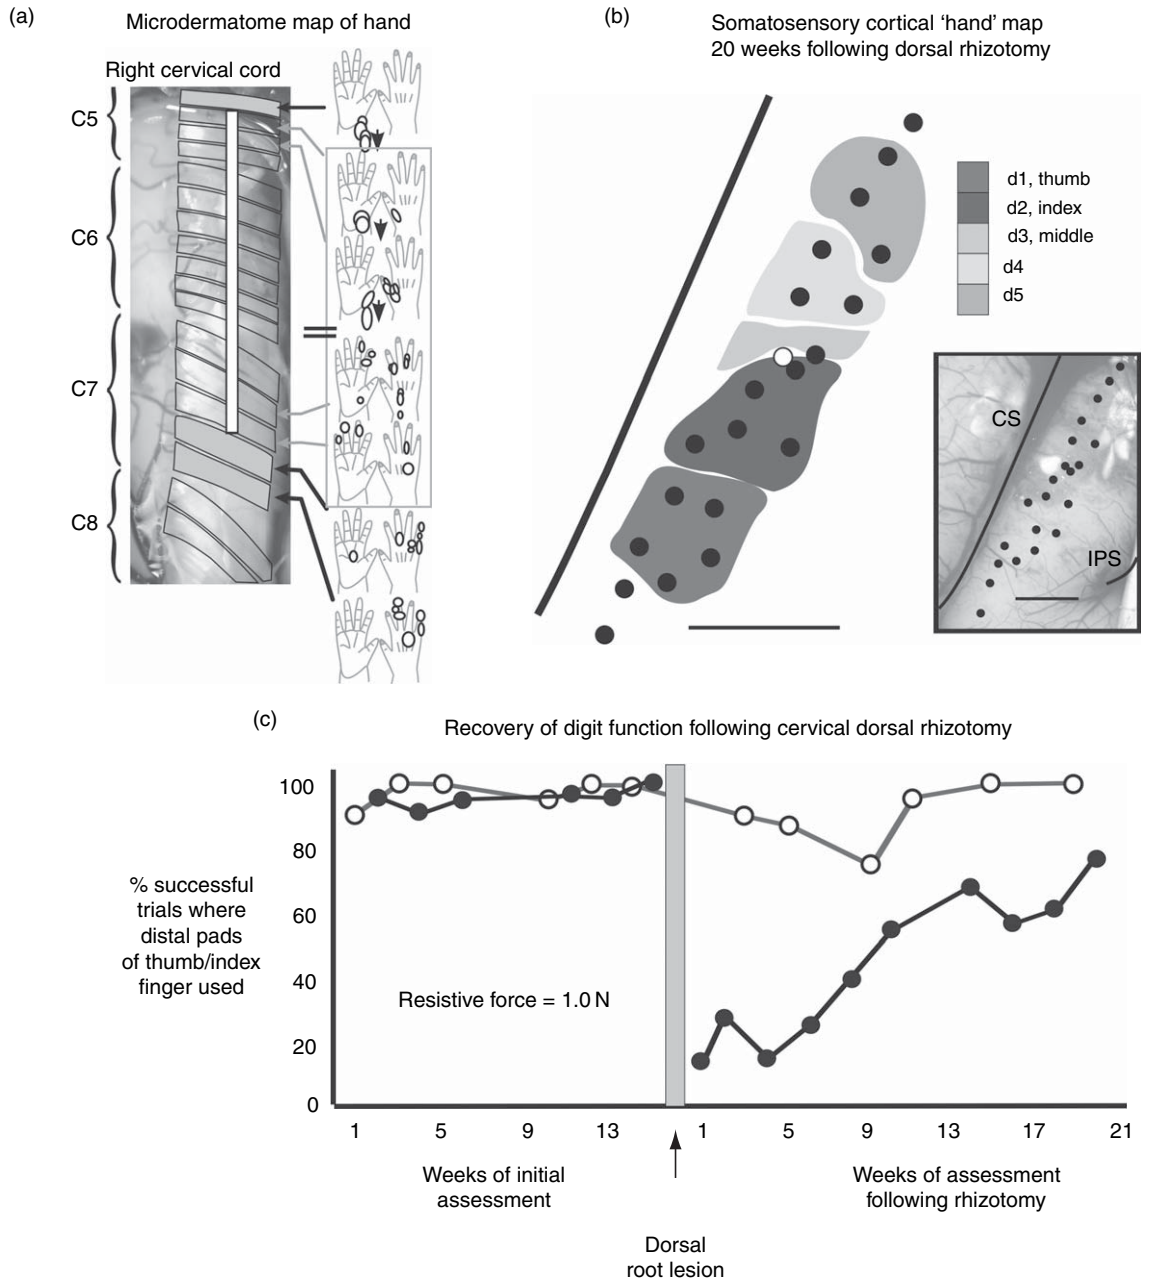

Figure 4 Changes following a dorsal rhizotomy. (a) Shows a laminectomy in a monkey (M-2) in which tactile input was selectively removed from the thumb and index finger. Cartoons of the hand show the distribution of cutaneous receptive fields on the palmar and dorsal surface of the hand in rootlets along the borders of the lesion zone, before rootlets were cut. The white bar marks extent of the lesion. Gray-shaded rootlets identify fascicles that were left intact following the lesion. Afferent fibers within these rootlets altered in their responses over several postinjury months such that cutaneous receptive fields could be mapped on the deafferented digits where this was not previously possible. (b) Shows the corresponding cortical hand map for the same monkey, 20 weeks following the lesion. By this time a complete hand map had reemerged and a silent region was not observed. Black dots indicate recording sites. Color coding shows digit representation as indicated. d1, thumb; d2, index finger; etc. (c) Shows the accompanying recovery of performance of a reach retrieval task in the same monkey over 20 postinjury weeks. The opposition of the pads of the index finger and thumb was the preferred stratagem used by the monkey before the lesion, and in the control hand (open circles). The use of this stratagem was lost immediately following the rhizotomy (black circles) but was gradually recovered over 20 postlesion weeks. The time of the dorsal rootlet section is indicated by the gray bar. Adapted from Darian-Smith, C. and Ciferri, M. 2005. Loss and recovery of voluntary hand movements in the macaque following a cervical dorsal rhizotomy. J. Comp. Neurol. 491, 27–45.

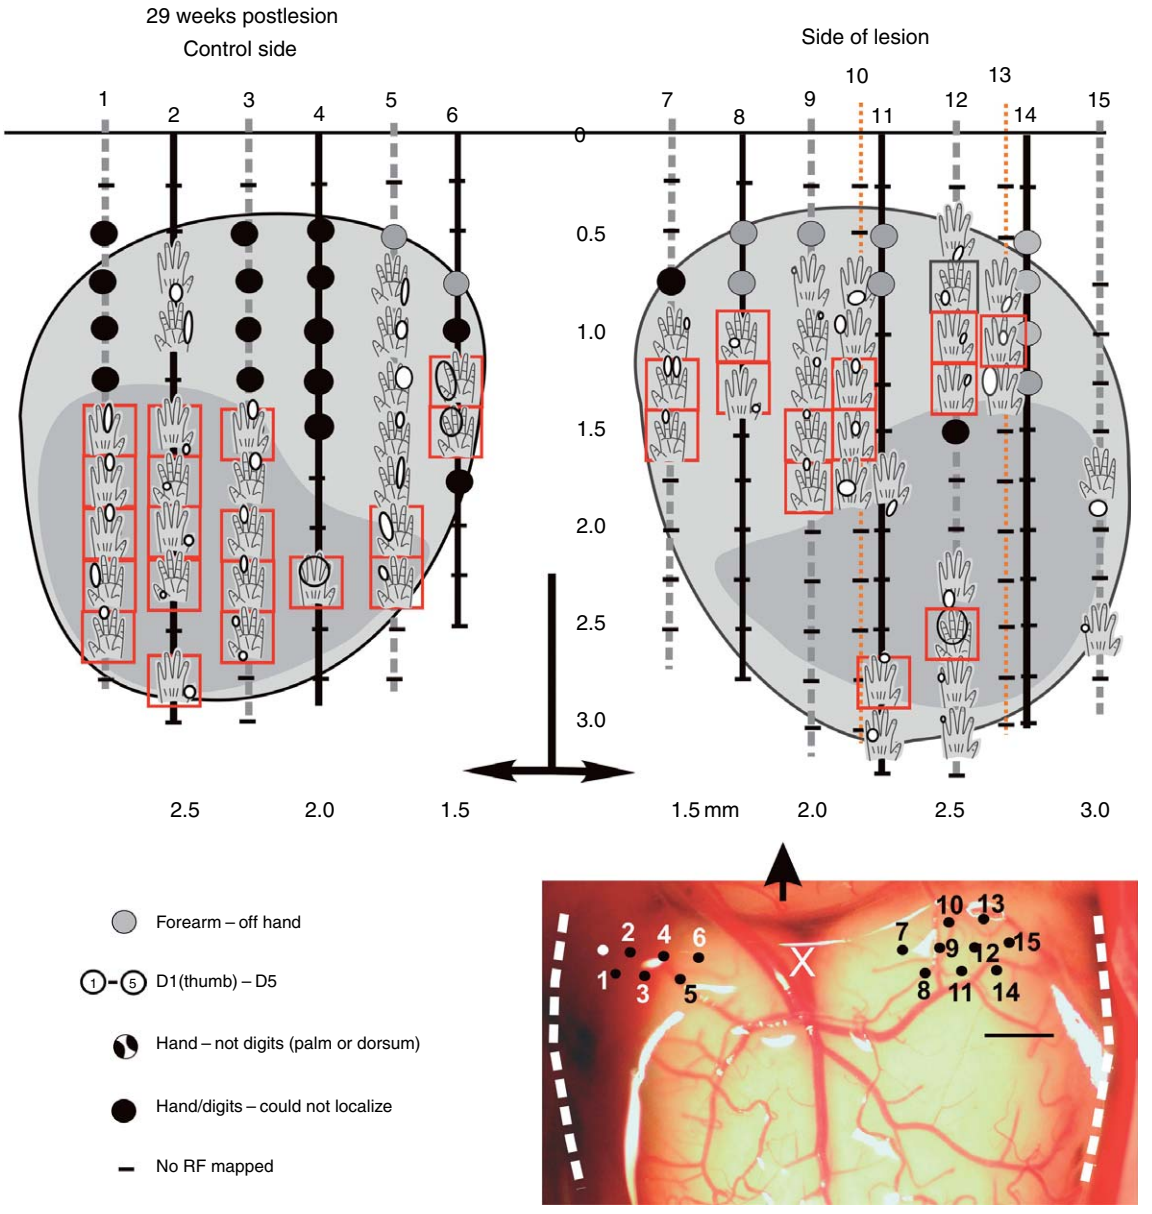

Figure 5 Changes in the pars rotunda of the cuneate nucleus in a monkey that received a DRL that removed input from the thumb, index, and middle fingers. At 2 weeks following the lesion, there were no inputs mapped in the cuneate nucleus on the first three digits of the hand. Twenty-nine weeks following the lesion, shown here, a silent region remained, but surrounding parts of the cuneate nucleus responded to stimulation of the initially deprived digits. Monkeys with slightly smaller lesions also showed a substantial reorganization of the hand map in the cuneate >16 weeks following the lesion, but did not have a silent zone. Electrode penetration sites are on photograph of the dorsal surface of the brainstem. Different rostrocaudal rows of penetrations are identified with different line formatting. Cutaneous receptive fields (RFs) on the digits are shown on cartoons of the hand surface. Shaded regions in the cuneate map on the normal side (right) outline the distribution of D1–D3 RFs. This input zone is transposed to the side of the lesion to help define the original region of input of the experimentally deafferented digits. Scale in photo = 1 mm; numbers refer to electrode penetrations. Adapted from Darian-Smith, C. and Ciferri, M. 2006. Cuneate nucleus reorganization following cervical dorsal rhizotomy in the macaque monkey: its role in the recovery of manual dexterity. J. Comp. Neurol. 498, 552–565.

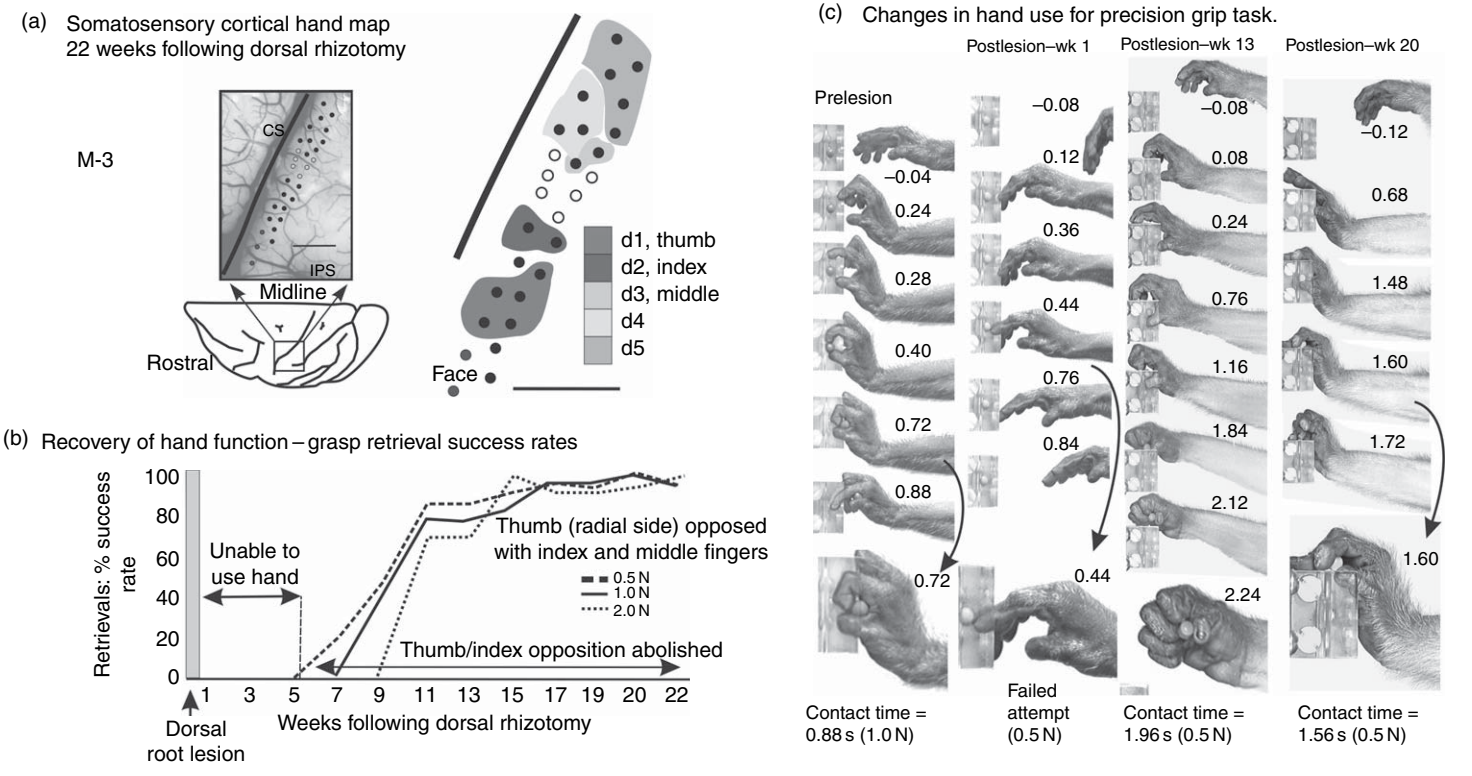

Figure 6 Data from a monkey that received a larger lesion than that shown in Figure 4. Here the dorsal rhizotomy removed all detectable sensory input from the thumb, index, middle finger, and thenar palm of the right hand. This monkey was initially unable to use its left hand at all and could not successfully perform a reach–retrieval task requiring cutaneous feedback for more than 2 months. (a) Shows the partial re-emergence of the somatosensory cortical hand map in this monkey 22 weeks following the lesion. Note that while there was a significant re-emergence of the digit map, a silent region remained. (b) Shows the rate of success of retrieving a target reward following the lesion. Data is given for three clamp forces holding the target, that the monkey had to overcome to retrieve the object. These correspond to increasing levels of difficulty with 2.0 N force being the most difficult and last to be successfully achieved. (c) Shows changes in the strategy used to perform the grasp–retrieval task. The prelesion stratagem shown in column 1, shows the target being grasped and removed by the opposing index finger and thumb. At one week postlesion, the monkey failed to perform the task, or preshape the digits. By the thirteenth postlesion week, the object could be grasped using an abnormal use of the first three digits, and by the twentieth postlesion week, cutaneous sensation had recovered sufficiently so that the monkey was able to retrieve the object 100% of the time, using opposition of the thumb and index fingers. Adapted from Darian-Smith, C. and Ciferri, M. 2005. Loss and recovery of voluntary hand movements in the macaque following a cervical dorsal rhizotomy. J. Comp. Neurol. 491, 27–45.

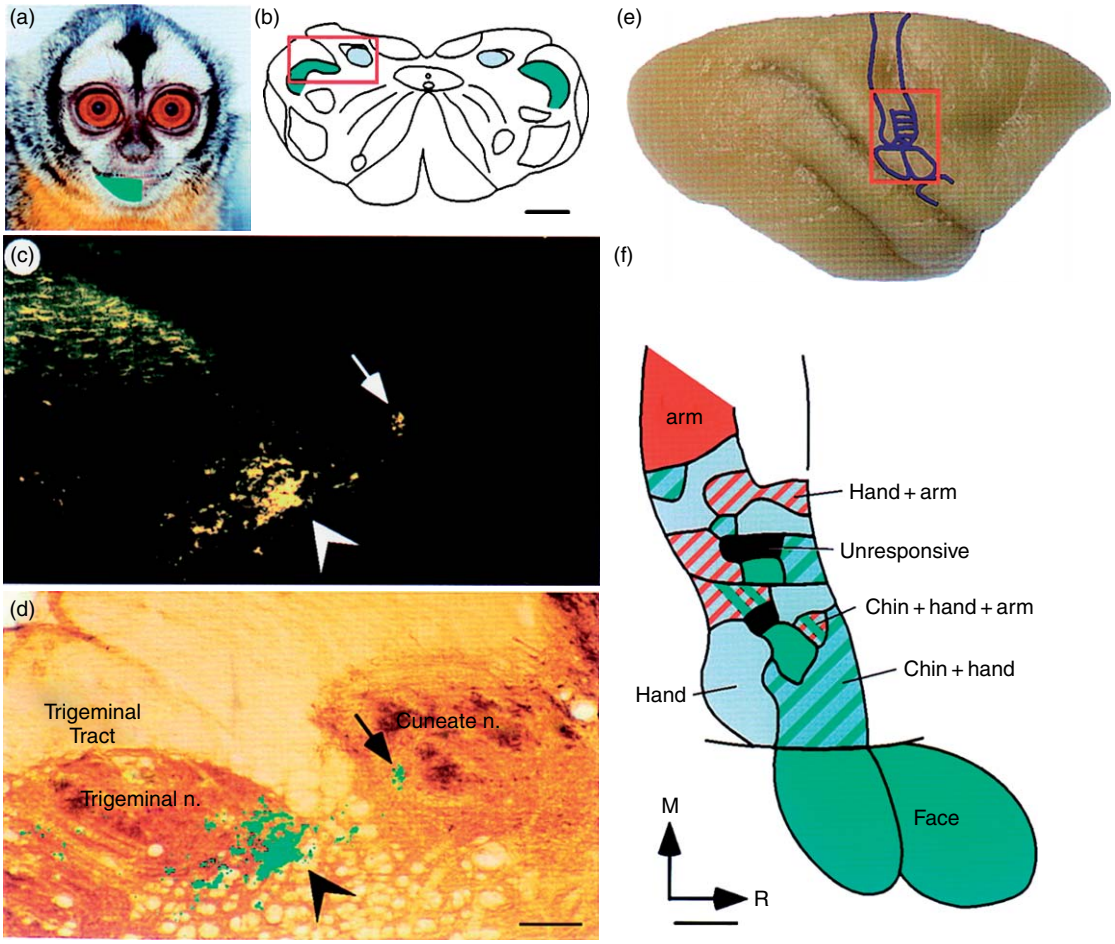

Figure 7 Jain N. *et al*. (2000) showed axon terminal growth from the trigeminal nucleus into the cuneate nucleus in an adult owl monkey 18 months following a complete cuneate fasciculus transection. (a) Shows the location of injections of the tracer B-HRP made into the chin. (b) Shows the cuneate (blue) and trigeminal nuclei (green) in a coronal section through the medulla. (c–d) Show brainstem section and corresponding cytochrome oxidase stained section. B-HRP labeling can be seen in the cuneate nucleus (arrow) following the injections made into the chin. Far stronger normal terminations of inputs from the face are indicated in the trigeminal nucleus (arrowhead). (e) A view of an owl monkey brain showing the somatosensory area 3b and the location of the map shown in (f). (f) Shows a reorganized somatotopy in area 3b following an incomplete dorsal column lesion at C4/C5 (right side). Inputs from the chin, and remaining parts of the hand and arm were observed in the deafferented hand region. Regions that only responded to chin stimulation = green, chin and hand = green and blue hatch, and chin, hand, and arm = green, blue, and red hatch. Regions responsive to hand stimulation = blue, and both hand and arm = blue and red hatch. R, rostral; M, medial; n., nucleus. Scale bar = 1 mm (b, f), 200 μm (d). Reproduced from Jain, N., Florence, S. L., Qi, H. X. and Kass, J. H. 2000. Growth of new brainstem connections in adult monkeys with massive sensory loss. Proc. Natl. Acad. Sci. U. S. A. 97(10), 5546–5550.

grown, over many months, from the adjacent trigeminal nucleus into denervated regions of the cuneate nucleus (Jain, N. *et al*., 2000). These results imply that the spinothalamic pathway does not play a defining role in the cortical reorganization observed, though some controversy regarding the compensatory role of mechanoreceptor afferents within the spinothalamic tract remains (Wall, J. T. *et al*., 2002).

In humans, spinal injuries are rarely restricted to the dorsal column, so it is more difficult to assess the neural bases of acute or chronic changes following such an injury.

6.13.3.2 Behavioral Changes Following Primary Afferent Injury

6.13.3.2.1 Nonhuman primate studies

Though behavioral testing has been used widely to provide a coarse assessment of dexterity (e.g., with the use of Kluver boards) over the years, surprisingly few

nonhuman primate studies have systematically examined behavioral changes following somatosensory pathway injuries, and linked these back to neuronal reorganization.

Investigations that have looked into the effects of dorsal column lesions on hand and digit use over the last several decades, have also been inconsistent in their findings. Deficits described for ostensibly similar lesions have ranged from subtle and insignificant (Leonard, C. M. *et al.*, 1992) to chronic and debilitating. A likely reason for the confusion stems from the lack of lesion reconstruction at the completion of many of these studies, and thus a lack of correlation between the anatomical and behavioral deficits. In studies by Vierck and colleagues, who made this link, transection of the dorsal spinal column was found to initially impair the monkey's ability to discriminate textures, or specifically – the frequency or duration of tactile stimulation (Vierck, C. J. and Cooper, B. Y., 1998). Some monkeys recovered this ability over several months of testing, and others did not. In the monkeys that did recover, it was proposed that they learned to use alternate cues and pathways to assess and discriminate textures (see Figure 8).

The behavioral effects of a spinal hemisection, which also involves the dorsal column, in addition to the corticospinal tract and other ascending and descending pathways on the lesion side of the cord, have also been studied in the macaque (Figure 7; Darian-Smith, I. *et al.*, 1996; Galea, M. P. and Darian-Smith, I., 1997b). Monkeys with a near-complete hemisection at spinal segments C3–C4 initially presented with a severe hemiparesis, but regained the ability to pick up objects with the impaired hand within one month of the lesion. By the end of the third postlesion month, monkeys were able to use their hand and digits quite efficiently in a reach-grasp-retrieval task, though recovery was never fully complete (up to 3 years postinjury). Persistent impairments included a less direct trajectory and preshaping of the hand during the reach component of the task, and some weakness of the opposing digits. The somatosensory component of the task was also clearly impaired, but not as completely as might have been expected. Somatotopic maps of the body representation showed a considerable reorganization of the deprived cortex and a greatly reduced hand map

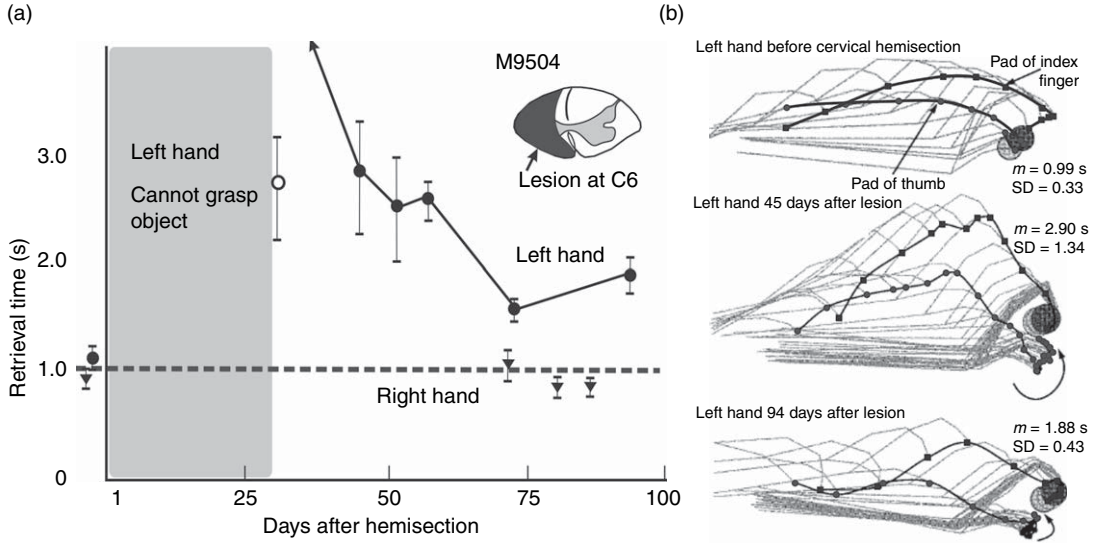

Figure 8 Behavioral changes following a cervical hemisection. (a) Shows changes in the time taken for the monkey to execute a reach–retrieval task following a near-complete left hemisection at C6. Solid circles = mean retrieval time for left hand, triangles = right hand. This monkey could not perform the task with the left hand for the first month following hemisection. (b) Shows stick figure sequences of trajectories of the pads of the index finger (squares) and thumb (circles) of the left hand of the same monkey. Sequences show retrieval prelesion, and at 45 and 94 days after hemisection. Interval period was 80 ms. Postlesion sequences show a slower, clumsier reaching trajectory and thumb opposition. Performance at day 94 was considerably improved from day 45. Adapted from Galea, M. P. and Darian-Smith I. 1997b. Manual dexterity and corticospinal connectivity following unilateral section of the cervical spinal cord in the macaque monkey. J. Comp. Neurol. 381, 307–319.

with abnormally large cutaneous receptive fields. In these studies, previously existing crossover corticospinal projections were thought, at least in part, to mediate behavioral recovery. It was also proposed that the localized sprouting of these or other preexisting pathways may also play a role. Recent examination of the behavioral effects of cervical hemisections supports these findings (Tuszynski and colleagues, personal communication).

Mott F. W. and Sherrington C. S. (1895) showed that sectioning the dorsal roots of spinal segments C4–T4 in the macaque completely blocked somatic sensation in the hand and voluntary digit movements, while sparing some controlled movements of the elbow and shoulder. They also observed that if a single dorsal root was cut in the same range of cervical segments, there was no identifiable impairment of voluntary hand function. In more recent studies of reaching movements following cervical dorsal root transection, some return of gross limb movement was reported in the monkey forelimb. Vierck C. (1982) studied the effects of a dorsal rhizotomy (C3–T3) on forelimb reaching to points in space and found an initially severe deficit, followed by a gradual recovery of some directed limb movements, after many months of training. However, voluntary hand function was not systematically examined.

What happens following a more circumscribed dorsal rhizotomy? Returning to work in our lab, we recently examined the effects of a restricted cervical dorsal rhizotomy on the macaque's ability to perform a voluntary task requiring cutaneous feedback (Darian-Smith, C. and Ciferri, M., 2005). Monkeys were divided into two groups and trained to retrieve a target object from a clamp (Figure 6(c)), using the thumb and index finger in opposition. In group 1, dorsal rootlets containing fibers supplying the thumb and index finger were cut, and in group 2, additional rootlets innervating the middle finger and thenar eminence, were also cut. Performance parameters were assessed before and following the lesion, and included (1) % successful retrievals; (2) digital stratagem (the pattern of digit opposition); and (3) the contact time (or duration of digit contact with the object prior to retrieval). During the first postoperative week, hand function was severely impaired in all monkeys, but over the following weeks, group 1 monkeys recovered the ability to retrieve the object by opposing the index finger and thumb in >80% of trials. Figure 4 shows the gradual recovery of the prelesion digit use over 21 postlesion weeks in one such monkey. Group 2 monkeys with the larger lesion also regained function in the impaired hand. Though this recovery was sometimes dramatic, as in the case of M-3 in Figure 6, it was never complete. Each of these monkeys quickly adopted a stratagem for grasping the target, using digits that were incompletely deafferented. At the end of these experiments, hand representations were mapped within the contralateral somatosensory cortex, and in the cuneate nucleus (Darian-Smith, C. and Ciferri, M., 2006) to define hand deafferentation and cortical reactivation, and in all cases, a tight correspondence was observed between these somatotopic maps and digit use. For example, if the monkey regained function in the thumb and middle finger but never again used the index finger, digit maps consistently showed a re-emergence of input from the thumb and middle finger, and a silent zone for the index finger.

These behavioral studies, which focus on hand sensorimotor function, consistently demonstrate that the sparing of even very small numbers of somatosensory fibers (<5%) can lead to quite dramatic behavioral recovery during the early postinjury months.

6.13.3.2.2 Behavioral studies in the rodent

A number of behavioral testing paradigms have been developed in recent years to assess sensorimotor deficits and recovery in rats following various injuries. Due to the relatively undifferentiated use of the forepaw in rodents compared with primate hand and digit function, the measurements that can be made in rodent limb behavior studies are inherently crude. However, they do provide a consistent measure of a particular sensorimotor capacity that can be followed over time. A full description of these sensorimotor tasks and rodent study outcomes falls outside the scope of this chapter (see Basso, D. M. *et al.*, 2002; Cenci, M. *et al.*, 2002; Nudo, R. J. *et al.*, 2006 for reviews and original articles). However, some examples for testing fore- and hindlimb function include the following. What is commonly referred to as the sticky tape test, involves placing stickers on the forepaws following a unilateral cortical (or subcortical) injury. Determining which sticker is removed first and the speed of removal measures sensorimotor deficit asymmetry. Rod, beam, and grid walking tests are commonly used to measure forepaw placement and thus sensorimotor coordination. Reach training has also been used to test and encourage the use of an impaired forelimb and paw following, for example, cortical ischemia (Biernaskie,

J. and Corbett, D., 2001), and finally, the Basso–Beattie–Bresnehan (BBB) scale is becoming widely used to test open field locomotion (Basso, D. M. *et al.*, 1995). Variations of a reach-grasp task are also used to measure grip force following spinal injuries that implicate descending as well as ascending sensorimotor pathways (Courtine, G. *et al.*, 2005). In studies looking at questions relating to plasticity in the barrel fields, a large number of whisker deflection, and object discrimination tasks involving the stimulation of one or more whiskers are used to alter or measure behavioral outcome.

6.13.4 Somatosensory Plasticity in Learning and Experience

A pervading theme through this chapter is that neuronal connections and cortical maps are continuously shaped and reshaped throughout life in accord with changes in our experience. This holds for injury, as we have seen; it equally holds for extensive training or use of a particular somatosensory or sensorimotor task. A persistent change in behavior is therefore sufficient to drive cortical and subcortical reorganization, which highlights the relevance of neuronal plasticity in our daily lives (Pascual-Leone, A. and Torres, F., 1993; Elbert, T. *et al.*, 1995; Buonomano, D. V. and Merzenich, M. M., 1998; Braun, C. *et al.*, 2001; Elbert, T. and Rockstroh, B., 2004).

6.13.4.1 Cortical Reorganization in Response to Learning

The somatosensory cortex lends itself well to the investigation of the role of sensory experience and learning in shaping neuronal circuitry, both because the S1 cortex is accessible, and because sensorimotor performance can be readily manipulated and assessed behaviorally. Merzenich and colleagues conducted seminal work on this during the early 1990s (Jenkins, W. M. *et al.*, 1990; Recanzone, G. H. *et al.*, 1992a; 1992b; 1992c; 1992d), in which monkeys were trained in various behavioral tasks that increased cutaneous stimulation to one part of the hand. A number of findings emerged, which have gathered much experimental support since. It was found that intensive repetitive stimulation of a skin surface, or the use of a part of the hand in a tactile discrimination task involving training over weeks and months, results in (1) the expansion of the representation of the stimulated skin surface in the corresponding somatosensory cortical map, (2) a decrease in RF size in the same region, signifying a greater sensitivity or focus of processing of input from this area, and (3) some shifting and reorganization of the surrounding cortical map representing adjacent parts of the hand. In tactile frequency discrimination tasks, where monkeys were rewarded for correct performance, an increased incidence of overlapping receptive fields (RFs) was also observed in areas 3b and 3a in regions representing the trained skin surfaces (Recanzone G. H. *et al.*, 1992a; 1992b; 1992c). Importantly, these and more recent investigations, have shown that spatial, as well as temporal response properties of cortical neurons can be altered with coherent, behaviorally relevant, and temporally coincident peripheral input. Behavioral relevance infers motivation, which can be correlated directly with more significant alterations to the cortex and improved motor performance (Jenkins, W. M. *et al.*, 1990; Lotze, M. *et al.*, 2003). Behaviorally induced cortical reorganization generally requires an intense training schedule, from several hours per day for many days, to a daily regimen over many weeks to months, and examples of this in humans (e.g., Braille-reading, instrumental playing) are discussed ahead. Training raises the activity level of the corresponding cortical and subcortical pathways, and leads to changes in the morphology and neurophysiology of the constituent neuron populations.

6.13.4.1.1 Activity-dependent changes in synaptic transmission – hebbian learning and long-term potentiation

An abundance of studies, primarily in the cortex, have shown that synaptic transmission and strength is greatly influenced by experience and learning. This activity-dependence, which follows Hebbian, or Hebbian-like rules (Hebb, D. O., 1949; Cooper, S. J., 2005), is important for altering synaptic efficacy, in response to changes in the input from the periphery (i.e., through injury, disease, or skill learning). The basic premise of Hebbian-based learning is that synaptic strength increases between neurons that are activated together. That is, synapses are modified when there is simultaneous activation of the presynaptic and postsynaptic neuron. More specifically, when the presynaptic action potential precedes the firing of the postsynaptic neuron, the synaptic response increases (long-term potentiation (LTP)).

Conversely, when the postsynaptic action potential precedes that of the presynaptic cell, the synaptic response decreases (long-term depression (LTD)). The temporal correlation of inputs (typically around a time window of ~100 ms) is therefore critical to synaptic state. Also critical to Hebbian learning is a cellular mechanism for detection of rapid successive pre- and postsynaptic activation. The *N*-methyl-D-aspartic acid (NMDA) receptor (a subtype of glutamate receptor) performs this role by enabling Ca^{2+} influx in the presence of Glu and postsynaptic depolarization, a step that is critical to LTP induction. NMDA-receptor activation requires sufficient depolarization to enable LTP induction, so the balance of inhibition and excitation is critical to synaptic plasticity. As such, a large number of studies have looked at the regulation of GABAergic pathways in the brain following injury, learning, and disease.

LTP has primarily been associated with learning in the hippocampus, but has also been demonstrated *in vivo* in sensory and motor cortex (Baranyi, A. and Feher, O., 1981; Iriki, A. *et al*., 1989; 1991; Baranyi, A. *et al*., 1991; Aou, S. *et al*., 1992; for reviews see Weinberger, N. M., 1995; Buonomano, D. V. and Merzenich, M. M., 1998; Garraghty, P. E. and Muja, N., 1996; Myers, W. A. *et al*., 2000; Elbert, T. and Rockstroh, B., 2004; Fox, K. and Wong, R., 2005). Either LTP or LTP-like mechanisms are inferred in all neuronal reorganization, and are thought to play a fundamental role in mediating the maintenance and modification of somatosensory plasticity, including plasticity that occurs with skill learning.

6.13.4.2 Cortical Plasticity in Braille Readers

A particularly striking example of tactile skill learning or use-dependent cortical reorganization can be seen in blind Braille readers (see Figure 9). Braille-reading involves intense stimulation of the digit pads of the reading fingers, sometimes for many hours per day, and over many years. With considerable experience, proficient Braille readers, and particularly those who use multiple fingers and both hands, are capable of reading speeds of 200 or more words per minute (Foulke, E., 1991). The sensorimotor cortex activated by the reading digits of Braille readers, has been shown to be enlarged relative to their

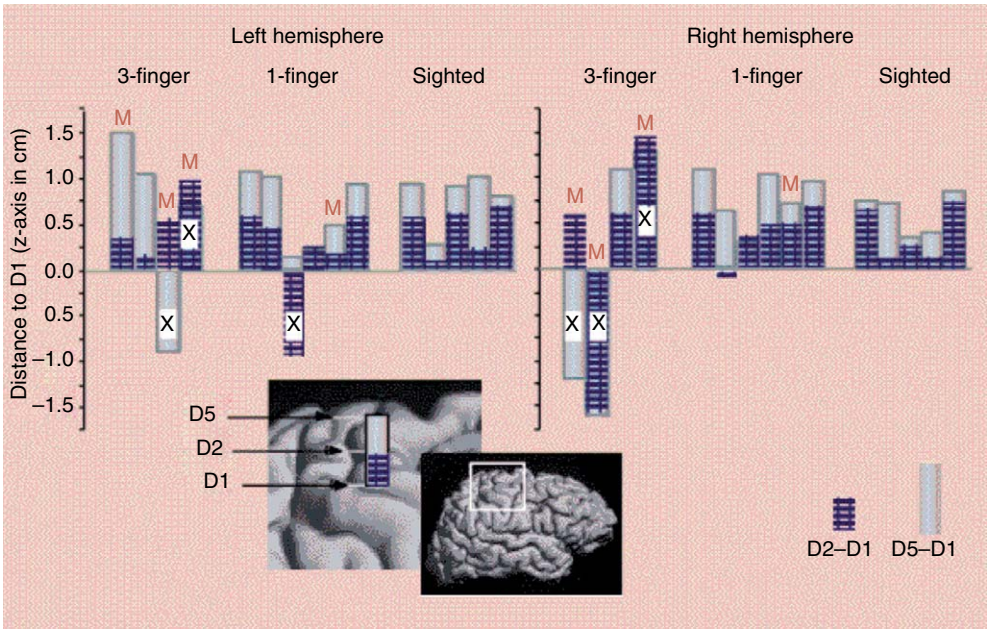

Figure 9 Using magnetic source imaging, Sterr A. *et al*. (1998a) showed that finger representations were topographically disordered in blind Braille readers who used 3 digits from both hands. These individuals also misidentified touched digits. Figure shows the distances between the centers of cortical activation. Distances are illustrated with reference to D1, which is shown as the zero line. The inset shows the relationship of responses of D1 (thumb), D2 (index), and D5 (little finger), as seen in a sighted subject. X – shows hemispheres where digit representation was disordered. M – indicates hemispheres where location of the tactile stimulation of the digits was mislocalized. Reproduced from Sterr, A., Muller, M., Elbert, T., Rockstroh, B., Pantev, C. and Taub, E. 1998a. Changed perceptions in Braille readers. Nature 391, 134–135.

nonreading digits (Pascual-Leone, A. and Torres, F., 1993; Sterr, A. *et al*., 1998b; 2003). This fits with other examples of use-dependent cortical reorganization following, for example, tactile discrimination or motor tasks in monkeys (Hlustik, P., *et al*., 2004; Recanzone, G. H. *et al*., 1992b), and string playing in musicians (see below).

In addition, blind Braille readers who use multiple fingers of the hands when reading, are able to very precisely attribute the Braille, but frequently mislocalize, or misidentify the digits of their hands when touched with a tactile stimulus (Sterr, A. *et al*., 1998a; 2003). When Sterr and colleagues used magnetic source imaging to examine the representation of the digits in S1 cortex in multidigit readers, they found that digit representations were also frequently disordered. The same was not true for single-digit users. It is plausible that the smearing of cortical digit representations has, in the example of multifinger Braille reading, an advantageous effect, and Sterr and colleagues suggest that a greater efficiency in information processing, when the incoming information can be processed as a whole. These data do, however, imply a dissociation between the perception of the position of the digits and the accurate localization of the tactile stimuli (i.e., the Braille). The neural basis of this distinction, however, is not yet understood.

Though several theories have been proposed to account for the phenomenon of mislocalization (Sterr, A. *et al*., 2003), perhaps the most plausible one suggests that the increased somatosensory input that occurs with Braille-reading, changes neural networks underlying cortical digit representations (in a Hebbian manner). Finger representations are disordered, overlapping, and enlarged in multidigit Braille readers who mislocalize, and by inference there will be a greater overlap of the neural networks processing information for each digit. When stimulus conditions provide a low signal-to-noise ratio in the underlying neuronal populations (which occurs with light tactile stimulation of the fingertips using von Frey hairs), the probability of stimulus mislocalization increases. In the same individuals, when the signal-to-noise ratio increases, as when the individual attends to the stimulus more carefully, or when the stimulus itself is more intense, the output from the network is more accurate and few, if any, errors occur. Since the reading digit representation dominates the cortical hand map in blind Braille readers, mislocalization occurs least often with the reading finger/s. However, when stimulation of surrounding digits results in mislocalization, the subject most commonly attributes the stimulus to the reading digit/s.

Digit mislocalization can also be demonstrated in sighted trained and untrained subjects. When Schweizer R. *et al.* (2001) applied near-threshold stimuli to the center of the subject's fingertips to evoke mislocalizations from fingers other than the one stimulated, they found a different response in trained and untrained individuals. In untrained subjects the digits adjacent to the stimulated digits were mislocalized more often than the digits further away. However, when the thumb and little fingers were simultaneously stimulated over many hours, these digits were more frequently mislocalized with each other and the incidence of mislocalizing adjacent fingers decreased. The first of these results harks back to findings in Braille readers and is not surprising, given that adjacent mislocalized digits have overlapping receptive fields and somatotopic positions within the pathway and cortex. The second finding is perhaps more surprising but does suggest some fusing of representations of the two simultaneously stimulated digits.

In another study, Braun C. *et al.* (2000) passively stimulated digits D1 and D5, and measured responses using high resolution EEG. They observed similar mislocalizations to the fourth rather than the first adjacent finger over time and were able to correlate the perceptual changes with an enlargement of the representations of the stimulated digits within S1 cortex, whereby D1 and D5 representations were closer together. Such findings suggest that tactile stimulus training strengthens the functional bond between the simultaneously trained areas. Where this perceptual fusion takes place is not yet known, but it may occur in higher somatosensory areas (i.e., areas 2 and 5) where RFs are larger and overlap to a greater extent than in area 3b.

6.13.4.3 Musicians: Training, Focal Hand Dystonia, and Rehabilitative Training

As with Braille readers, musicians provide excellent examples of the trained brain, and the adjustments made to brain organization throughout life that reflect the experiences of the individual. Magnetic source imaging studies have shown an increased representation of the digits of the left hand of string players (Elbert, T. *et al*., 1995), with digit representation correlated with the age of playing onset, with those training from a younger age having a larger

digit representation. Recent fMRI analysis of professional versus amateur musicians (Lotze, M. *et al.*, 2003) has also shown that sensorimotor and auditory cortical activation are more focused in the professional musician's brain than in the amateur. This supports the idea that task-specific neural networks are established and strengthened over a long period of training, and that these networks provide a greater efficiency of neuronal activation during performance. Task-specific networks also enable additional connections to be formed with higher order regions of the brain. In support of this, professional musicians show activation of regions of the auditory and somatosensory cortex not observed in the amateur, and it is thought that this may account for higher performance (e.g., the application of emotion and nuance to the playing) in such individuals (Lotze, M. *et al.*, 2003).

Overtraining in musicians can lead to a painless motor disorder known as focal hand dystonia, characterized by the loss of independent finger control (usually 2–3 adjacent digits) during the performance of the trained task. This condition is greatly feared by professional musicians and generally effects string, piano, keyboard, and wind players, who move their digits in rapid, repetitive, synchronous, and stereotyped ways and who hold their hands in abnormal or awkward postures over long periods. Seminal work in the owl monkey (Byl, N. N. *et al.*, 1996; 1997) provided a nonhuman primate model for the study of this syndrome, though there remains some question as to the model's equivalence with focal hand dystonia in humans (Chen, R. and Hallett, M., 1998). In the first of the studies by Byl and colleagues, monkeys were trained to repetitively grasp a handpiece that opened and closed over short distances, and the task was repeated at least 300 times per day. After many months of training, monkeys deteriorated in their motor performance and were unable to make complete contact with the handpiece. In a second study, two monkeys were trained to actively squeeze a hand grip that then vibrated. In one monkey that squeezed the handpiece using the digits, performance degraded from 80–90% to <50% over 5 months, before the digit representation was mapped electrophysiologically within the S1 cortex. In both studies, cortical area 3b was found to be remarkably degraded compared with the untrained hand. RFs were greatly enlarged in size (~10 times), overlapped extensively, and there was a breakdown of the normal segregation of RFs on the hand. These, and follow-up studies from the same lab (Blake, D. *et al.*, 2002a; 2002b; 2002c), showed that digit representations in S1 cortex degrades when inputs from multiple digits of the hand to the cortex are synchronous, repetitive, spatially stereotyped, and cognitively important to the monkey.

To investigate similarities in the human, Elbert T. *et al.* (1998) used magnetic source imaging to investigate changes in dystonic musicians. As with the owl monkey studies, they found significant disruptions of the cortical map, with fusion of the digit representations in the S1 cortex of dystonic musicians compared with nondystonic musicians and nonmusician controls.

Recordings made in the somatosensory thalamus in humans undergoing thalamotomies showed similar degradation in the thalamus of dystonic patients, such that there were greater numbers of RFs with multiple overlapping body parts (Lenz, F. and Byl, N., 1999). Similar findings have also been reported in the thalamus of dystonic monkeys (Blake, D. *et al.*, 2002a).

6.13.4.3.1 Rehabilitative strategies

From these studies and a growing understanding of cortical and subcortical use-dependent reorganization, new techniques have recently been developed to treat focal hand dystonia (Pantev, C. *et al.*, 2001; Candia, V. *et al.*, 2003; 2005). Termed sensorimotor retuning (SMR), this form of rehabilitation is context-specific and involves the splinting of one or two digits while subjects perform sequential extensions of the fingers and train in a manner that breaks the synchrony and repetition of dystonic digit use. Figure 10 shows functional improvements in dystonic fingers following SMR treatment in one of many such subjects (Candia, V *et al.*, 2003; 2005). magnetoencephalography (MEG) studies indicate that S1 cortical digit representations alter over the course of treatment to resemble the contralateral normal side. Beneficial changes also persist in string players for more than 2 years.

6.13.4.4 The Dynamics of the Somatosensory Cortex during Learned Sensorimotor Tasks

Once training of a precision sensorimotor task (e.g., learning a musical instrument, handwriting, or typing) has occurred and the underlying connectivity has been altered and set to accommodate the learned task, recent studies (Moore, C. I. *et al.*, 1999; Braun, C. *et al.*, 2000; 2001) suggest that the somatosensory cortex can then switch dynamically between

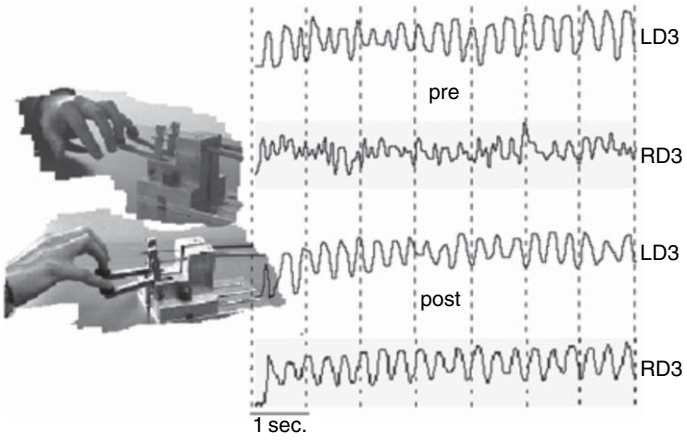

Figure 10 A dexterity displacement device is illustrated which was used for SMR in a subject with focal hand dystonia. Segments of pre- and posttreatment movement slopes are shown for the right D3 (RD3) and left D3 (LD3) during the execution of a trill-like task. Prior to treatment, movements of the dystonic digit (RD3) were uneven and uncontrolled (upper RD3 profile) compared with the control LD3 (upper LD3 profile) finger. Following treatment, the RD3 movements resemble performance in LD3 (lower LD3 and RD3 profiles, respectively). Only D4 and D5 are shown. Reproduced from Candia, V., Wienbruch, C., Elbert, T., Rockstroh, B. and Ray, W. 2003. Effective behavioral treatment of focal hand dystonia in musicians alters somatosensory cortical organization. PNAS 100, 7942–7946.

concurrently preexisting representational maps (or neural networks), according to the requirements of the task. Braun C. *et al.* (2001), for example, obtained MEG data from the somatosensory cortex while subjects wrote with their left or right hands, and compared the distance between the center of D1 and D5 activation during the writing and rest states. As shown in Figure 11, the distance between D1 and D5 activation increased significantly while subjects were writing, compared with rest. This was interpreted as demonstrating the activation of a preexisitng task-specific map. This and other studies in the motor cortex (Karni, A. *et al.*, 1995; 1998; Korman, M. *et al.*, 2003; Lotze, M. *et al.*, 2003) suggest that optimal performance of highly trained sensorimotor tasks may be achieved by the rapid activation of task-specific cortical networks, which develop over time.

Karni and colleagues (Karni, A. *et al.*, 1998) have proposed several distinct phases for learned motor skill acquisition, including (1) an initial rapid learning phase, (2) a longer phase of consolidation of the learned task, and (3) a slow learning phase where small incremental gains in performance occur with continued practice. In sensorimotor learning, as in injury-induced plasticity, initial rapid changes are followed by a longer period of correlated activity, possibly accompanied by structural changes to sensorimotor neuronal populations specific to the sensorimotor task. At least superficially, it seems likely that many of the same mechanisms may be involved.

6.13.5 Somatosensory Plasticity in Response to Disease

Models of disease such as stroke and ischemia, multiple sclerosis, spinal neuropathies, and pain-related disorders, are also associated with the loss of somatosensory and motor information, and frequently result in quite severe behavioral disturbances. As with peripheral and central injuries, and task learning, the adult CNS shows a remarkable capacity for reorganization in response to such disease states.

6.13.5.1 Changes in Response to Somatosensory Cortical Ablation, Ischemia, or Stroke

Somatosensory cortex damage can result in an impaired capacity for directed voluntary movement and tactile discrimination. In monkeys, the removal of the distal forelimb region in S1 cortex, for example, results in a severe loss of tactile discriminatory ability (see LaMotte, R. H. and Mountcastle, V. B., 1979), while the ablation of different functional subdivisions of the somatosensory cortex produces region modality-specific deficits (Randolph, M. and Semmes, J., 1974; Murray, E. A. and Mishkin, M.,

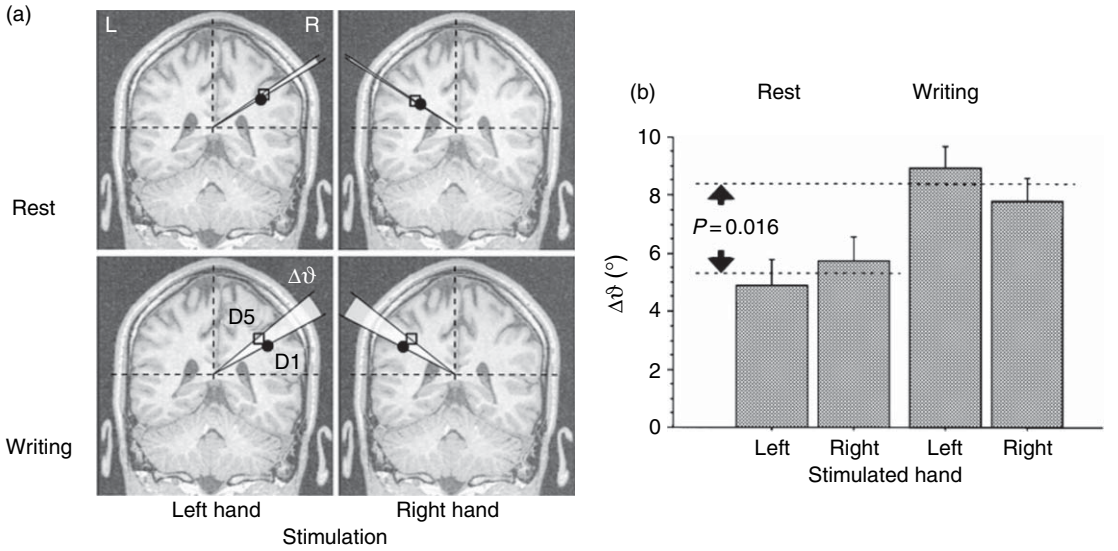

Figure 11 Braun C. *et al*. (2001) used source localization to look at the distance between D1 and D2 activation during an overlearned handwriting task. (a) Data are shown for the contralateral S1 cortex in this subject, at rest (top), and while writing (bottom). The distance between D1 (filled circle) and D5 (open square) was shown to be significantly greater during the writing task compared to rest. (b). Group data (means and standard error) are given for the cortical distance between D1 and D5 representation for the left and right hand during rest and writing. Reproduced from Braun, C., Heinz, U. *et al*. 2001. Dynamic organization of the somatosensory cortex induced by motor activity. Brain 124, 2259–2267.

1984). For example, the removal of area 3b leaves only a gross ability to detect size, while the ablation of area 2 leaves tactile discriminatory abilities intact and results in the loss of shape recognition only (Randolph, M and Semmes, J., 1974; Carlson, M., 1981). Such studies, combined with our understanding of the anatomy of the system, support the view that the connections between somatosensory functional subdivisions, including SII, are parallel, distributed, and hierarchical, and are structurally and functionally interdependent. Complex sensorimotor tasks require the coactivation of area 3b and numerous other specialized somatosensory and motor cortical and subcortical regions. How these different neuronal networks are activated and interact during normal and impaired sensorimotor performance, however, remains unclear.

That the S1 cortex is capable of functional recovery following cortical injury has long been recognized (Cole, J. and Glees, P., 1954; Glassman, R., 1971) but has been examined in more detail in recent decades. Monkey studies have been fundamental to this. Jenkins W. M. and Merzenich M. M. (1987) used intracortical microelectrode mapping techniques in owl monkeys to look at changes in the somatosensory hand map following focal ischemic lesions in somatosensory area 3b (see Figure 12). Several months following the lesion, they observed the emergence of a new map within a part of area 3b left intact following the lesion. The new map was smaller than in the normal cortex and somatotopy was greatly reorganized, with RFs observed on that part of the hand previously ablated by the lesion site. Soon after, Doetsch G. S. *et al.* (1990) reported a similar finding in the raccoon. In their study, digit 3 representation was ablated within S1, and the region mapped electrophysiologically 4 months later. They observed the emergence of a new representation of digit 3 within intact cortex adjacent to the lesion site, and substantial changes in the response properties of neurons within the reorganized cortex, including enlarged, and overlapping RFs.

The neural basis of skill recovery has also been examined following cortical lesions, such as might occur following stroke. Xerri C. *et al.* (1998) trained owl and squirrel monkeys to perform a sensorimotor retrieval task, and then removed functionally relevant parts of area 3b using a series of microlesions. Monkeys were behaviorally impaired in task performance following the lesion, but were retrained to perform the same task over several weeks with the initially impaired digits. Maps obtained across the S1 hand representation following functional recovery showed a newly emerged representation of

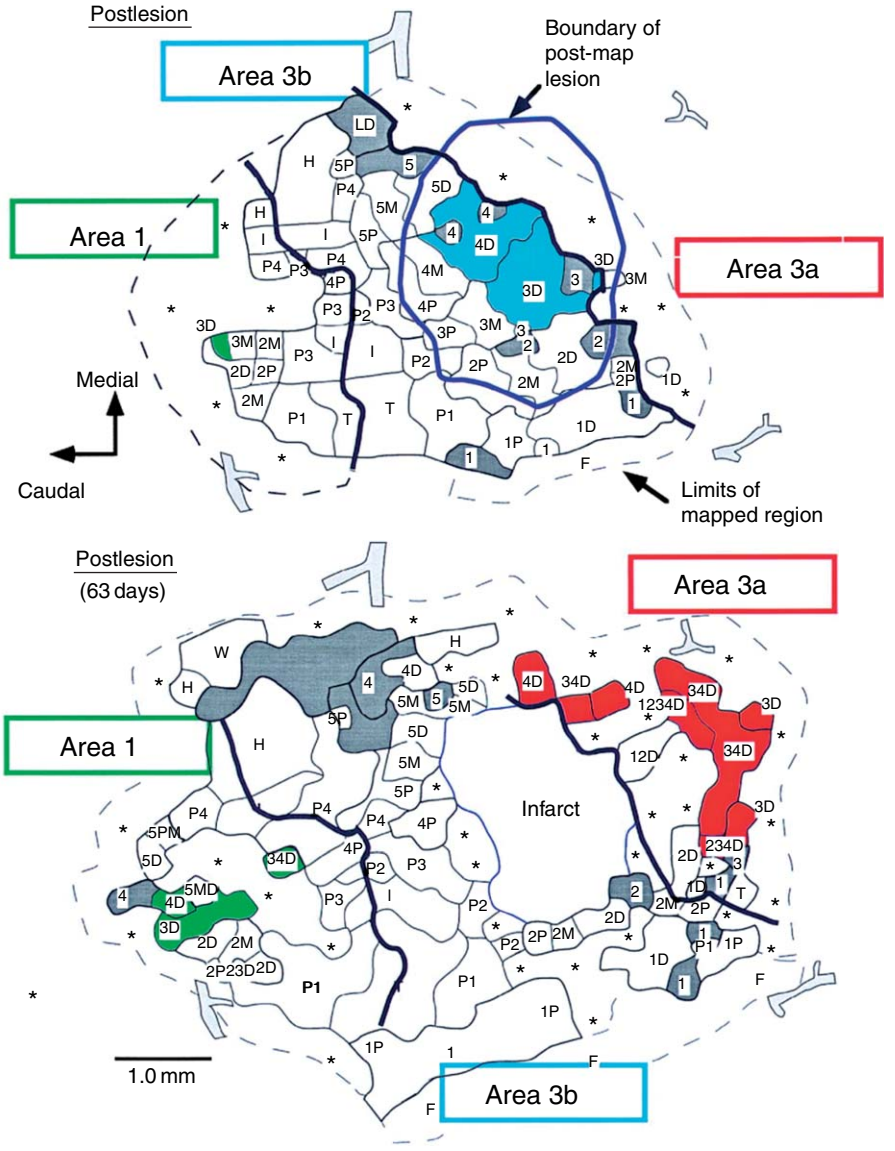

Figure 12 Reorganization of the hand map in primary somatosensory cortex in an owl monkey, following a cortical lesion. Top panel shows the somatotopically organized hand map before a cortical lesion was made in the region of digit representation in area 3b. Lower panel shows the same region of cortex as it was mapped 98 days after the cortical lesion. There was an emergence of cutaneous representational zones in both area 3a and area 1. Cortical representation of the tips of digits 3 and 4, that were heavily used in recovered behavior, are colored: blue indicates area 3b representations, green = area 1, red for area 3a. Numbers 1–5 denote the digits (i.e., 1 = thumb); D, M, and P, distal, middle, and proximal phalanges, respectively W, wrist; F, face; LD, large dorsum surfaces; * indicate where no receptive fields could be mapped. Estimated area 3a–3b border is delineated with dark gray lines. From Xerri, C., Merzenich, M. M. *et al*. 1998. Plasticity of primary somatosensory cortex paralleling sensorimotor skill recovery from stroke in adult monkeys. J. Neurophysiol. 79(4), 2119–2148.

the same fingertips in a novel region of area 3b. New and enlarged cutaneous inputs were also observed in area 3a from the same region of the hand. Though results were variable between monkeys, all showed newly emerged fields, and a disproportionate representation of the fingertips relevant to the task (whose cortical fields had originally been destroyed). In effect, regions of S1 cortex that normally played a nondominant role in cutaneous activation, gradually adopted the role of the missing cortex. Similar changes have also been reported in the primary motor cortex hand area of

squirrel monkeys following focal vascular infarct (Nudo, R. J. and Milliken, G. W., 1996; Nudo, R. J. *et al.*, 1996), which suggests a generalized response to cortical injury.

Topographic reorganization also occurs in cortical regions remote to the site of the lesion. This was shown in monkeys in the second somatosensory area (SII) following damage to the primary somatosensory cortex (Pons, T. P. *et al.*, 1988), where ablation of the hand area in cortical areas 3b, 1, and 2 enabled the target zone in SII to respond to input from the foot. Similar changes have now been seen in motor cortex, where post-ischemia reorganization has been observed in premotor cortex; a region which is functionally and anatomically aligned but spatially distant to the injury site (Frost, S. *et al.*, 2003).

These data suggest that connected regions of the cortex, regardless of whether they are adjacent to, or spatially remote from the injury site, reorganize in response to brain injury. Rodent studies, particularly in the barrel cortex, have provided additional insights into the plastic changes that accompany somatosensory cortical ablation (see Sachdev, R. N. S. *et al.*, 2001 for review).

In humans, changes that occur following ischemic brain disease have been investigated extensively using a range of imaging techniques, including transcranial magnetic stimulation (TMS), fMRI, PET, and MEG, or combinations of these. These techniques show changes in regional activity (e.g., regional cerebral blood flow, regional cerebral metabolism of glucose, oxygen, or neuroreceptor or transmitter systems) in the brain during specific sensorimotor tasks. Such studies can be difficult to interpret, both technically, and because brain injury following a cerebral artery infarct, for example, can be difficult to define in the individual, since it changes from the acute to chronic phases. It is also often difficult to find patients with sufficiently similar injuries that they can reasonably be compared. Even so, several patterns of reorganization have been identified that accompany the recovery of sensorimotor function following injury to the hand/forearm region of the somatosensory and motor cortex. Since middle cerebral artery (MCA) infarcts are common and cause the most circumscribed damage to the sensorimotor cortex in a region supplying the hand and forelimb, data pertinent to MCA infarcts will mainly be reviewed here.

A number of groups have shown significant contrainfarct sensorimotor cortex activation but little additional perilesion cortical reorganization following an MCA infarct (Seitz, R. J. *et al.*, 1998; 2004). For example, when Cramer S. *et al.* (1997) asked MCA stroke patients with good recovery to perform a finger-tapping sequence, they found increased activation in the contralesion sensorimotor cortex (hand representation), but little, if any, increased activation in the ipsilateral hemisphere adjacent to the injury site. In addition, when infarction involved just the motor cortex, activity was localized to the primary somatosensory cortex, and when it involved the somatosensory cortex, sensorimotor activity centered around the motor cortex. In contrast, Butefisch C. *et al.* (2005) reported bilateral sensorimotor and SMA activation during finger tapping in patients with cortical MCA infarcts, compared with control subjects where only the sensorimotor cortex contralateral to the performing hand was activated during hand performance (see Figure 13). In yet another study, Carey J. *et al.* (2002) used fMRI to show that when MCA stroke patients received training in a finger-tracking dexterity task, sensorimotor cortical areas were activated in both the contralateral and ipsilateral hemispheres (Figure 14). In untrained stroke patients, activation was observed mainly on the side contralateral to the infarct or ipsilateral to the performing hand. In healthy control subjects, activity is localized to the hemisphere contralateral to the moving hand.

From these and other clinical studies (see Seitz, R. J. *et al.*, 2004 for review; Nelles, G. *et al.*, 1999), it is clear that the hemisphere contralateral to the lesion plays an important compensatory role in postischemic reorganization (Johansson, B., 2000).

6.13.5.2 Cortical Plasticity in Multiple Sclerosis

Multiple sclerosis (MS) is a disease that causes the breakdown and destruction of the myelin sheath surrounding neurons and thus the disturbance of signal transmission. The disease is progressive with episodes of near-complete functional recovery and relapse, though eventually symptoms become chronic as the myelin and axonal injury become irreversible (DeStefano, N. *et al.*, 1998; Scolding, N., 1999 for review). Through the different phases of the disease the brain undergoes reorganization, presumably as a compensatory or adaptive response to initially temporary, and later chronic functional loss. Though MS does not specifically target somatosensory and motor regions of the cortex and related subcortical structures, it does eventually involve

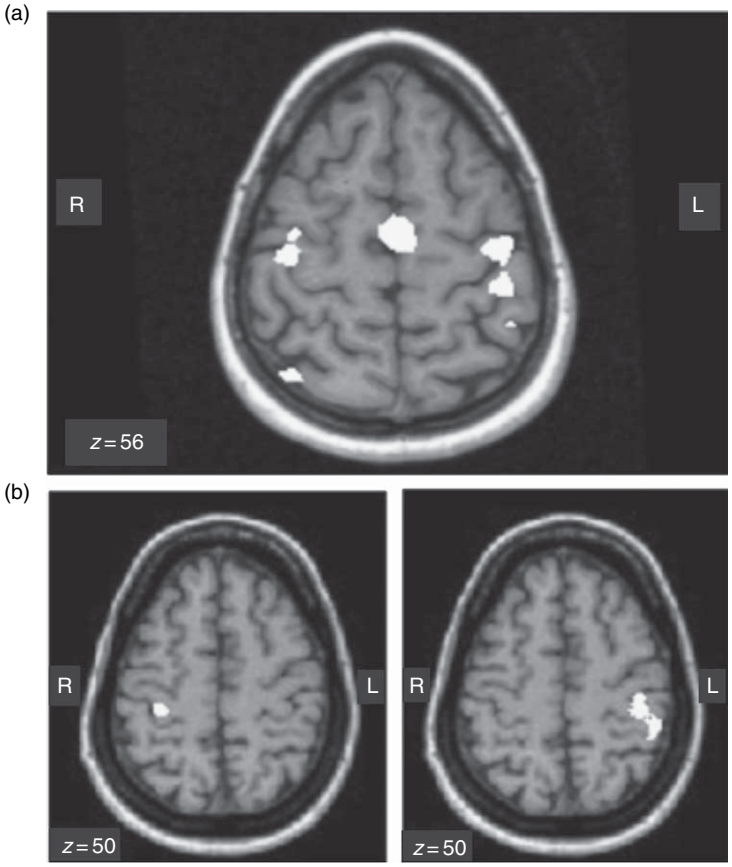

Figure 13 fMRIs showing mean activation during a fingertapping sequence with the affected hand in five patients with cortical MCA infarcts (a) and in controls (b). In (a) the right hemisphere r corresponds to the affected hemisphere and l refers to the unaffected hemisphere. The activation of the contralesion side is evident during the hand task in (b) control subjects performed the finger-tapping sequence with the left and right hands, respectively, and activation is evident in the pericentral gyrus only on the side contralateral to the performing hand. This patient had excellent recovery of function at 6 weeks postinfarction. Adapted from Butefisch, C., Kleiser, R., Korber, B., Muller, K., Wittsack, H. -J., Homberg, V. and Seitz, R. J. 2005. Recruitment of contralesional motor cortex in stroke patients with recovery of hand function. Neurology 64, 1067–1069.

these regions of the brain and cause sensorimotor dysfunction. A number of studies have used fMRI to look at changes in cortical activation during simple passive or active sensorimotor tasks during different phases of MS to determine patterns of reorganization that might characterize disease progression (Buckle, G., 2005 for review). In spite of individual differences in disease phenotype and response, cortical activation patterns do alter with disease progression. At early stages of MS, as the patient performs a simple voluntary manual task with their dominant hand, more contralateral sensorimotor cortical regions normally associated with movement are recruited compared with healthy controls. In patients experiencing relapse and remission, these same regions are activated bilaterally and there is some recruitment of the premotor and supplementary motor areas either ipsilaterally or bilaterally. Figure 15 shows an example of a patient at this stage (Lee, M. *et al.*, 2000). Late in the disease, additional regions are recruited (e.g., middle and the inferior frontal gyrus bilaterally, the ipsilateral cingulate motor area and the inferior parietal lobule), that are normally only activated in normal subjects during more complex tasks (Reddy, H. *et al.*, 2002; Rocca, M. *et al.*, 2005). Though studies differ in their detail, they do provide consistent evidence of a progressive adaptive ongoing reorganization in the brain that involves the gradual recruitment of bilateral and then higher order neural networks. Such changes are presumed to reflect and enable true functional compensation.

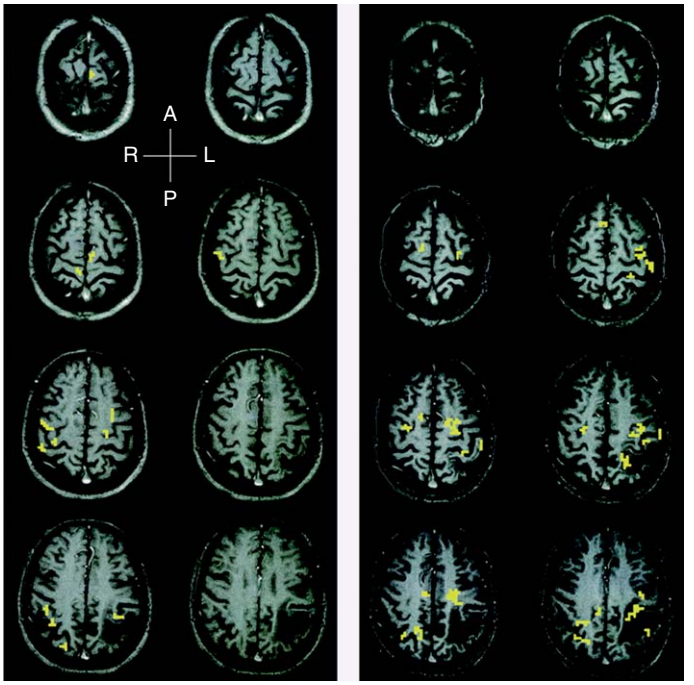

Figure 14 fMRIs from a subject in a stroke treatment group who underwent finger-tracking training. (Subject had stroke 9.4 years previously.) Images were taken while the partially paralysed right hand performed a finger-movement tracking test before (pretest) and after (posttest) 20 sessions of training. The infarct is visible in left parietal cortex in the lower three images in each panel. Cortical activation was evident mainly on the side ipsilateral to the paretic hand (or contralateral to the infarct) prior to training. After training, activation was predominantly contralateral to the paretic hand (or ipsilateral to the infarct). Reproduced from Carey, J., T. Kimberley, T. Lewis, S., Auerbach, E., Dorsey, L., Rundquist, P. and Ugurbil, K. 2002. Analysis of fMRI and finger tracking training in subjects with chronic stroke. Brain 125, 773–788.

6.13.5.3 Cortical Plasticity in Response to Other Diseases

Cortical plasticity also contributes to functional recovery from diseases that affect the spinal cord. One example of this is myelitis, a transient inflammatory disease of the spinal cord that seldom involves the brain. Patients exhibit a wide range of sensorimotor deficits, and while there is residual damage to the cord, there is frequently some return of function following the disease. Cramer S. *et al.* (2001) used fMRI to examine potential cortical contributions to the restoration of hand function in patients with cervical myelitis. They found that the return of upper limb function (in the form of a finger-tapping task) correlated with an increased activation volume in the contralateral primary sensorimotor and premotor cortex. The extent to which additional cortex was activated, directly correlated with the daily use of the affected hand, meaning that use of the recruited circuitry was critical to its formation and stability. Though some cortical activation was probably the result of spinal recovery following the disease, the increase in regional activation demonstrated compensatory plasticity and reorganization.

However, not all diseases induce adaptive plastic responses. In Huntington's disease (HD), for example, it seems that one of the earliest signs of the disease is the lack of normal plastic neuronal responses. A defining feature of Huntington's disease (caused by a CAG repeat in chromosome 4) is that it is progressive and results in extensive neurodegeneration in the striatum and cerebral cortex. Symptoms include motor disturbances such as chorea, athetosis, and cognitive impairment. Mazarakis N. *et al.* (2005), recently used a presymptom mouse model of Huntington's disease to assess possible abnormalities in neocortical plasticity and synaptic function. To do this they used a known model of plasticity in the rodent barrel cortex which involved the cutting of all but one row of whiskers. In normal control mice this resulted in an enlarged representation of the remaining whiskers,

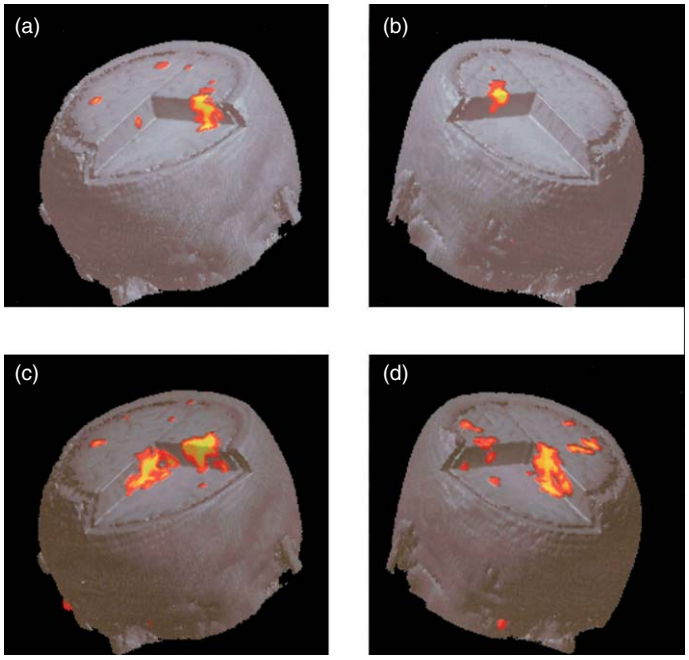

Figure 15 fMRI 3D rendered reconstructions showing patterns of cortical activation associated with finger-tapping in a normal control subject ((a) right hand and (b) left hand), and a patient with MS ((c) right hand and (d) left hand). Note activation of the sensorimotor cortex contralateral to the moving limb and supplementary motor cortex (SMA). In the MS patient, there was an increased activation in the ipsilateral sensorimotor cortex and the SMA. The right hemisphere is to the viewer's left. Reproduced from Lee, M., Reddy, H., Johansen-Berg, H., Pendlebury, S., Jenkinson, M., Smith, S., Palace, J. and Matthews, P. 2000. The motor cortex shows adaptive functional changes to brain injury from multiple sclerosis. Ann. Neurol. 47, 606–613.

but such changes were not observed in the HD mice. In addition, HD mice showed a severe impairment of somatosensory discrimination learning in a whisker discrimination learning task that required an intact cortex. Thus the HD mice exhibited somatosensory cortical dysfunction and an abnormal plastic response before exhibiting any motor disturbances symptomatic of the disease state.

6.13.5.4 Cortical Reorganization and Chronic Pain

While the neural basis of pain is covered in Volume 3, pain is mentioned briefly here in the context of somatosensory plasticity. Pain is complex, involves multiple levels of the somatosensory pathway and cortex to varying degrees, and is caused by multiple mechanisms. It can be divided into physiological, inflammatory, and neuropathic categories. Physiological pain is initiated by nociceptors responding to noxious stimuli, either from chemical irritants, or noxious heat/cold differentials. These pathways are subject to activity-dependent plasticity, so that increased activation can eventually result in an increased response, or a lowering of the high-threshold nociceptor terminal response to the stimulus. Inflammatory pain is induced following inflammation or damage to tissue, and neuropathic pain by injury. Both produce hypersensitivity at and surrounding the injury site. During the normal course of healing, the hypersensitivity produced by inflammation usually dissipates and goes away. Neuropathic pain, however, remains and manifests long after the injury site has healed, and is an expression of aberrant neuronal function rather than a response to the initial pathology.

Phantom limb pain is a form of neuropathic pain. It occurs with the loss of input following amputation, and is usually associated with cortical reorganization. In upper limb amputees who experience phantom limb sensation, stimulation of the face can elicit a point-to-point referred sensation on the phantom limb or hand, and perceived sensations on the phantom match the stimulus modality (e.g., vibration, heat, and painful stimuli are all perceived as such on the phantom limb). Ramachandran V. S. *et al.*

(1992; Ramachandran, V. S., 2005 for review) described this clinically known phenomenon in some detail, and proposed that phantom sensations, including pain, were likely to be the perceptual correlate of cortical reorganization. Since the hand and forelimb are represented adjacent to each other in the cortex, it seemed reasonable that inputs from the adjacent mouth and face region, that invaded what was previously the hand region, could form the neural substrate for phantom sensation and pain. This was tested in imaging studies in humans (Elbert, T. *et al.*, 1994; Yang, T. T. *et al.*, 1994), with somewhat surprising results. As with the earlier animal studies, cortical reorganization was demonstrated in upper extremity amputees, with the mouth representation shifted into the former hand/limb representation. However, cortical reorganization occurred irrespective of whether the patient perceived phantom limb sensation or not. Studies on chronic back pain subsequently showed a positive correlation between the amount of pain and the extent of cortical reorganization, and this relationship was then tested in patients with phantom limb pain. It was shown that as with chronic back pain (Flor, H. *et al.*,1995), the magnitude of phantom pain, rather than the referred sensation, correlated significantly with the extent of cortical reorganization. The same correlation was not seen in amputees without chronic pain.

More studies in the early 2000s (Grusser, S. *et al.*, 2004; Karl, A. B. N. *et al.*, 2001) have shown that stimulation of body parts far from the region of amputation (e.g., the foot) can also elicit referred sensation on the amputated limb. Current evidence suggests that nonpainful phantom limb sensations are associated with changes in area 5 and SII, in addition to S1 reorganization that does not involve large shifts of face representation into the hand/arm cortex. It has also been proposed that phantom limb sensation involves the coactivation of nonadjacent representations rather than somatotopic cortical reorganization (Moore, C. I. *et al.*, 2000). Phantom limb pain, on the other hand, is strongly correlated with the magnitude of S1 reorganization (Figure 16; Flor, H. *et al.*, 2000; Flor, H., 2002; 2003; Grusser, S. *et al.*, 2004).

In addition to cortical changes, it is likely that a number of subcortical mechanisms also contribute to phantom limb pain. Nerve endings that have been directly damaged by the amputation may, for example, grow erroneously within the stump region and develop abnormal discharge that is perceived as painful. Evidence for peripheral involvement comes from Birbaumer N. *et al.* (1997), who used brachial plexus nerve blocks to anesthetize the forearm in upper extremity amputees suffering from phantom limb pain. They found that the symptoms were eliminated in about 50% of patients. Neuroelectric source imaging showed that in individuals relieved of their phantom limb pain, cortical reorganization was reversed, and in individuals not relieved, cortical reorganization was increased. These data suggest that peripheral input plays a large role in phantom limb pain in some patients and in others, symptoms are caused or maintained by factors independent of the periphery. In addition to cortical reorganization, and maladaptive input from the periphery, changes may also take place within the dorsal root ganglia, the spinal dorsal horn, and/or the thalamus that cause or maintain phantom pain. In the spinal circuitry, for example, localized axon terminal growth of the injured neurons within the spinal dorsal horn may contribute.

Additional studies suggest that chronic back pain may also lead to an expansion of the cortical

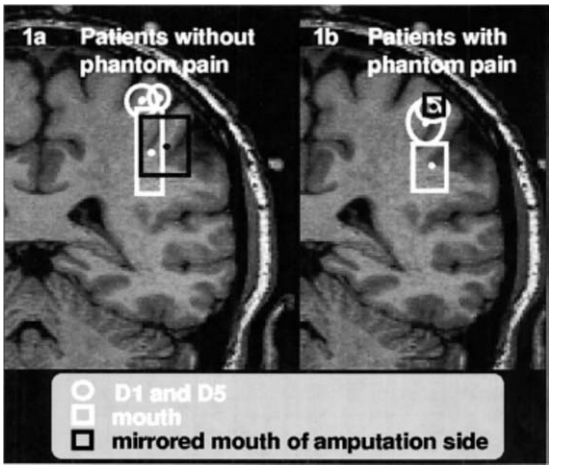

Figure 16 Flor and colleagues used neuromagnetic imaging techniques to demonstrate differences between phantom limb sensation and phantom limb pain in human subjects. Panel (1a) shows the mean and standard deviations of digit (circles) and mouth (rectangles) localization in patients without phantom limb pain. Mouth representations were symmetrical bilaterally and clearly separated from the digits. In panel (1b) the same representations are illustrated for a group of upper extremity amputees, all with phantom limb pain. Where phantom pain is present, the mouth representation on the affected side was found to have moved into the cortical hand region. From Flor, H. 2002. The modification of cortical reorganization and chronic pain by sensory feedback. Appl. Psychophysiol. Biofeedback 27, 215–227.

Figure 17 Using mirror visual feedback (MVF) in treating complex regional pain syndrome. Left panel shows a subject viewing a nonreflective surface with the painful limb hidden on the other side. Right panel shows the same subject viewing the nonpainful limb in the mirror with the painful limb hidden. McCabe and colleagues found that in early complex regional pain syndrome patients (CRPS) of $\leq$ 8 weeks, the MVF immediately stopped the pain. In patients with CRPS $\leq$ 1 year, stiffness in the limb was reduced, and in chronic patients there was no effect. From McCabe, C., Haigh, R., Ring, E., Halligan, P., Wall, P. and Blake, D. 2003. A controlled pilot study of the utility of mirror visual feedback in the treatment of complex regional pain syndrome (type 1). Rheumatology (Oxford) 42, 97–101.

representation of the pain region, and that this is often accompanied by a lower pain response threshold. The magnitude of the cortical expansion of the back region is positively correlated with the chronicity of the back pain, so that the longer the patient has experienced the pain, the greater the cortical representation of the nociceptor input. Nociceptor response thresholds also decrease with chronicity (Flor, H., 2002 for review).

Rehabilitation methods and models of phantom limb and chronic pain are now beginning to take these data into consideration. The idea that chronic pain states lead to somatosensory pain memories, which may lead to pain perception in the absence of noxious stimuli, has gained considerable attention in recent years. This means that patients who experience pain for an extended period prior to forelimb amputation are more likely to suffer the effects of phantom limb pain postoperatively, than those experiencing only acute pain prior to amputation. The implication is that there is a pain memory trace. Innovative techniques that use mirrors and visual input to trick the brain into counterlearning these memory traces, are meeting with some success (McCabe, C. *et al.*, 2003; Ramachandran, V. S., 2005). As illustrated in Figure 17, McCabe and colleagues found that when patients with early complex regional pain syndrome (CRPS) of less than 8 weeks onset visually experience movements of the phantom hand (or leg), with mirror images of the normal side, the analgesic effect is immediate. By one year of CRPS onset, the benefit is reduced to a reduction in the stiffness of the limb, and in chronic sufferers, the visual feedback had no impact on the condition. These findings indicate that visual input from the normal limb can be enough during the early months to re-establish the pain-free connections between the sensory feedback and the movement. However, the chronic state becomes less plastic in its ability to re-establish a pain-free relationship between feedback and movement execution. Consequently, in chronic patients the phantom limb pain is commonly intractable.

6.13.6 Neural Basis/Mechanisms of Somatosensory Plasticity

6.13.6.1 Pathway Divergence and Disinhibition

The somatosensory pathways are divergent and hierarchical in their organization, from their point of entry to the spinal cord, to the brainstem nuclei, the thalamus, and cortex. This divergence is undoubtedly responsible for some plasticity within the system, particularly during the acute phase of the injury. This is well demonstrated in the cortical map, immediately following a peripheral nerve cut, where receptive fields from adjacent body parts enlarge and fill in the edges of the deafferented (silent) cortex (up to 1 mm). This can occur within minutes to hours and is enabled by the normal

divergence of thalamocortical afferents (up to 2 mm in the monkey) within the cortex, and the unmasking or disinhibition of connections that normally keep receptive fields in check. Unmasking during the acute phase occurs when excitatory inputs to inhibitory neurons within the cortex are removed by the lesion. This removes local GABAergic inhibition to latent excitatory synapses within adjacent cortex, and unmasks or disinhibits the underlying preexisting circuitry. Available data indicates that disinhibition can also operate at subcortical levels. The demonstration that GABAergic pathways are modulated following peripheral lesions (or by pharmacological blockade) demonstrates the importance of this neurotransmitter in cortical and subcortical plasticity, particularly during the initial acute phase of injury (for reviews see Chen, R. *et al.*, 2002; Ding, *et al.*, 2005; Ojakangas, C. L. and Donoghue, J. P., 2006).

Longer-term changes following injury, skill learning, or disease involve additional synaptic mechanisms, including LTP or LTP-like events (Malenka, R. C. and Nicoll, R. A., 1999), in addition to some of the structural changes described ahead.

6.13.6.2 Structural Plasticity

A substantial body of evidence shows that the adult somatosensory system retains some capacity for neuronal structural plasticity in response to changes in input. Both axons and dendrites can undergo structural modification in response to injury, and determining the conditions that best support this plasticity in a way that benefits functional recovery, remains a major direction of study in the field.

6.13.6.2.1 Injury-induced structural changes: axonal sprouting

Neurons in the adult mammalian CNS generally show only a limited capacity for repair, particularly when compared with peripheral or embryonic neuronal populations. Despite this, axonal sprouting can occur in response to injury in the adult mammal, and has now been demonstrated in different species and across different levels of the neuraxis. Axon terminal growth that leads to functional recovery generally takes weeks to many months to occur. This has to do with the growth process – axon extension, the assemblage of new synapses, and an activity-driven dynamic process of pruning, strengthening, and stabilization of new connectivity along Hebbian-like principles.

It has been known for several decades that primary afferent sprouting can occur centrally when the peripheral axon of proliferating neurons is itself damaged (Liu, C. N. and Chambers, W. W., 1958; Goldberger, M. E. and Murray, M., 1974; Molander, C. *et al.*, 1988; LaMotte, C. and Kapadia, S. E., 1993; Woolf, C. J. *et al.*, 1995; Florence, S. L. and Kaas, J. H., 1995; Jain, N. *et al.*, 2000). More recently, it has become evident that central as well as uninjured neurons also retain some capacity for axonal growth in adult mammals. Most reports in the rodent are from spinal cord or barrel cortex (for reviews see Feldman, D. E. and Brecht, M., 2005; Maier, I. and Schwab, M., 2006). In the mouse barrel cortex, for example, neurons that have their principle whisker input spared following vibrissectomy, project their axons further than cells in deprived barrel columns (Kossut, M. and Juliano, S., 1999). In another recent example, Bareyre and colleagues (Bareyre, F. M. *et al.*, 2004), showed that following a partial thoracic spinal injury, transected hindlimb corticospinal tract axons sprouted into the cervical gray matter to form new connections with propriospinal neurons (PSNs). Over 3 months, sprouts that contacted long PSNs that bridged the injury, were maintained, and those contacting short PSNs, that did not bridge the injury, were lost. Such studies are important mechanistically, though the relevance of long PSNs, in the latter example, to the human in SCI compensation, remains questionable, given inherent species differences (Nakajima, K. *et al.*, 2000; Lemon, R. *et al.*, 2004).

In nonhuman primates, axonal sprouting has been shown in response to various forms of deafferentation in the spinal cord (Florence, S. L. *et al.*, 1993; 1998; Florence, S. L. and Kaas, J. H., 1995; Wu, C. W. and Kaas, J. H., 2002; Darian-Smith, I., 2004), in visual (Darian-Smith, C. and Gilbert, C. D., 1994) and somatosensory cortex (Florence, S. L. *et al.*, 1998), and in the cuneate nucleus of the brainstem (Jain, N. *et al.*, 2000; Wu, C. W. and Kaas, J. H., 2002; Darian-Smith, I., 2004).

Importantly, recent primate studies have demonstrated that central neurons left intact following an injury (but adjacent to the injury site), are capable of localized terminal sprouting in the adult primate sensorimotor pathways (Darian-Smith, C. and Gilbert, C. D., 1994; 1995; Florence, S. L. *et al.*, 1998). Jain and colleagues (Jain, N. *et al.*, 2000) showed this in monkeys with dorsal column lesions or arm amputation. Over many months, face afferents from the trigeminal nucleus were found to grow into

the adjacent cuneate nucleus. This likely accounted for the expansion of the face representation into the S1 cortical hand region, that occurred following the deafferentation. The sprouting of spared primary afferents also occurs in macaque monkeys following a cervical dorsal rhizotomy (Darian-Smith, C., 2004). Primary afferents that are spared by the injury, sprout locally within the spinal dorsal horn and cuneate nucleus (Darian-Smith, C., 2004). This process takes several months and likely leads to cuneate nucleus map reorganization (Darian-Smith, C. and Ciferri, M., 2006) and the circuitry changes that mediate recovery of dexterity in the deprived digits (Darian-Smith, C. and Ciferri, M., 2005). Evidence supports the idea that axon terminal sprouting enables local synapse formation on deprived postsynaptic neurons, which then amplifies an initially weak signal from the periphery to suprathreshold levels (using an LTP-like process). The benefit gained by such sprouting is behaviorally important (Darian-Smith, C. and Ciferri, M., 2005), but nonetheless limited. If the initial deafferentation of one or more digits is complete, the proliferation of primary afferent terminals does not compensate for the loss.

There are few other examples of injury-induced axonal growth in the somatosensory and motor pathways of the adult monkey. Corticospinal axonal sprouting following hemisection or other spinal injuries may mediate circuit reorganization and functional compensation, but the normal collateral branching of descending fibers has so far made this difficult to assess (Galea, M. P. and Darian-Smith, I., 1997a).

The reduced capacity for axon growth in the adult CNS, as opposed to the embryonic or peripheral nervous system, appears to be determined not by specific differences in the CNS neurons themselves, but according to the permissiveness of the cellular environment. This has long been recognized in primary afferent neurons, with their peripheral and central axonal branches having different capacities for regeneration, and was demonstrated more than 25 years ago in experiments (Richardson, P. *et al.*, 1980; David, S. and Aguayo, A., 1981) in which CNS axons were able to grow into peripheral nerve grafts.

Both physical (e.g., glial scarring hemorrhagic cysts) and chemical barriers, can act to inhibit growth in the CNS, and a number of proteins and neurotrophic factors have been identified that inhibit or augment axon growth (e.g., myelin-associated proteins, chondroitin sulphate proteoglycans, semaphorin-3A, Nogo-A). Amongst the better studied of the myelin-associated inhibitors is Nogo-A, which is synthesized mainly in oligodendrocytes and localized in myelin (Schwab, M. E., 2004; Maier, I. and Schwab, M., 2006 for reviews). By using one of two neutralizing antibodies now available against Nogo-A (mAb IN-1), Schwab and others have begun investigating the role of this growth inhibitor in the adult CNS. In adult control rats, transection of the corticospinal tract leads to minimal terminal growth. In contrast, in adult rodents treated with mAB IN-1 after a complete transection of the corticospinal tract, new collaterals were shown to sprout from the rubrospinal tract into the cervical spinal ventral horn, where they synapsed with forelimb motor neurons not normally receiving rubrospinal input (Raineteau, O. *et al.*, 2001; 2002). In another series of studies, adult rats treated with mAb IN-1 following a focal cortical ischemic lesion, recovered the ability to perform a forelimb reaching task (Papadopoulos, C. *et al.*, 2002; Weissner, C. *et al.*, 2003). In similarly treated rats, motor cortical neurons also showed an increased dendritic arbor complexity and spine density (Papadopoulos, C. *et al.*, 2006), suggesting significant remodeling of the cortical circuitry. Corticospinal axon terminal sprouting has recently been reported in marmoset (Fouad, K. *et al.*, 2004) and macaque monkeys (Freund, P. *et al.*, 2006) that received mAB IN-1 following a unilateral corticospinal lesion. Though potentially exciting, these results should be interpreted with a modicum of caution. For example, in the recent work of Freund and colleagues (Freund, P. *et al.*, 2006), unilateral corticospinal lesions were made in macaque monkeys at cervical level C7–C8, and manual dexterity and corticospinal axon density assessed over the first 7–8 postinjury weeks. Since there is interanimal variability in the exact location of motor neuron pools that innervate the hand, the behavioral recovery reported may be due in part to small variations in the placement of the lesion, and not to the effects of the Nogo-A specific antibody treatment. In addition, nothing is known about how or if sprouts find functionally relevant targets, and whether or not these results are clinically meaningful. Despite such hurdles, such studies hold enormous potential.

6.13.6.2.2 Injury- and experience-induced structural changes in dendrites

Dendritic spines are the postsynaptic target for most excitatory cortical synapses, and because they are easily visualized, they can be quantified as an indirect

measure of synapse density along dendrites. With the recent introduction of 2-photon imaging (in rodent models), it is also now possible to study the dynamics of dendrites in living neurons *in vivo* that express fluorescent proteins (i.e., GFP; Lendvai, B. *et al.*, 2000; Hickmott, P. and Ethell, I., 2006 for review). Most studies of dendritic structure modification have been done in rodents.

A number of studies have looked at synaptic changes in the form of dendritic spine density and dynamics with respect to experience, in the adult S1. In the barrel cortex, spine loss has been shown to be regulated by experience during adolescence (Zuo, Y. *et al.*, 2005), and in adult mice, whisker stimulation over just 24 h increases the co-innervation of layer IV spines by excitatory and inhibitory inputs by 36% (Knott, G. *et al.*, 2002). These and other studies (Kleim J. A. *et al.*, 2002; Trachtenberg, J. *et al.*, 2002; for reviews see Feldman, D. E. and Brecht, M., 2005; Fox, K. and Wong, R., 2005) indicate that activity-driven changes in synaptic circuitry occur throughout life in the cortex, and that sensory information flow is modified according to changes in experience.

An increase in dendritic arborizaton has also been reported in cortical layer V pyramidal neurons following sensorimotor cortical lesions (forelimb region) in the adult rat (Jones, T. A. and Schallert, T., 1994), and this was directly related to forelimb use. With use of both forelimbs, or just the limb ipsilateral to the lesion, neuronal arbor size was found to peak by 3 postlesion weeks, and then prune back over time. Restricted forelimb use on the side ipsilateral to the lesion, however, blocked dendritic growth.

Dendritic arbor bias can also alter following denervation. For example, layer III barrel neurons tend to project their dendrites toward the center of their home barrel, but 2–3 months after their home follicle is ablated, dendrites lose this orientation and extend in all directions (Tailby, C. *et al.*, 2005). In a similar way to barrel architecture, the dendrites of pyramidal neurons in the S1 of the rat have a direction bias away from the border of the forepaw/jaw representation (Hickmott, P. and Merzenich, M., 1999). When Hickmott and Steen (Hickmott, P. and Steen, P., 2005) cut the radial and median nerves to the forelimb, they showed a shift in dendritic bias over 2–4 weeks, that matched the resulting new functional border between the forepaw and jaw. These studies suggest that dendritic structural changes are induced by altered activity patterns in the cortex resulting from denervation, and not by degenerative changes within the cortex. Two-photon imaging studies have shown that following whisker trimming, which is known to induce functional reorganization, spine turnover is substantial (Trachtenberg, J. *et al.*, 2002). This suggests synaptic plasticity, but changes in dendritic branch complexity have yet to be demonstrated following whisker deprivation.

Little equivalent work has been completed in the primate. However, similar changes in dendritic structure have been demonstrated in S1 in the monkey following peripheral nerve cut that partially denervated the hand (Churchill, J. *et al.*, 2004). In this study, it was shown that there was increased complexity in the distal branches of dendrites in deprived cortex, compared with those in cortex unaffected by the lesion. Further investigations are needed to determine the underlying relevance of changes in dendritic structure to functional reorganization.

Increased dendritic complexity implies that the neuron is primed to receive new input. That is, it has a greater surface area available for receipt of new inputs and synapse formation. Changing connectivity patterns across a network of neurons likely facilitates changes in the role of the neuronal population in signal processing, which may then lead to the functional map changes described throughout this chapter. See Hickmott P. and Ethell I. (2006) for a review of the various cues that have been linked with the modification of neuronal structural elements (e.g., hormones, neurotrophins, neurotransmitters).

6.13.6.2.3 Atrophy, transneuronal atrophy, and degeneration

Atrophy and degeneration (e.g., Wallerian) occur in any chronic peripheral nerve or central injury that involves the death of axons entering, or coursing through the spinal cord.

In monkeys that received large-scale dorsal root injuries (C4–T2), 12–20 years earlier, transneuronal atrophy was considerable, and occurred at the level of the cuneate nucleus and the thalamus. In these monkeys, the brainstem cuneate and thalamic VPLc nuclei were reduced in overall volume by as much as 50%, though volume loss involved neuropil more than the total neuron numbers. As expected, somatotopic maps were greatly altered in these monkeys but after this length of time, no inactive or silent regions remained. These studies indicate that following a large peripheral injury, long-term transneuronal atrophy continues over many years and is a slow but dynamic process (see Jones, E. G., 2000 for review).

In the shorter term and to some extent, chronically, a number of nonneuronal cells types (e.g., macrophages, oligodendrocytes, microglia, and astrocytes) are recruited and activated. These cells perform many roles in addition to cleaning up and managing the structural integrity of the injury site. In chronic injuries, and most obviously in traumatic injuries of the spinal cord and CNS, astrocytes are known to play a major role in gliosis and scar formation. Activated astrocytes within the scar tissue secrete molecules (e.g., chondroitin sulphate proteoglycans, ephrins,), that can either permit or inhibit axon terminal growth and synapse formation (Fawcett, J. W. and Asher, R. A., 1999; Ullian, E. M. *et al.*, 2004; Miller, J. H. and Silver, J., 2006). Their secretion of inhibitory factors can present a major barrier to axon growth and recovery following traumatic spinal injury, and the effects of these cells on neuronal reorganization forms an important focus of investigation. Their role in somatosensory plasticity, however, is complex, and requires further investigation.

6.14.1 Intrinsic Signal Imaging of Somatosensory Cortex Organization

This chapter reviews some exciting new studies on primate somatosensory cortex (SI) using intrinsic signal optical imaging methods. Previous electrophysiological approaches have provided a great deal of information regarding neural processes in the SI. However, there is a limited understanding of the functional organization of such representation in SI. Optical imaging is a method well suited for revealing such functional organizations. In the visual cortex, understanding functional organization has offered significant insight into the segregation and integration of different visual perceptual channels and has inspired a large number of studies. The hope is that greater understanding of functional organizations in SI will similarly illuminate the role of SI in tactile perceptual behaviors.

This chapter will be restricted to the imaging of intrinsic optical signals *in vivo* (i.e., without the use of dyes; *cf.* Bonhoeffer, T. and Grinvald, A. 1996, for review). The intrinsic signal arises from various sources including changes in blood volume due to local capillary recruitment, activity-dependent changes in the oxygen saturation level of hemoglobin (increase or decrease in deoxyhemoglobin), and light-scattering changes that accompany cortical activation. In this method, stimulus-induced changes in neural activity produce local decreases in blood oxygenation detected as local decreases in tissue reflectance. These minute changes in optical absorption (typically in the 0.1% range), which are recorded by a charge-coupled device (CCD) camera, can be highly spatially localized because local capillary-related blood flow is highly localized. Thus, functional organizations in sensory cortices can be mapped at high resolution, permitting the visualization of 100-μm-sized structures. The magnitude and timecourse of reflectance change is dependent on the illumination wavelength used (Vanzetta, I. *et al.*, 2005). In the visual cortex, the typical intrinsic signal timecourse (under 600–630 nm illuminant, wavelengths at which the oxymetry component is relatively large) peaks within 2–4 s followed by a several-second undershoot (Bonhoeffer, T. and Grinvald, A., 1996; Vnek, N. *et al.*, 1999). The optical signal in primate SI is similar in timecourse and magnitude (Chen, L. M. *et al.*, 2001; 2003; 2005; for different wavelengths, see Tommerdahl, M. *et al.*, 1998; 1999). Although intrinsic imaging lacks the temporal resolution offered by dyes, it is a high-spatial-resolution imaging method that does not require application of any external agents to the brain. The intrinsic signal has been associated with so-called initial dip in blood-oxygen-level-dependent functional magnetic resonance imaging (BOLD fMRI)

studies (e.g., Kim, D. S. *et al.*, 2000; Cannestra, A. F. *et al.*, 2001; Devor, A. *et al.*, 2003; Sheth, S. *et al.*, 2003; Thompson, J. K. *et al.*, 2003; Fukuda, M. *et al.*, 2006; Roe, A. W. *et al.*, 2006) and has been shown to be correlated with both spiking and subthreshold components of neural response. For a recent review and Zepeda A. *et al.* (2004).

New World monkeys are an attractive species for optical imaging studies because their lissencephalic cortex allows unobstructed viewing of multiple visual cortical areas in both dorsal and ventral streams (see Figure 1(a), *cf.* for visual cortex Malach, R. *et al.*, 1994; Lyon, D. C. *et al.*, 2002; Xu, X. *et al.*, 2004; Roe, A. W. *et al.*, 2005). Thus, it is possible, for example, to image areas 3a, 3b, 1, and 2 simultaneously by optical methods. The functional organization of SI in New World monkeys largely parallels those in Old World monkeys (*cf.* Sur, M. *et al.*, 1982) and has been studied extensively in physiological, anatomical, and behavioral studies, making them prime candidates for studies of functional organization of sensation and sensory behavior. For this reason, the studies summarized in this chapter are mostly derived from studies on New World monkeys.

To underscore the importance of this developing approach, one of the challenges of optical imaging is to understand the modular basis of cognition. How do networks of modules within and across cortical areas achieve vision or memory or emotion? Visualization of such modular activations during behavior is tantamount to watching the brain at work. Over the past decade, researchers have developed methods to visualize activations through implanted windows on the brain (e.g., Chen, L. M. *et al.*, 2002). By applying these methods to the awake, behaving animal, it is hoped that this method can open new vistas in our understanding of the neural basis of cognitive function. Furthermore, the ability of these studies to forge a critical link between a large body of work on animal models and functional imaging in humans will be invaluable. There are now a handful of optical

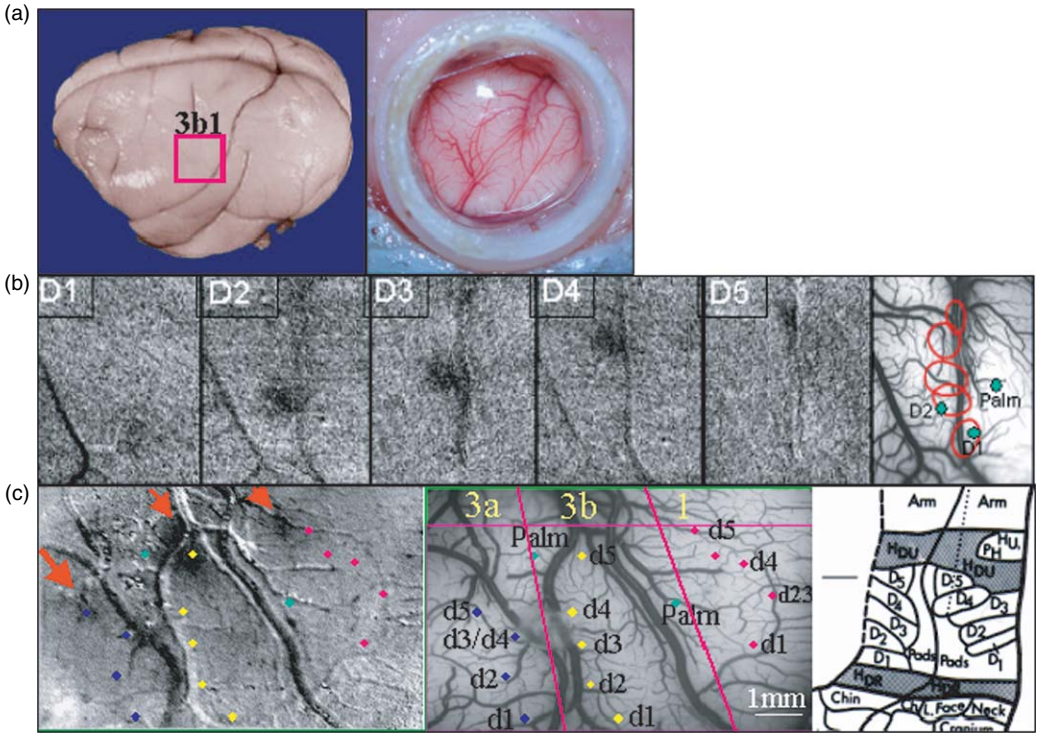

Figure 1 Optical imaging of digit topography in somatosensory cortex (SI) of anesthetized squirrel monkey. (a) Locations of areas 3b and 1 in squirrel monkey brain. Optical window over this area (Sur, M. *et al.*, 1982). (b) Five images obtained in response to indentation of digits D1–D5, respectively. Dark pixels indicate cortical activation. D1–D5 activation locations overlaid on blood vessel map (from Chen, L. M. *et al.*, 2001). (c) Imaging of areas 3a, 3b, and 1 in squirrel monkey in response to indentation of digit D5. D5 activation zones (orange arrows) correlate well with electrophysiological map (dots). Topography and size of focal activations (0.5–1 mm) area consistent with published maps (Sur, M. *et al.*, 1982).

imaging studies on visual behaviors in the awake monkey (Grinvald, A. *et al.*, 1991; Vnek, N. *et al.*, 1999; Shtoyerman, E. *et al.*, 2000; Seidemann, E. *et al.*, 2002; Slovin, H. *et al.*, 2002; Siegel, R. M. *et al.*, 2003; Roe, A. W. *et al.*, 2004). However, such studies in alert tactile behaviors are still few (Chen, L. M. *et al.*, 2005).

6.14.2 Topographic Representation in Primary Somatosensory Cortex

6.14.2.1 Topography in Somatosensory Cortex

Orderly topographic sensory maps in primary SI serve as an anchor for our understanding of somatosensory cortical organization (Woolsey, C. N. *et al.*, 1942; Nelson, R. J. *et al.*, 1980; Sur, M. *et al.* 1982; Pons, T. P. *et al.*, 1985; 1987). Primate primary SI in the postcentral gyrus contains four complete topographic maps of the body surface that fall within the architectonically defined Brodmann's areas 3a, 3b, 1, and 2 (e.g., Woolsey, C. N. *et al.*, 1942; Powell, T. P. and Mountcastle, V. B., 1959; Kaas, J. H. *et al.*, 1979; Nelson, R. J. *et al.*, 1980; Sur, M. *et al.* 1982; Pons, T. P. *et al.*, 1985; 1987). Areas 3b and 1 receive input primarily from cutaneous afferents where areas 3a and 2 receive input from deep afferents (muscle spindles and joints) (e.g., Tanji, J. and Wise, S. P., 1981). Other parietal areas, such as areas 5 and 7, also process somatosensory information (Murray, E. A. and Mishkin, M., 1984; Dong, W. K. *et al.*, 1994; Burton, H. *et al.*, 1997; Duhamel, J. R. *et al.*, 1998; Debowy, D. J. *et al.*, 2001). Somatotopic maps are also found laterally in SII and adjacent area PV (Burton, H. *et al.*, 1995; Krubitzer, L. *et al.*, 1995), and there are other somatosensory areas in insular cortex that receive cutaneous and visceral information (Robinson, C. J. and Burton, H., 1980; Schneider, R. J. *et al.* 1993; Craig, A. D., 2003).

6.14.2.2 Optical Imaging of Cortical Topography in Anesthetized Monkeys

A number of studies have employed the optical imaging approach to examine topographic representation in SI. Such studies have revealed organizations quite consistent with previous electrophysiological studies of SI topography (e.g., in rats: Masino, S. A. and Frostig, R. D., 1996; Sheth, B. R., *et al.*, 1998; Goldreich, D. *et al.*, 1998; in non-human primates and humans: Narayan, S. M. *et al.* 1994; Cannestra, A. F. *et al.*, 1998; Schwartz, T. H. *et al.*, 2004). In the nonhuman primate, studies of somatotopy have produced images of the body map in the squirrel monkey (radial interdigital pad, D2 fingertip, and similar sites on the leg and foot) (Tommerdahl, M. *et al.*, 1999), distal fingerpads of the squirrel monkey (Chen, L. M. *et al.*, 2001), and area 1 of the macaque monkey (Shoham, D. and Grinvald, A., 2001).

As shown in Figure 1(b), focal activations roughly 0.5–1 mm in size are obtained following stimulation of individual digit tips with indenting probes. Comparison of D1 (thumb) to D5 digit tip activations reveals an orderly map within area 3b of the squirrel monkey. These maps are quite consistent with published maps obtained with electrophysiological methods (e.g., Sur, M. *et al.* 1982; Merzenich, M. M. *et al.*, 1987). Imaging a larger field of view reveals multiple representations, which include areas 3a, 3b, and 1 (Figure 1(c)). For example, stimulation of a single digit tip (D5) elicits three activations in areas 3a, 3b, and 1, respectively (Figure 1(c), orange arrows); the locations of these activations are consistent with electrophysiological recordings in this case (colored dots). Thus, intrinsic signal imaging is a useful tool for quickly and clearly revealing tactile topography in primates.

6.14.2.3 Optical Imaging of Cortical Topography in Alert Monkeys

Our view of somatosensory topography is largely based on data collected in the anesthetized animal. However, little is known about these topographies in the awake primate (McKenna, T. M. *et al.*, 1982; Iwamura, Y. *et al.*, 1993; Blankenburg, F. *et al.*, 2003). The question remains as to whether the fundamental structure of topographic maps is the same in the anesthetized and the awake, behaving animal. For example, does topography remain stable over time in the awake animal or is it dependent on behavioral context? Neither is much known regarding the relative activations of different cortical areas (within primary SI of the primate are cortical areas 3a, 3b, 1, and 2). Since different cortical areas are characterized by distinct stimulus preferences (Mountcastle, V. B. and Powell, T. P. S., 1959; Hyvarinen, J. and Poranen, A., 1978; Costanzo, R. M. and Gardner, E. P., 1980; Carlson, M., 1981; Sur, M. *et al.*, 1985; Iwamura, Y. *et al.*, 1993), it is possible that different cortical areas become dominant under changing stimulus and behavioral contexts. A number of studies have investigated behavioral modulation of neuronal response within single cortical areas (Iwamura, Y.

et al., 1983; Nelson, R. J., 1987; Nelson, R. J. *et al.*, 1991; Burton, H. and Sinclair, R. J., 2000; Meftah, el-M. *et al.*, 2002; Fitzgerald, P. J. *et al.*, 2006); however, little is known about the modulation of interareal dominance or of patterned area-specific functional organizations during behavior (Hsiao, S. S. *et al.*, 1993; Buchel, C. and Friston, K. J. 1997; Friston, K. J., 1998; Kastner, S. *et al.*, 1998; Mesulam, M. M., 1998; Ungerleider, L. G. *et al.*, 1998). Indeed, what is the behavioral relevance of known functional organizations and topographies? Such studies would provide important constraints for studies on feedforward versus feedback influences in cortical processing (*cf.* Roe, A. W., 2003).

One recent optical imaging study in SI revealed that activation patterns can differ significantly between anesthetized and awake preparations. Using intrinsic signal optical imaging of areas 3b and 1, awake squirrel monkeys were imaged repeatedly for over a period of 2 years in awake and anesthetized states in response to vibrotactile and electrocutaneous stimuli presented to individual fingerpads (Figure 2). Imaged somatotopic maps were in general stable over this period in both the anesthetized and the awake states, consistent with electrophysiologically recorded maps in areas 3b and 1 in the anesthetized state.

However, in the awake animal, signal sizes were larger and more variable, leading to larger activations (both in area and in amplitude), suggesting a less precise topography. Topographically, the map in the awake state appears less precise and also different from that in the anesthetized state. As shown in Figure 3, in the awake state the activations to D3 and D4 stimulation are highly overlapped. The significance of this finding remains to be explored. Larger activations and larger receptive field sizes are traditionally associated with less refined topography and perhaps decreased discriminability. However, the possibility remains that larger imaged activations reflect a substrate for greater cortical dynamics. Indeed, these findings are consistent with some previous studies in the awake animal that have shown large receptive fields and dynamic changes in receptive fields (such as increases in receptive field size, shifting hot spots, or changes in spatial sensitivity profiles within receptive fields) or other modulation of cortical activity within the behavioral context (Chapin, J. K. and Lin, C. S., 1984; Nelson, R. J., 1987; Lee, C. J. and Whitsel, B. L., 1992; Nicolelis, M. A. *et al.*, 1993; Schroeder, C. E. *et al.*, 1995). Thus, topographic organizations present in the anesthetized animal may be used in different ways in the awake animal.

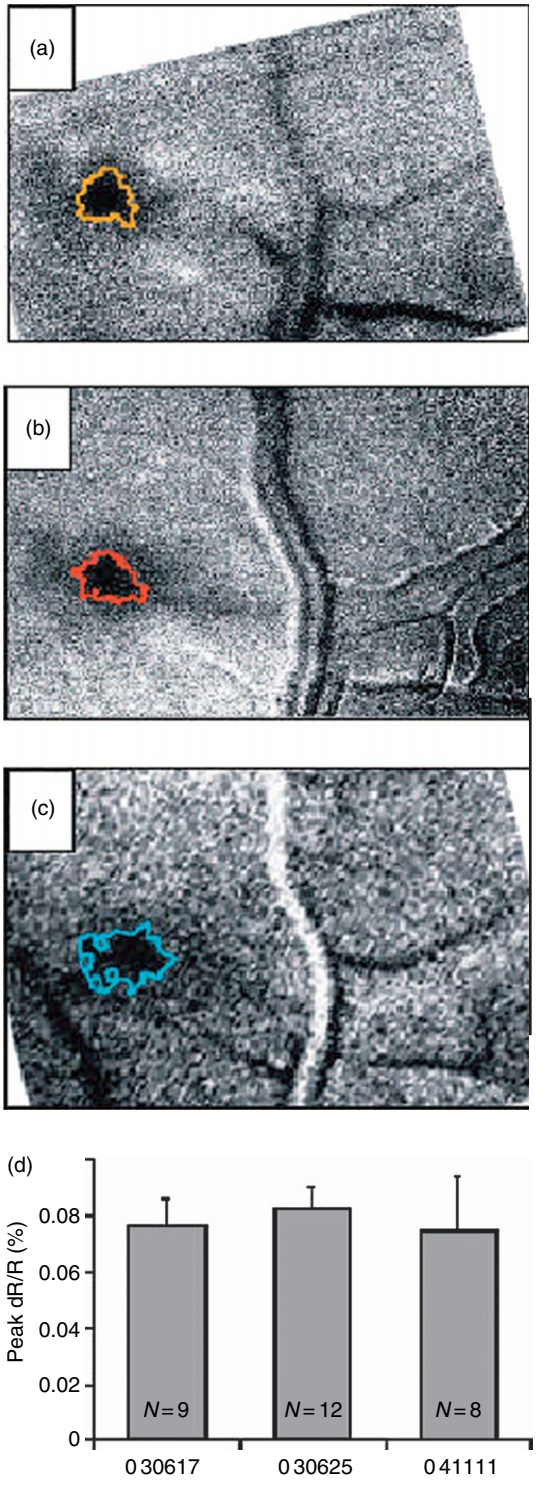

Figure 2 Cortical topography is stable over time in awake squirrel monkey somatosensory cortex (SI) (from Chen, L. M., Friedman, R. M., and Roe, A. W. 2005. Optical imaging of SI topography in anesthetized and awake squirrel monkey. J. Neurosci. 25, 7648–7659). Images taken over three different imaging sessions.

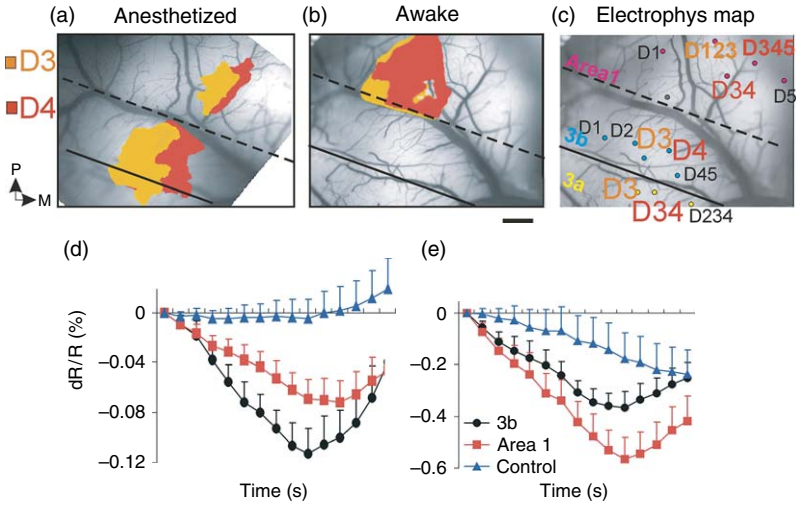

Figure 3 Comparison of topographic activations in the anesthetized and awake states. Cortical response to vibrotactile stimulation of D3 (orange) and D4 (red) in the squirrel monkey. (a) Anesthetized activation is more prominent in area 3b (see (d)). (b) Awake activation is more prominent in area 1 (see (e)). (c) Electrophysiological mapping of areas 3a, 3b, and 1. (d) and (e) Optical signal time course for D4 locations in anesthetized (d) and D3 locations in awake (e) in areas 3b and 1.

Another difference between anesthetized and awake activation patterns lies in the strength of activations across cortical areas. Whereas in the anesthetized animal strongest imaging signals are obtained from area 3b, in the awake animal area 1 activation dominates over that in area 3b, suggesting that interareal interactions in the alert animal differ substantially from that in the anesthetized animal. In the anesthetized state, we generally observe stronger activations in area 3b than in area 1 (Figure 3(d)). The opposite is observed in the awake state, where area 1 activations are more prominent (Figure 3(e)). These results suggest significant awake versus anesthetized differences in somatosensory activations, due to differences in neural response and/or vacular response.

6.14.3 Topographic Representation of Tactile Perception in the Somatosensory Cortex

The long-standing view that sensory topography in SI reflects a body map is well supported. However, a recent study has called into question traditional views of somatosensory cortical maps (Chen, L. M. *et al.*, 2003). This study used the so-called funneling illusion to demonstrate that topographic maps in SI can reflect the perceived location of tactile stimulation rather than the location of physical stimulation on the skin. This finding suggested that, in contrast to previous views, the topographic map in area 3b is a perceptual map rather than a physical one.

6.14.3.1 The Funneling Illusion

The funneling illusion is the illusory perception of skin stimulation at a single site central to a line of multiple stimulation sites (Sherrick, C. E., 1964; von Bekesy, G., 1967; Gardner, E. P. and Spencer, W. A., 1972; Gardner, E. P. and Tast, J. M., 1981; Hashimoto, I. *et al.*, 1999). Inputs at lateral sites are funneled centrally so that perceived intensity at the central site is greater than that to stimulation at the middle site alone. With two-point stimulation, a funneled sensation is produced at a central location that is without direct stimulation. This illusion has been reported on the forearm, palm, and fingers. When two digit tips are simultaneously stimulated, subjects report sensations such as a mound or trapezoid centered over a finger, a mound or trapezoid bridging fingers, or a mound bridging fingers with two lateral humps (Chen, L. M. *et al.*, 2003 supplemental material). Thus, the funneling illusion is characterized by a perception of spatial mislocalization and increased tactile intensity. The neural basis for this illusion is thought to involve a complex integration of inhibitory interactions. Previous studies have shown that the funneling illusion is encoded in primary SI, and not peripherally at the skin (Gardner, E. P. and

Spencer, W. A., 1972). Responses of SI neurons to three-point skin stimulation have demonstrated that a broad distribution of cortical neurons are recruited (Gardner, E. P. and Spencer, W. A., 1972; Gardner, E. P. and Costanzo, R. M., 1980).

6.14.3.2 Two-Point Stimulation Produces Cortical Merging in Area 3b

The central representation of this phenomenon was not expected to be in primary SI. Since the illusion involves integration across multiple digits, it was unlikely to occur in area 3b where receptive fields are confined to single-digit tips. However, a recent study has demonstrated that this integration does indeed occur in early somatosensory areas. Figure 4 illustrates that stimulation of D2 alone (a,b), D3 alone (c,d) or D4 alone (e,f) elicits single focal millimeter-sized activations. However, stimulation of adjacent digits D4 + D3 (g,h) produces a single activation site whose center lies between the D3 and D4 sites (l). This merged activation is not observed for nonadjacent digits D4 + D2 together (i,j) (n). Thus, stimulation of each location alone activates spatially distinct locations in the cortex, but together produces a single centrally located peak of activation.

6.14.3.3 Intensity of Funneling Percept

The second notable characteristic of multipoint stimulation (two or more points) is the increased intensity of the funneled sensation in comparison to stimulation of a single point. Gardner E. P. and Costanzo R. M. (1980) demonstrated that responses of cortical neurons to multipoint stimulation were often similar in magnitude to single-point stimulation and were always less than the sum of component single-point responses. From this, they suggested that the increased intensity is not due to greater neuronal firing rates, but rather due to recruitment of a broader distribution of neurons. Such broader distribution can be reflected in either greater area of activation or greater amplitude of imaged signal.

Chen L. M. *et al.* (2003) found that both the area and the amplitude of activation produced by paired digit stimulation (both adjacent and nonadjacent) is smaller than the sum of the single-digit activation areas. This reduction was observed in all digit pairs examined (both adjacent and nonadjacent). Thus, two-finger stimulation leads to a reduction in activation area (for both adjacent and nonadjacent digit pairs).

Electrophysiological recording of single units also show similar reductions in activation. As shown in Figure 5, two units (one rapidly adapting (RA) and one slowly adapting (SA)) were recorded with receptive fields on the D4 fingerpad. Stimulation of D4 alone (left column) revealed an early transient component and a weak late component (indicated by arrows) in both of the RA and SA cells' responses. Stimulation of either adjacent D3 or nonadjacent D2 alone produced no initial transient and relatively weak late response. Simultaneous stimulation of two adjacent fingerpads (right column, D4 + D3) reduced the amplitude of the initial transient. This reduction of the initial transient was not observed with simultaneous stimulation of nonadjacent fingerpads (right, D4 + D2). Thus, adjacent digit stimulation leads to weakening of digit activation as evidenced by decreased area and amplitude of optical signal, late component suppression in optical signal (not shown, Chen, L. M. *et al.*, 2003), and decline in size of single-unit response.

We suggest that the decreased cortical activation observed during two-digit stimulation may be due to inhibitory interdigit interactions. Lateral inhibition is a well-described phenomenon in the somatosensory pathways. Somatosensory afferents produce both inhibition and excitation in central neurons, including the dorsal horn, dorsal column nuclei, the ventrobasal complex, and SI. These inhibitory processes are thought to be mediated by local feedforward or feedback circuits within the target nuclei. The spatial profiles of inhibition are often larger than that of excitation, producing a center-surround receptive field organization (e.g., Janig, W. *et al.*, 1979); this sharpening has also been referred to as coning. Stimulus-induced inhibition has longer latencies than excitation and may last for 100 ms or more (e.g., Laskin, S. E. and Spencer, W. A., 1979). These lateral inhibitory processes may serve to limit the spatial extent of discharge zones and enhance stimulus contrast, thereby improving spatial and form discrimination.

In sum, simultaneous digit stimulation produces a reduced activation at the sites of digit representation. This reduction is coupled with an increased response amplitude in the merged zone (where no actual stimulation occurs); this increased response at the merged zone is comparable in magnitude to that of single-digit activations. In other words, even though no physical stimulus occurs at the merged site, the response is similar in size to that of an actual single-digit stimulus. We speculate that a change in the balance of interaction between neurons at the merged

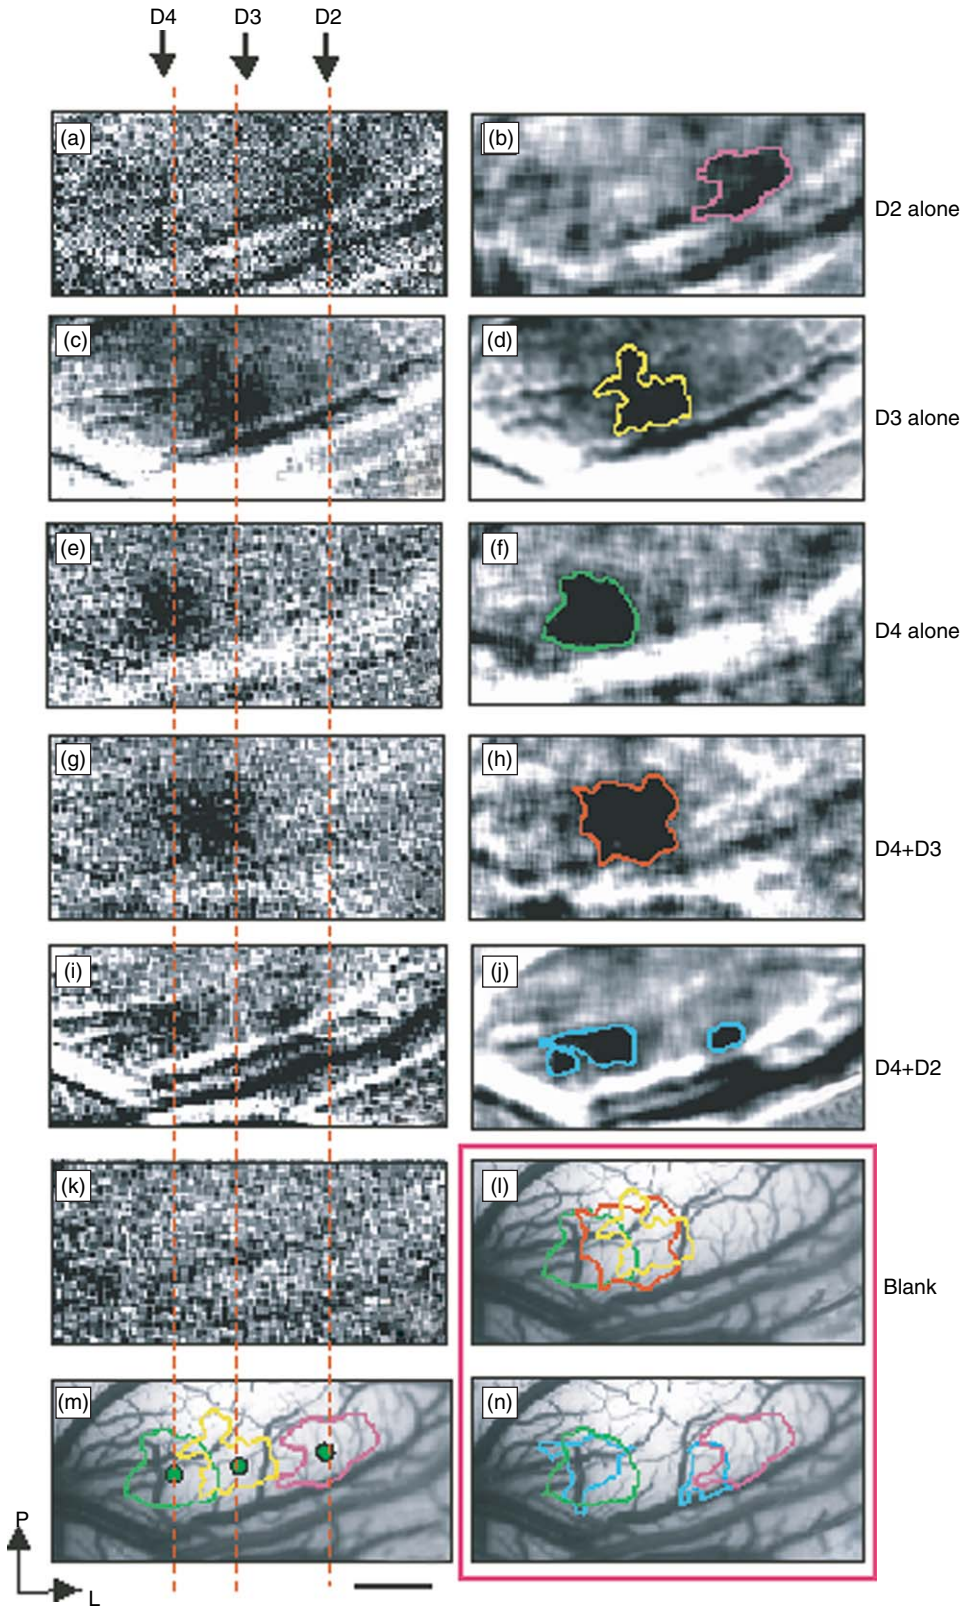

Figure 4 Cortical activations by one- and two-digit stimulation in area 3b. Raw images of D2, D3, D4, D3 + D4, D2 + D4 stimulation (a,c,e,g,i); low-passed images with threshold outlines (b,d,f,h,j). Digit activation centers are indicated by red dashed lines. (k), blank condition. (l–n) overlay of outlines of adjacent digit (l), single digit (m), and nonadjacent digit (n) activations. (m) penetrations show lateral to medial topographic locations of D2, D3, and D4 (green dots). Scale bar: 1 mm.

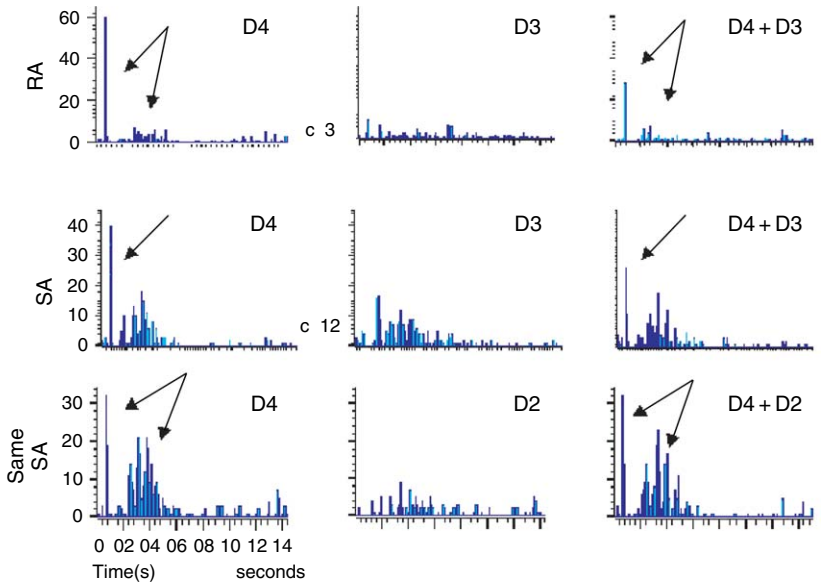

Figure 5 Two units recorded on D4 fingerpad. Top row: Rapidly adapting (RA) cell response to D4, D3, and D4 + D3 stimulation. Middle row: Slowly adapting (SA) cell response to D4, D3, and D4 + D3 stimulation. Bottom row: Same SA cell response to D4, D2, and D4 + D2 stimulation. Twenty trials, bin width 100 ms. Arrows specify early and late components of response.

site (increased amplitude) and those at nearby sites (decreased amplitudes) serves to heighten the perceived intensity and sharpen the focus (decreased area) during the funneling illusion (Figure 6). The fact that activation of nearby cortical sites leads to single merged activations suggests that spatial percepts are strongly dictated by central representations. Indeed, physical perception can occur where no physical stimulus occurred. This study further suggests that, under certain contextual situations, receptive fields of neurons in area 3b can span more than a single digit. The extent of these contextual influences are likely to be determined by mechanisms dependent on intracortical distance, center and surround interactions, and cortical feedback.

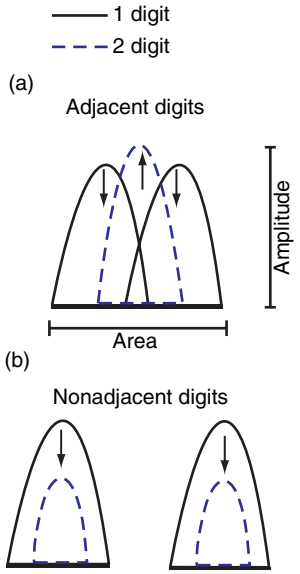

Figure 6 Summary of cortical merging. (a) Adjacent digit stimulation results in merging to a single central site, and increased signal amplitude at the merged location concomitant with decreased amplitudes nearby. (b) Nonadjacent digit stimulation results in decreased signal area and amplitude at each of the stimulation sites.

6.14.4 Modality Representation in the Somatosensory Cortex

6.14.4.1 Presence of Interdigitated Multiple Maps

Both anatomical and physiological evidence suggests labeled lines of modality-specific cutaneous information (Verrillo, R. T., 1966; Talbot, W. H. *et al.*, 1968; Verrillo, R. T. and Bolanowski, S. J., 1986). Psychophysically, vibrotactile stimuli produce three distinct sensations on the skin (Johansson, R. S. *et al.*, 1982):

1. A pressure sensation is induced by stimuli below 2 Hz.
2. A flutter sensation is evoked by stimulation in the 2- to 40-Hz range.
3. A vibration sensation is evoked by higher frequencies (40–200 Hz).

These pressure, flutter, and vibratory sensations are mediated by SA, RA, and pacinian (PC) receptors, respectively (Mountcastle, V. B. *et al*., 1972; LaMotte, R. H. and Mountcastle, V. B., 1975; Cohen, R. H. and Vierck, C. J., 1993). These modalities remain largely separate in their central projections. For example, direct electrical stimulation of single identified low-threshold mechanoreceptive afferents (SA, RA, or PC) evokes only one type of perception (pressure, flutter, or vibration, respectively) (Torebjork, H. E. and Ochoa, J. L., 1980; Vallbo, A. B., 1981). Psychophy-sical studies fail to find vibrotactile masking and adaptation between stimulus frequencies that produce pressure (0.5 Hz), flutter (20 Hz), and vibratory sensations (200 Hz) (Gescheider, G. A. *et al*., 1979; 1985; Bolanowski, S. J. *et al*., 1988). In addition, frequency-specific electrical stimulation of a cortical RA-dominated site in area 3b mimics the effect of stimulating RA receptors of the skin (Romo, R. *et al*., 1998). Remarkably, even the transfer of tactile learning from one digit to another is modality-specific (Harris, J. A. *et al*., 2001). These studies suggest a marked degree of separation in the experiences of pressure, flutter, and vibration, mediated by separate populations of receptors that remain separate in their central projections, and perhaps even to higher cortical areas involved in tactile learning and memory (also Romo, R. *et al*., 2000). Thus, both psychophysical and neurophysiological studies suggest some degree of modality-specific functional segregation in SI.

Anatomical and physiological evidence also suggest parallel modality-specific pathways, from periphery through the dorsal column nuclei, to the thalamus, and into early somatosensory cortical areas. Dykes R. W. *et al*. (1981) have described the segregation of RA, SA, and PC responses in the VPL and VPI. Jones E. G. and coworkers (1982) have suggested that rods of topography and modality-specific cells project to similar modality-specific bands in area 3b, and perhaps also area 1. Connections between areas 3b and 1 are topographically homotopic, with feedforward projections being more robust than feedback (e.g., Jones, E. G. and Powell, T. P. S., 1969; Jones, E. G. *et al*., 1978; Cusick, C. G. *et al*., 1985; Burton, H. and Fabri, M., 1995). Using 2-deoxyglucose labeling methods combined with anatomical tracer injections, Juliano S. L. *et al*. (1990) suggest that excitatory information is transmitted from area 3b to area 1 in a way that connects clusters of cells with similar response properties.

However, there is limited evidence as to whether different tactile features form multiple functional domains within each of areas 3a, 3b, 1, and 2. Electrophysiological mapping studies describe zones of neurons with SA, RA, and PC mechanoreceptor responses within area 3b (Paul, R. L. *et al*. 1972; Sur, M. *et al*., 1981; Sretavan, D. and Dykes, R. W., 1983; Sur, M. *et al*., 1984). Based on densely spaced electrode penetrations, Sur M. *et al*. (1981; 1984) found a segregation of SA and RA cells in the middle layers of area 3b and suggested that these are organized in irregular anteroposterior bands. This ground-breaking work was the first to suggest the presence of multiple maps in single cortical areas in SI.

Recently, studies using optical imaging methods have revealed networks of vibrotactile domains in SI. Vibrotactile stimulation of the digit fingerpads at frequencies that produce the sensations of pressure (1 Hz), flutter (30 Hz), and vibration (200 Hz) was used in the anesthetized squirrel monkey. These stimuli produced characteristic SA-dominated, RA-dominated, or PC-dominated responses, respectively. Intrinsic signal optical maps were obtained in response to each of these stimuli. A vector summation method was used to determine a pixel-by-pixel weighted response to the pressure, flutter, and vibration stimuli (similar to that used for visual cortical orientation maps, methodology details are described in Friedman R. M. *et al*. (2004)). Clusters of pixels with saturated color indicate that one vector magnitude dominates the other two. Three examples of such pixel-wise SA/RA/PC vector summation are illustrated in Figure 7(a–c). Pixel locations with a dominant SA response appear bright red, those with a dominant RA response appear bright green, and those with a dominant PC response appear bright blue. Patches of cortex that are coded white indicate areas with strong response to each of the pressure, flutter, and vibratory stimuli. These vibrotactile domains are typically 200–300 μm in size in both area 3b and area 1 (Figure 8).

Imaging using near-infrared signals has also shown a fine topography consistent with previous electrophysiological methods. Further research using 25-Hz flutter and 200-Hz vibratory stimuli on the palm found that flutter stimulation led to focal topographic activation in area 3b, whereas vibration only led to delayed reduced activation or an inhibition in areas 3a and 3b that was supported by a reduced activation to paired stimulation (Tommerdahl, M. *et al*., 1999). The apparent contradiction between a

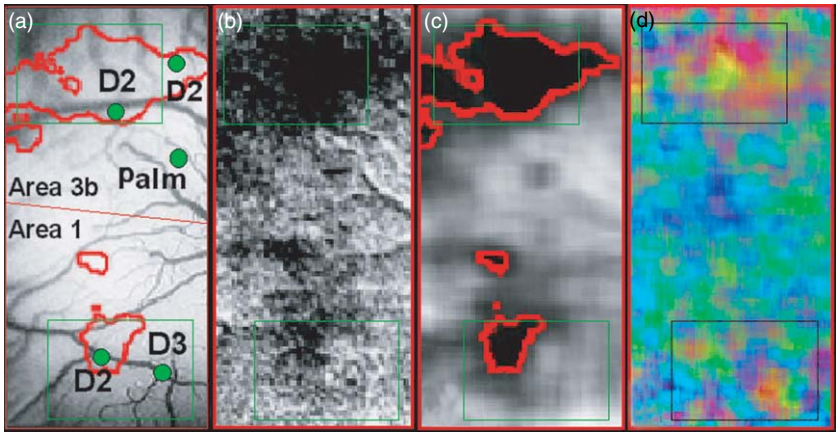

Figure 7 Relationship of topography and vibrotactile response. D2 activation in areas 3b and 1. (a) Vessel map. D2 activations in area 3b (above) and area 1 (below). (b–c) Raw and filtered image of D2 indentation. Red outline delineates strongest activation zones. (d) Modality vector map (red, green, blue: response for somatosensory cortex (SA), rapidly adapting (RA), and pacinian (PC), respectively) shows strongest activation in centers.

Top: Vibrotactile frequency-specific responses are plotted in different directions of color space (red: slowly adapting (SA), 1 Hz; green: rapidly adapting (RA), 30 Hz; blue: pacinian (PC), 200 Hz). (a–c) Three cases: vector maps obtained through pixel-by-pixel vector summation. Domains dominated by single colors indicate regions preferentially responsive to a single vibrotactile frequency. Scale bar: 1 mm. (d) Size distribution of vibrotactile domains in area 1 (left) and area 3b (right).

lack of activation to 200-Hz vibration in studies by Tommerdahl M. *et al.* (2005) and the focal activation observed by Chen L. M. *et al.* (2001) and Friedman R. M. *et al.* (2004) in areas 3b and 1 has been reconciled by the finding that the responses to vibration are site-dependent (i.e., digits vs. palm). Further research has shown that the extent and magnitude of cortical response to flutter stimuli is duration-dependent (Simons, S. B. *et al.*, 2007; see also Simons, S. B. *et al.*, 2005; Chiu, J. S. *et al.*, 2005), with longer (2–5 s) stimulation leading to suppression in surrounding regions. This finding parallels the improved ability to spatially localize following presentation of longer-adapting stimulation (Tannan, V. *et al.*, 2006). Surprising evidence demonstrates that ipsilateral input can modify responses in SI, suggesting significant interhemispheric interactions (Tommerdahl, M. *et al.*, 2006). In sum, the research of Tommerdahl and associates in anterior parietal cortex has revealed complex spatial and temporal responses to relatively simple tactile stimuli that might reflect the sensations in humans to the same kinds of stimuli (Tommerdahl, M. *et al.*, 2005; Tannan, V. *et al.*, 2005; 2006).

6.14.4.2 Relationship of Vibrotactile Domains to Topography

It is evident that the modality-specific response extends beyond the classically defined topographic map as revealed by simple indentation stimuli. As shown in Figure 7(b), an indentation stimulus (which activates all three receptors types) to digit D2 produces a fairly focal activation in both area 3b and area 1 (outline in red in Figure 7(c)). In response to pressure, flutter, and vibration stimulation, the vector summation map reveals that the strongest responses (most saturated red, green, and blue regions) correspond with the topographic digit locations. However, clustered responses, though weaker, are also evident away from the location of D2 representation (outside the boxes). This additional nontopographic activation is reminiscent of the finding in visual cortex in which complete orientation maps are obtained even though only a single eye is stimulated (Blasdel, G. G., 1992). Thus, modality maps and topographic maps exhibit some degree of independence. Whether this extended nontopographic region of activation is due to spiking and/or subthreshold activity remains to be determined.

6.14.5 A New Model of Somatosensory Cortex Organization

The finding that somatosensory cortical domains are roughly 200–300 μm in size strengthens the view that modularity is a common organizational feature of cortical representation. Cortical domains of similar size have been described in multiple cortical areas (in V1 and V2 (see Roe, A. W., 2003 for review), and V4 (Felleman, D. J. *et al.*, 1997), IT (Tsunoda, K. *et al.*, 2001), area 7 (Siegel, R. M. *et al.*, 2003), and in prefrontal areas (Kritzer, L. and Goldman-Rakic, P. S., 1995)). These findings suggest a revision of previous views of SI organization that were based primarily on electrophysiological recordings. Previously, each cortical hypercolumn was thought to contain segregated SA and RA columns innervated predominantly by thalamocortical fibers of a single vibrotactile modality (Sur, M. *et al.*, 1980). Optical imaging evidence now suggests a modification of this view (Figure 9). As shown by reconstruction of single thalamocortical arbors (Garraghty, P. E. *et al.*, 1989), inputs to SI have multiple arbors (200–300 μm in size) that span several millimeters of the cortex (see also Jones, E. G. *et al.*, 1982). These and other cortico-cortical arbors are likely to give rise to clustered activations that have been observed in 2-deoxyglucose studies (Juliano, S. L. *et al.*, 1981; Juliano, S. L. and Whitsel, B. L., 1987; Juliano, S. L. *et al.*, 1990; *cf.* Burton, H. and Fabri, M.,

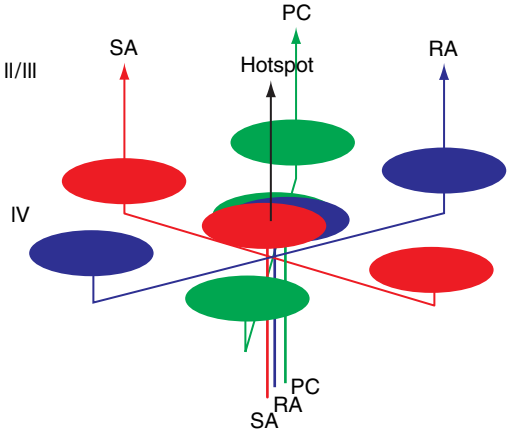

Figure 9 Proposed model of vibrotactile representation in somatosensory cortex (SI). Single slowly adapting (SA) (red), rapidly adapting (RA) (blue), or pacinian (PC) (green) fibers terminate in layer IV, each with several arbors (colored disks). These arbors project in turn to superficial layers II/III (vertical arrows). Thus, some cortical columns are dominated by a single SA, RA, or PC input, while others have mixed input (central overlapping disks).

1995). Such arbors could give rise to either an array of discrete clusters or, by varying arbor overlap, continuous modality maps. Thus, regions dominated by single SA, RA, or PC inputs would give rise to SA (red), RA (blue), or PC (green) domains. Regions of some overlap would appear as magenta or yellow-green colors (not depicted). And regions of high SA, RA, and PC overlap could underlie the so-called hotspots commonly described in SI receptive fields (in optical images these locations would appear as black, gray, or white domains); these would be well activated by broadband stimuli such as skin indentation. Other arbors extend to nontopographic locations away from the hotspot and establish locally some degree of modality-specific dominance (*cf.* Figure 9). Thus, not unlike the way horizontal iso-orientation, networks in V1 give rise to resulting orientation map structure; the observed maps result from overlapping horizontal networks of patchy, modality-specific dominance. In sum, in the revised view, each digit representation is served by collections of interdigitating SA, RA, and PC columns. The effect of topographic stimulation is therefore no longer so discrete and can, under certain stimulation conditions, have nontopographic consequences.

Glossary

barrel Region in layer IV of S1 with a patchwork of regions that stain dark with cytochrome oxidase. Neurons in each barrel respond most vigorously to a particular body part. Barrels are arranged somatotopically across S1, and in the rat the whisker barrels make up almost half of barrel cortex. The regions of S1 that do not contain barrels are known as dysgranular cortex.

barrelet A cluster of brainstem neurons corresponding to a single facial whisker.

barreloid A cluster of thalamic neurons corresponding to a single facial whisker.

bilateral On both sides of the body.

contralateral On the opposite side of the body.

deafferentation The elimination or interruption of sensory nerve inputs.

$GABA_A$ Fast-responding receptors for the brain's main inhibitory neurotransmitter.

granular layer Cortical layer IV.

infragranular layers Cortical layers deeper than layer IV.

ipsilateral On the same side of the body.

mystacial pad The thick muscular pad on the side of the face of the rat that contains the whisker follicles.

plasticity Long-term changes in anatomy, topographic maps, or neuronal responses.

principal whisker (PW) The whisker that evokes the greatest response in a particular neuron.

receptive field (RF) The region of stimulus space that evokes a response in a neuron. In the somatosensory system, an RF is defined as the part of the body whose stimulation evokes a response.

somatotopic A topographic neural representation of the body's surface, such that neighboring neurons respond to neighboring body regions.

supragranular layers Cortical layers superficial to layer IV.

trigeminal nerve The fifth cranial nerve, through which sensory inputs from the face enter the brainstem. The nerve is split into three divisions, the mandibular, maxillary, and ophthalmic. The whisker information comes in through the infraorbital branch of the maxillary division.

vibrissa The large stiff facial whiskers of mammals such as rats and cats.

whisking The rhythmic large-amplitude 9 Hz back-to-front movement of the facial whiskers. The behavior is exhibited by rats during active exploration, used to sample certain tactile objects, and possibly also to enhance olfaction.

6.15.1 Introduction

The modern era of somatosensory neurophysiology was inaugurated in 1983 by the discovery of widespread plastic functional reorganization in the primary somatosensory cortex (S1) of adult monkeys (Merzenich, M. M. *et al.*, 1983a; 1983b). In essence, this discovery marked the first evidence that the somatotopic representations found in the S1 cortex are rather dynamical entities, whose functional organization can be shaped over time as a function of the state of the body's periphery (Merzenich, M. M. *et al.*, 1983a; 1983b) or the animal's sensory experience (Jenkins, W. M. *et al.*, 1990). Yet, in these first few studies the dynamics of such a process of functional reorganization was measured on a timescale of days or even months.

Soon after the original findings of Mike Merzenich and Jon Kaas, the process of plastic reorganization in the somatosensory system was found to occur in a matter of seconds and minutes (Calford, M. B. and Tweedale, R., 1991a; 1991b; 1991c; Nicolelis, M. A. *et al.*, 1993).

As these discoveries unfolded, a new neurophysiological method began to be employed to investigate the functional properties of the somatosensory system in behaving animals (Chapin, J. K. and Woodward, D. J., 1981; 1982; Nicolelis, M. A. *et al.*, 1993). Known as chronic, multielectrode recordings, this approached allowed for the first time the simultaneous quantification of the physiological properties of small populations of single neurons, distributed across distinct cortical and subcortical structures that form the mammalian somatosensory system (Nicolelis, M. A. *et al.*, 1995). These studies indicated the existence of a dynamic functional organization throughout the somatosensory system on a timescale of tens of milliseconds (Nicolelis, M. A. and Chapin, J. K., 1994). Moreover, such a dynamic structure was suggested to serve as the basis through which the process of plastic reorganization could be triggered (Faggin, B. M. *et al.*, 1997).

The goal of this review, therefore, is to provide a brief description of the findings that followed the introduction, 25 years ago, of the multielectrode recording method as an experimental tool to characterize the functional organization of the somatosensory system, with particular emphasis on the rat trigeminal system.

Since the 1970s, the facial vibrissal system of the rat (Figure 1) has been a popular model for studying somatosensory processing (Woolsey, T. A. and Van der Loos, H., 1970; Jones, E. and Diamond, M., 1995; Nicolelis, M. A. and Fanselow, E. E., 2002a; 2002b). This interest is due to a confluence of several attractive features. First, rats are known to employ their whiskers flexibly for a variety of sensitive discrimination, recognition, and navigation tasks (Whishaw, I. and Kolb, B., 2005). A variety of behavioral tasks now exist that probe the limits of this behavioral repertoire. Second, the central brain representation of the whiskers is large, facilitating electrophysiological study. That is, almost half of the S1 cortex is responsive to whisker stimulation (Woolsey, T. A. and Van der Loos, H., 1970). Moreover, early anatomical and single-unit electrophysiological studies of the rat vibrissae system revealed a relatively simple organization such that neurons that respond preferentially to individual whiskers are anatomically segregated into topographically arranged modules (barrellets in the brainstem, barreloids in the thalamus, and barrel columns in the S1 cortex) (Jones, E. and Diamond, M., 1995). This later feature suggests a conceptually simple model of coding in which the activity in these modules represents stimulation of specific whiskers on the contralateral face.

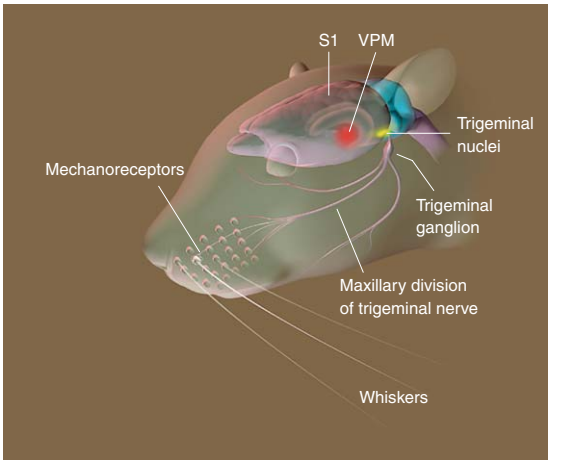

Figure 1 Schematic of the rat whisker system. Whisker stimulation activates mechanoreceptors whose somata lie in the trigeminal ganglion (at the root of the fifth cranial nerve). These primary afferents synapse onto neurons in multiple trigeminal brain stem nuclei. The primary pathway proceeds from the trigeminal nuclei of the brainstem, across the midline via the medial lemniscus, onto neurons in the ventral posterior medial (VPM) nucleus of the thalamus. VPM neurons synapse onto neurons in primary somatosensory (S1) cortex.

6.15.2 Single-Whisker Stimulation

6.15.2.1 Location Coding

The anatomical organization of the whisker system suggests that it consists of arrays of dedicated detectors that function to indicate the deflection of individual contralateral whiskers (Welker, C., 1971). However, it was soon observed that whiskers other than the principal whisker (PW) modulate responses in a barrel or a barreloid. For instance, ventral posterior medial nucleus of the thalamus (VPM, see Figure 1) neurons in both awake and anesthetized animals have large multiwhisker receptive fields (RFs) (Armstrong-James, M. and Fox, K., 1987; Nicolelis, M. A. and Chapin, J. K., 1994), and the same is true for S1 barrel neurons (primary somatosensory cortex layer IV; Figure 1) (Zhu, J. J. and Connors, B. W., 1999; Ghazanfar, A. A. and Nicolelis, M. A., 2001). In the supra- and infragranular layers of S1, intercolumnar connections are more common, and RFs in these layers are correspondingly larger, including up to 20 whiskers (Armstrong-James, M. *et al.*, 1992; Ghazanfar, A. A. *et al.*, 2000; Schubert, D. *et al.*, 2001).

These results suggest that stimulus location on the mystacial pad is coded in a distributed manner across the rat S1 cortex. With the advent of multielectrode array (MEA) technology, it has been possible to test specific hypotheses about how activity in S1 encodes information about which whisker was deflected. Candidate codes include the number of spikes following stimulation, time-varying firing rate, and correlated activity between neurons.

In one study, researchers implanted 16-electrode arrays into S1 and VPM and delivered mechanical stimuli to each whisker of the anesthetized rat (300 trials per whisker) (Ghazanfar, A. A. *et al.*, 2000). They used classification algorithms to estimate which whisker was deflected on each trial, quantifying discrimination performance as the percentage of stimuli correctly predicted by the classifier (Ghazanfar, A. A. *et al.*, 2000; Thomson, E. E. and Kristan, W. B., 2005). The study revealed many details of how ensembles of cortical neurons encode stimulus location. First, the ensemble of S1 neurons discriminated much better than any individual neuron, suggesting that S1 encodes stimulus location using a population of neurons rather than individual neurons. They also showed, by repeating the analysis with different numbers of neurons from their data, that the discrimination performance decreased gradually with the number of neurons, suggesting that no individual neuron is privileged in this distributed representation of stimulus location (Figure 2). In a related study, it was found that the knowledge of the activity of additional neurons within a column, in contrast to activity of neurons in different columns, provided little new information about stimulus location (Petersen, R. S. *et al.*, 2001).

In addition to examining the effects of neuronal population size, studies described in Ghazanfar A. A. *et al.* (2000) examined a set of possible ensemble codes for stimulus location. Overall, the analysis showed that while the firing rate of neurons in an ensemble contributes most to stimulus discrimination, the temporal structure of the neural response provides a significant boost in performance. For instance, by shifting the spike trains in time, such that the single-neuron temporal patterns of spikes would remain the same but the onset times (i.e., latencies) would be randomized, they found a small but significant reduction in discrimination. This suggests that the onset time of evoked activity in a population of somatosensory neurons codes for stimulus location, a conclusion confirmed in a later study (Petersen, R. S. *et al.*, 2001).

In the same study, Ghazanfar A. A. *et al.* (2000) parametrically varied the bin widths of neural response histograms between 40 and 1 ms and found that classifier performance was reduced by a small but significant amount when larger bin widths were used. This analysis suggested the importance of temporal patterning of spike trains. On the other hand, when trials were shuffled to eliminate correlated firing among neurons while preserving time-varying firing rates, the discrimination performance was not significantly affected. This suggests that synchronous activity, and cross-correlations more generally, over and above that expected due to stimulus-locked firing rate modulations, do not encode the location of single whisker stimuli. A similar study performed during recording of multiple units in S1 and S2 of monkey found similar results in S1, but found that in S2 stimulus location discrimination was impaired when correlations between neurons were disrupted by shuffling (Nicolelis, M. A. *et al.*, 1998). This suggests that S2 uses a strategy different than S1 for coding the location of point stimuli.

The findings of multiwhisker RFs and distributed stimulus coding are in some tension with the single-whisker modular model of S1 stimulus coding, but do not rule it out. Petersen R. S. *et al.* (2001) have recently noted that the earliest evoked spike after a

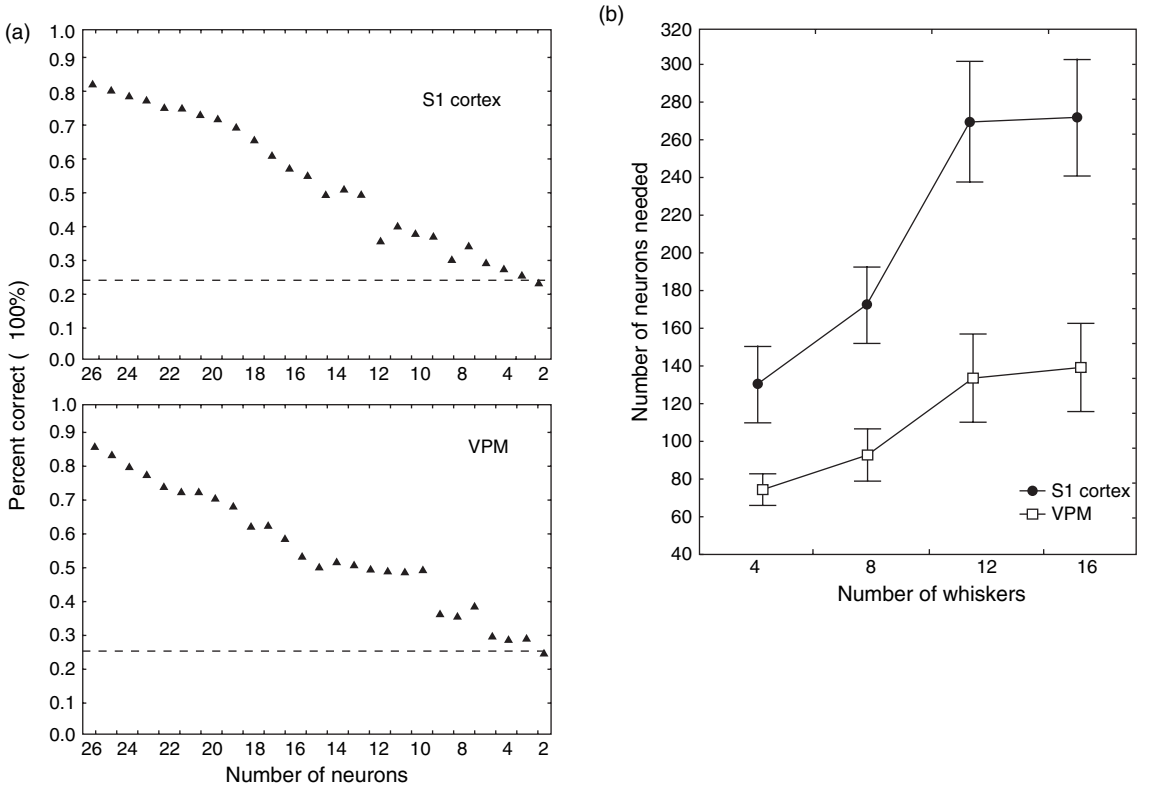

Figure 2 Neuron-dropping analysis suggests a distributed code. (a) Graceful degradation of ensemble performance discriminating four different whiskers after the sequential one-by-one removal of the best predictor neuron from an S1 ensemble (top panel) and a ventral posterior medial nucleus of the thalamus (VPM) ensemble (bottom panel). The dashed line at 25% indicates chance performance. (b) The number of neurons needed within a cortical or a thalamic population to achieve 99.9% correct performance was extrapolated from their average performance discriminating 4, 8, 12, and 16 whiskers. The number of cortical neurons needed to achieve near-perfect performance was approximately twice as many for discriminating 16 versus 4 whiskers (black line). The plateau between 12 and 16 whiskers suggests that the number of neurons needed is not linearly related to the number of classes to be discriminated. From Ghazanfar, A. A., Stambaugh, C. R., *et al.* 2000. Encoding of tactile stimulus location by somatosensory thalamocortical ensembles. J. Neurosci. 20(10), 3761–3775.

single-whisker stimulus contains most of the information about which whisker was stimulated. From this they concluded that later activity, reflecting interactions between different barrels, was largely redundant for neural coding of stimulus identity. In line with a model of barrel columns as single-whisker processing units, Brumberg J. C. *et al.* (1996) proposed that inhibitory circuitry within barrels functions to "increase the 'principal whiskerness' of the cortical column" by suppressing weaker responses so that "only . . . the initial perturbation of the principal whiskers will overcome the . . . cortical inhibition." Mirabella proposed that inhibitory intercolumnar interactions may also function to maintain a dynamic range and to prevent response saturation (Mirabella, G. *et al.*, 2001).

6.15.2.2 Spatiotemporal Receptive Fields Point to Multiwhisker Integration over Time

The finding that multiwhisker RFs are dynamic over poststimulus time (Nicolelis, M. A. and Chapin, J. K., 1994; Ghazanfar, A. A. and Nicolelis, M. A., 1999; Ghazanfar, A. A. *et al.*, 2000) makes it more difficult to interpret neural tactile responses solely in terms of the stimulation of individual whiskers. Ghazanfar A. A. and Nicolelis M. A. (2001) characterized both spatial and temporal aspects of single-neuron responses in VPM and S1 cortex to single-whisker stimulation. A single neuron's responses to deflections of each whisker in a 5×5 spatial array on the face were divided into time bins. The PW, or RF center, at each poststimulus time bin was defined as the whisker that led to the strongest

response at that poststimulus time, leading the generalized notion of a spatiotemporal RF whose center or PW drifts across the whisker pad over poststimulus time.

Similarly, recordings in VPM through multisite chronic microwire arrays revealed VPM neurons whose poststimulus RF center moved over poststimulus time, and others whose RF center was fixed at one whisker (Nicolelis, M. A. and Chapin, J. K., 1994). The dynamic RF centers tended to shift in a caudal-to-rostral direction. In other words, caudal whiskers dominated short-latency responses of these neurons, whereas the response to more rostral whiskers grew large at longer poststimulus times. The neurons with fixed RF centers, on the other hand, invariably had their PW in the rostral part of the whisker pad among the small and immobile vibrissae.

An analogous multielectrode study of layer V S1 neurons in anesthetized rats (Ghazanfar, A. A. and Nicolelis, M. A., 1999) found more heterogeneous spatiotemporal RFs than in VPM. They observed time-dependent RF-center shifts in 88% of these cortical output neurons. In contrast to VPM neurons, the pattern of RF-center shifts varied widely, including rostral-to-caudal, caudal-to-rostral, dorsal-to-ventral, and ventral-to-dorsal trajectories. Moore saw similar poststimulus variation in the center of subthreshold RFs of neurons in all cortical layers using *in vivo* whole-cell recordings in anesthetized rats (Moore, C. I. and Nelson, S. B., 1998).

Ghazanfar reviewed evidence for analogous spatiotemporal RFs in the auditory and visual systems and suggested the hypothesis that tactile spatiotemporal RFs function to integrate time-varying multiwhisker inputs (Ghazanfar, A. A. and Nicolelis, M. A., 2001). The discovery of single-neuron spatiotemporal RFs in which the PW varies over poststimulus time suggests that each neuron will respond maximally to a specific spatiotemporal sequence of whisker deflections. The Ghazanfar study therefore predicted that multiwhisker stimuli constructed to match the spatiotemporal RF of a neuron should evoke supralinear responses (Ghazanfar, A. A. and Nicolelis, M. A., 2001). Such combination selectivity would encode particular temporal sequences of stimulation, as has been shown in the rat auditory system (Irvine, D. R. *et al.*, 1995). In support of this possibility, DiCarlo found that a delayed inhibitory component of the responses of neurons in primate S1 (area 3b) to tactile stimuli scanned across the fingertips was at a different latency for different scanning directions (DiCarlo, J. J. and Johnson, K. O., 2000). This sensitivity to the direction of scanning movements is an example of sensitivity to distributed spatiotemporal patterns of tactile stimulation.

Nicolelis hypothesized that spatiotemporal RFs of tactile neurons at each level arise from the asynchronous convergence of multiple feedforward and feedback pathways (Nicolelis, M. A. and Chapin, J. K., 1994). For example, the short-latency component of VPM RFs would result from the fast ascending lemniscal pathways from the principal and spinal trigeminal brainstem nuclei (which reach VPM at different latencies). The long-latency component could be due to feedback connections from cortical somatosensory areas (Veinante, P. *et al.*, 2000).

These ideas were tested in the Nicolelis lab by combining multielectrode recordings with methods to reversibly inactivate specific afferent inputs and specific sources of descending feedback onto VPM neurons. The contribution of feedforward inputs to VPM spatiotemporal RFs was assessed by temporary deafferentation using subcutaneous infusions of lidocaine, a local anesthetic, into a small region of the whisker pad (Nicolelis, M. A. *et al.*, 1993). The effect of deafferentation was a temporal shift due to the reduction of early components from the anesthetized area, and enhancement of later components, together with a spatial shift of RFs to outside the anesthetized region. The contribution of corticothalamic feedback to spatiotemporal RFs in VPM was assessed by temporarily inactivating the S1 cortex with the gamma-amino butyric acid $(GABA)_A$ agonist muscimol (Krupa, D. J. *et al.*, 1999; Ghazanfar, A. A. *et al.*, 2001). Spatiotemporal RF mapping of VPM neurons in the presence and the absence of cortical feedback revealed that corticofugal projections contributed to both the short and long latency components of VPM responses. These effects likely reflect both direct cortical inputs to VPM and indirect cortical influences via the thalamic reticular nucleus (Lee, S. M. *et al.*, 1994) and the trigeminal brainstem (Jacquin, M. F. *et al.*, 1990).

Subsequent studies addressed whether the development of spatiotemporal RF properties is related to whisking, a fundamental behavior that rats use to explore their environment. This idea was hinted by the above-mentioned finding that fixed PWs of VPM neurons were the small rostral whiskers that are not involved in whisking. To test whether spatiotemporal RFs of VPM neurons reflect the pattern of spatiotemporal inputs that occurs during active whisking over object surfaces, Nicolelis denervated the facial muscles used for whisking by cutting the facial nerve early in postnatal life (Nicolelis, M. A. *et al.*, 1996).

Preventing voluntary whisker movements in this way, which does not affect the sensory innervation of the vibrissae, led to (1) a dramatic reduction in VPM neurons' RF size from 13 to 6 whiskers and (2) a dramatic reduction in the percentage of VPM neurons with caudal short-latency PWs exhibiting time-varying PWs, from 100% in normal animals to 19% in animals whose facial motor nerve had been cut. These results suggest that active whisking plays an important role in sculpting VPM spatiotemporal RFs.

In summary, detailed investigation of single-neuron responses to single-whisker deflections led to the idea that single somatosensory neurons may code for specific spatiotemporal patterns of stimulation of multiple whiskers.

6.15.3 Multiwhisker Stimulation

In general, the large size of somatosensory RFs, and their spatiotemporal structure, suggests significant degrees of functional intercolumnar connectivity, convergence from multiple whiskers, or modulation from other cortical areas. Some authors propose that such interactions lead to redundant activity (Armstrong-James, M., 1995; Petersen, R. S. *et al.*, 2001). In contrast, Simons D. J. (1985) concluded "that an important function of the S1 cortex is to integrate information from different, individual vibrissae on the contralateral face". He suggested that intercolumnar integration functioned to make S1 neurons sensitive to spatiotemporal patterns of whisker activity characterizing the movement of particular objects across the contralateral whisker pad (Simons, D. J., 1985). Experimental findings of spatiotemporal RFs, as reviewed above, and supralinear interactions of multiple whiskers (Ghazanfar, A. A. and Nicolelis, M. A., 1997; Shimegi, S. *et al.*, 2000), as reviewed below, led to a more detailed prediction that single neurons should respond preferentially to the specific time-varying multiwhisker stimulation patterns that match their spatiotemporal RFs (Ghazanfar, A. A. and Nicolelis, M. A., 2001).

Direct measurements of spatiotemporal integration of multiwhisker inputs in the rat whisker system have found evidence of both inhibitory and excitatory interactions. Extra- and intracellular studies of S1 responses to combinations of unilateral stimuli found inhibitory interactions dominating between pairs of neighboring whiskers (Simons, D. J., 1985; Brumberg, J. C. *et al.*, 1996; Higley, M. J. and Contreras, D., 2003) at interstimulus intervals (ISIs) of around 10–20 ms. Responses to pairs of synchronous stimuli were found to sum linearly (Simons, D. J. and Carvell, G. E., 1989; Mirabella, G. *et al.*, 2001), whereas Mirabella reported that synchronous stimulation of four whiskers usually resulted in sublinear response summation (Mirabella, G. *et al.*, 2001). These studies focused on responses of neurons in middle and supragranular layers of S1 in immobilized or anesthetized rats.

Using chronic multisite recordings in freely moving rats, Fanselow found comparable temporal interactions of multiple unilateral inputs by neurons in S1 layer V (Fanselow, E. E. and Nicolelis, M. A., 1999). Responses to the second of a pair of unilateral electrical stimulations of the infraorbital (IO) nerve in awake rats were suppressed, with the strongest effect at ISIs of around 25–50 ms. This suppression was most pronounced when rats were in a quiet behavioral state as compared to the whisking and active exploring states. Recent recordings using moveable MEAs in freely moving rats engaged in an active whisker-dependent discrimination task have suggested that inhibitory response modes in all layers are significantly more common in the discriminating animals as compared to passively stimulated animals and moreover that inhibitory response modulations contribute significantly to encoding the behaviorally discriminated tactile feature (Krupa, D. J. *et al.*, 2004). (We will return to discuss these experiments further below.)

However, not all unilateral multiwhisker interactions are inhibitory: synchronous multiple-whisker deflections have also been reported to sum supralinearly. Shimegi S. *et al.* (2000) reported supralinear summation of neighboring single-whisker stimuli in 37% of S1 neurons, primarily by cells in supragranular layers. They noted that enhanced responses were often selective for specific combinations of stimulus features such as whisker position, angle of deflection, and relative timing of multiwhisker stimuli, supporting the idea that S1 cells code for spatiotemporal patterns of whisker stimulation. Ghazanfar found that 81% of units in S1 layer V showed supralinear responses to simultaneous stimulation of triplets of whiskers as compared to single-whisker stimulations (Ghazanfar, A. A. and Nicolelis, M. A., 1997). They reported a bias toward supralinear summation of within-column triplets as compared to within-row triplets. They pointed out that their findings were consistent with the reports of sublinear summation of unilateral stimuli, since sublinear spatial summation was reported in studies of responses to pairs of neighboring whiskers in granular and

supragranular layers, as opposed to the layer V responses to stimulation of triplets of relatively distant whiskers in their study. Together these findings suggest excitatory as well as inhibitory nonlinear interactions among multiple-whisker stimuli, which could encode spatiotemporal patterns of unilateral whisker stimulations.

Combining the methods for inactivating specific neural inputs with ensemble recordings led to a further important conclusion that the integration of multiwhisker stimuli by somatosensory neurons is shaped not only by intrinsic local properties of neurons and their neighbor connections, but also by interactions among multiple levels of the somatosensory system. As mentioned above, Ghazanfar A. A. *et al.* used muscimol to reversibly inactivate the S1 cortex and to evaluate the contribution of corticothalamic feedback projections to the definition of tactile responses in populations of VPM neurons (Ghazanfar, A. A. *et al.*, 2001). S1 inactivation effectively linearized VPM responses, abolishing the supralinear summation of VPM neural responses to multiwhisker stimuli. These results show that the response properties of VPM neurons to multiwhisker stimuli are shaped by corticothalamic feedback from S1. In Section 6.15.6, we review evidence that tactile responses in S1 are similarly shaped by descending inputs when rats are performing a whisker-guided discrimination task.

6.15.3.1 Bilateral Interactions

All the studies mentioned above have in common that neural activity in the whisker cortex (or VPM barreloid field) is interpreted as a topographic map of whisker deflections exclusively on the contralateral whisker pad. This picture is overly restrictive. It has long been known that callosal cross-projections connect the two S1 hemispheres (White, E. L. and DeAmicis, R. A., 1977; Olavarria, J. *et al.*, 1984; Koralek, K. A. *et al.*, 1990; Cauller, L. J. *et al.*, 1998). Interhemispheric projections are concentrated in the homologous portions of the barrel field, innervating primarily but not exclusively the supra- and infragranular layers (Hayama, T. and Ogawa, H., 1997). Those callosal connections that do innervate layer IV are concentrated in the regions outside the barrel centers, called septa (Olavarria, J. *et al.*, 1984; Hayama, T. and Ogawa, H., 1997), as are unilateral interbarrel connections in layer IV (Kim, U. and Ebner, F. F., 1999).

One potential function of the commissural interhemispheric connections is to transfer learned associations from one hemisphere to the other (Ebner, F. F. and Myers, R. E., 1962; Calford, M. B. and Tweedale, R., 1990). Such transfer of plasticity on relatively long timescales might be assumed to preserve the unambiguous representation of the contralateral whisker pad in each S1 hemisphere implied by the traditional models mentioned above.

However, growing evidence points to robust synaptic interactions between the S1 hemispheres on millisecond timescales. Pidoux B. and Verley R. (1979) recorded S1 local field potential (LFP) responses to ipsilateral whisker stimulation in anesthetized rats, the first electrophysiological evidence of cross talk between the S1 hemispheres. Shuler, M. G. *et al.*, (2001) used bilateral MEA recordings to demonstrate that whisker stimulation on either side of the face of an anesthetized rat could evoke responses in the same layer V S1 neuron. This result has been recently confirmed by intracellular recordings (Manns, I. D. *et al.*, 2004). By reversibly inactivating individual hemispheres of S1 using micro infusion of the $GABA_A$ agonist muscimol, Shuler also showed that S1 single-neuron responses to ipsilateral whisker deflection likely propagate across the corpus callosum from the contralateral S1 hemisphere where neurons receive the primary afferent sensory signal from the whisker pad (Shuler, M. G. *et al.*, 2001). Other studies have shown that the responses of individual neurons in S1 are suppressed in the absence of activity in the contralateral hemisphere (Shin, H. C. *et al.*, 1997). Rema V. and Ebner F. F. (2003) found similar response suppression as well as changes in whisker-pairing plasticity in all layers, due to contralateral lesions.

Following Shuler M. G. *et al.* (2001), Wiest used bilateral multielectrode recordings of layer V S1 neurons to characterize responses to bilateral whisker stimulation in head-immobilized awake rats (Wiest, M. C. *et al.*, 2005). This study revealed that S1 neurons continue to respond to bilateral whisker stimuli in the awake state (Figure 3(a)). S1 neurons integrated bilateral inputs over more than 100 ms, with suppressive interactions dominating at ISIs of about 30 ms, in agreement with recordings in anesthetized rats. As in the anesthetized state, responses to ipsilateral whisker stimulation tended to appear at longer latencies than contralateral responses (24 vs. 15 ms), consistent with the afferent ipsilateral input's propagation across the corpus callosum from the contralateral to the ipsilateral S1 hemisphere.

In anesthetized rats the contralateral stimulus universally suppressed the responses to simultaneously presented ipsilateral stimuli. This is understandable

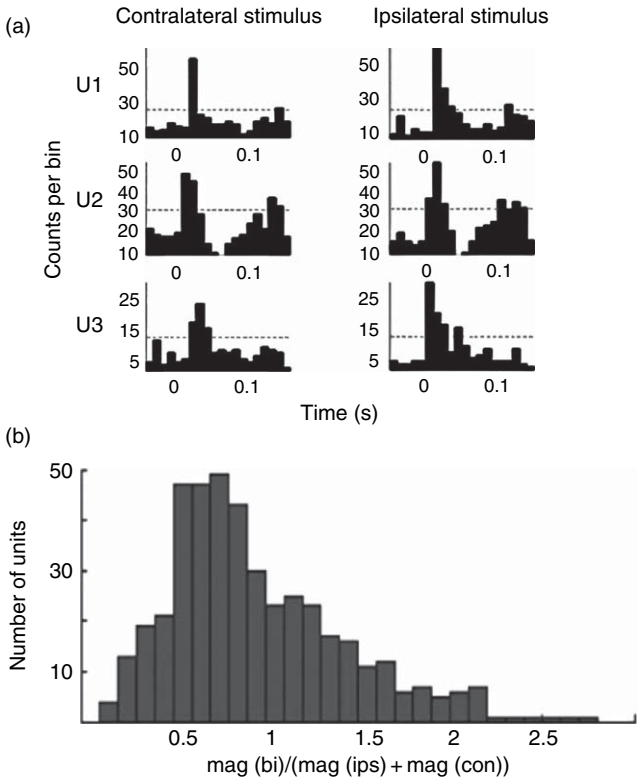

Figure 3 S1 neurons in awake rats integrate bilateral whisker inputs. (a) Example of a single-unit responses to whisker stimulation on either side of the face. Each row shows poststimulus time histograms (PSTHs, 10 ms bins) of one layer V single unit to contralateral (left column) and ipsilateral (right column) whisker stimulation at $t = 0$. Dashed lines show the 99% confidence limit for the spike counts based on the prestimulus baseline firing rate. (b) Histogram of the ratio of multiunit response magnitudes to simultaneous bilateral whisker stimulation over the sum of contralateral and ipsilateral response magnitudes. A ratio >1 indicates supralinear summation of the two whisker arc stimuli; a ratio <1 indicates sublinear summation of bilateral inputs. In contrast to bilateral interactions in anesthetized rats (Shuler, M. G. *et al.*, 2001), which are exclusively sublinear, many units summed bilateral inputs supralinearly in awake S1 rats. Adapted from Wiest, M. C., Bentley, N., *et al.* 2005. Heterogeneous integration of bilateral whisker signals by neurons in primary somatosensory cortex of awake rats. J. Neurophysiol. 93(5), 2966–2973.

since the latency for the contralateral response is shorter, so the ipsilateral excitatory response can be suppressed before it occurs by the inhibitory phase of the contralateral response. In contrast, in the awake rats many individual units showed significant supralinear spatial summation as well as sublinear summation of synchronous bilateral inputs (Figure 3(b)). This difference suggests that the profile of excitatory and inhibitory contributions to ongoing S1 responses to bilateral stimuli is substantially altered in the anesthetized animal. The heterogeneity of responses we observed in the awake animals could function to enhance discrimination of multiwhisker patterns of whisker stimulation (Maass, W. *et al.*, 2002).

The cross talk between S1 hemispheres observed in both anesthetized and waking animals, as reviewed above, challenges the conception of the S1 barrel cortex as an encoder for exclusively contralateral whisker activity and suggests the potential importance of bilateral interactions in S1 for whisker-guided behavior.

We do not know yet whether neural activity in one hemisphere of S1 could interfere with stimulus representations in the contralateral S1, or if in some behavioral contexts, rats can make positive use of bilateral interactions in S1 to solve tactile discrimination tasks. Previous behavioral experiments have demonstrated that rats use whisker signals from both sides of the face in tactile discrimination tasks (Krupa, D. J. *et al.*, 2001; Maass, W. *et al.*, 2002; Shuler, M. G. *et al.*, 2002). In fact, rats used bilateral whisker signals even in an aperture-width discrimination task that in principle could be solved without integrating information from both sides of the face

(Oliveira, L. M. *et al.*, 2003; Krupa, D. J. *et al.*, 2004), suggesting that bilateral interactions are functionally important. S1 is the first locus of bilateral interactions (Waite, P. M., 1969; Smith, R. L., 1973; Erzurumlu, R. S. and Killackey, H. P., 1980). Accordingly, Shuler M. G. *et al.* (2002) found that intact S1 cortex in both hemispheres was required for successful performance of a bilateral tactile discrimination task. These connections between the S1 hemispheres are fully functional in awake rats (Wiest, M. C. *et al.*, 2005), suggesting that S1 is a potential site of bilateral integration used by the animals for discrimination performance, rather than merely a conduit for sensory information that is integrated at higher processing stages.

Just as the variety of cortical spatiotemporal RFs suggested a basis for discriminating different spatiotemporal patterns of unilateral multiwhisker stimulation, the heterogeneity of bilateral interactions in S1 neurons might provide the basis for discriminating different spatiotemporal patterns of bilateral whisker stimulation.

Over longer timescales, if a rat's different behavioral goals require attention to different aspects of the bilateral pattern of whisker deflections, integration may be optimized (see also Sections 6.15.5. and 6.15.6. below) by changes in the functional connectivity between the hemispheres. Studying bilateral integration of whisker sensory signals in S1 may offer an advantageous window on the larger issue of the dynamic integration of distributed sensory representations, because the peripheral signals to be integrated are clearly segregated in space and may be independently manipulated up to the level of the S1 cortex, and so it may be possible to gain experimental access to the brain's mechanisms for adjusting the functional connectivity between neural populations in the two hemispheres.

6.15.4 Coordinated Firing of Simultaneously Recorded Neurons

In the past 30 years, correlated activity among neurons has received a great deal of attention for its potential role in the binding of sensory features into complex objects and scenes (Singer, W., 1999), motor coordination (Sanes, J. N. and Truccolo, W., 2003), and attention (Tiesinga, P. H. *et al.*, 2004). The only way to empirically determine the extent of such correlations is by recording the responses of multiple neurons simultaneously. We have already touched on the role of temporal patterning across multiple neurons in the context of coding the location of single-whisker stimuli. In that context it was found that S1 ensembles code stimulus location in the relative response latencies of their neurons, but not in single-trial covariations among the neurons (Nicolelis, M. A. *et al.*, 1998; Ghazanfar, A. A. *et al.*, 2000). In S2 of the primate, on the other hand, single-trial covariations among multiple neurons did contribute significantly to coding the location of a punctate stimulus (Nicolelis, M. A. *et al.*, 1998; Ghazanfar, A. A. *et al.*, 2000).

It seems theoretically plausible that the importance of such correlated activity among populations of neurons should increase when more complex spatiotemporal patterns of multiwhisker deflections are to be discriminated. While the investigation of the functional role of correlated firing in somatosensory behavior is still at an early stage, there is some empirical support for this idea. For example, it was recently shown that, in response to the simultaneous deflection of multiple whiskers, there is a higher prevalence of synchronous responses between neurons in the infragranular layers of S1 than in other layers (Boyden, E. S. *et al.*, 2005; Zhang, M. and Alloway, K. D., 2006). Even if such synchrony does not mathematically improve stimulus discrimination using local ensemble activity, it might be more likely to generate responses in downstream neurons (Tiesinga, P. H. *et al.*, 2004). Ahrens K. F. and Kleinfeld D. (2004) showed that activity in S1 is correlated with large-amplitude whisking even after the sectioning of the infraorbital nerve (IO), suggesting close coordination with activity in the motor cortex (the IO nerve is a branch of the trigeminal nerve that carries sensory information from the vibrissae to the CNS).

Another set of studies has recorded synchronous activity among ensembles of neurons at multiple levels of the lemniscal pathway, recording from the spinal trigeminal nucleus in the brainstem (Vg), VPM, and S1. It was found that, before bouts of high-frequency low-amplitude whisker twitching, correlated activity in the range of 7–12 Hz began in S1 and then emerged in VPM and the spinal nucleus (Nicolelis, M. A. *et al.*, 1995). Such correlated activity remains even after the transection of the facial nerve, which suggests that such synchronous activity is generated centrally. Although the high coherence among large populations of neurons associated with this oscillatory 7–12 Hz brain state suggested the absence of seizures to a number of authors (Marescaux, C. *et al.*, 1992; Shaw, F. Z. *et al.*, 2006; Shaw, F. Z., 2007), a direct test showed that rats respond robustly to mild tactile stimulation during bouts of 7–12 Hz oscillations in S1, contradicting the absence

of interpretation (Wiest, M. C. and Nicolelis, M. A., 2003). Subsequent work showed that under analogous oscillatory activity in the gustatory cortex, the neural representation of the tastant palatability was actually enhanced (Fontanini, A. and Katz, D. B., 2006).

Recent multielectrode recordings in the primary auditory cortex during somatosensory stimulation (Lakatos, P. *et al.*, 2007) support the general idea that oscillatory activity could modulate neural coding in functionally important ways. These authors reported that somatosensory stimulation resets the phase of ongoing oscillatory activity in the auditory cortex, such that responses to synchronous auditory stimulation were enhanced whereas responses to asynchronous auditory stimuli were suppressed. They suggested that this oscillatory phase-resetting effect could account for aspects of auditory–somatosensory integration psychophysics.

Finally, results in Section 6.15.5., suggest that long-term plasticity between cortical barrels in S1 can be induced more easily during bouts of synchronous firing (Erchova, I. A. and Diamond, M. E., 2004).

6.15.5 Plasticity

The primary somatosensory cortex is not a static entity whose functional role is fixed after a critical developmental period. Rather, a range of experiments suggests that the cortex is organized to adaptively adjust its responses to the statistical structure of inputs received as well as to the specific demands that an organism faces (as was hypothesized in Gilbert, C. D., 1996; Buonomano, D. V. and Merzenich, M. M., 1998; Plumbley, M. D., 1999; Calford, M. B., 2002; Elbert, T. and Rockstroh, B., 2004). The somatosensory system has been a font of insight into the phenomenology and mechanisms of such neuronal plasticity (we define plasticity as the induction of long-term changes in anatomy, topographic maps, or response properties of neurons). For a review, see Ebner F. (2005).

We will focus mainly on studies that have employed multielectrode recordings to monitor plasticity in the adult primary somatosensory cortex (for a review of plasticity during development, see Feldman, D. E. and Brecht, M., 2005). Studies of adult plasticity typically fall into two categories: first, plasticity induced by directly modifying the inputs from the periphery and second, plasticity induced by operant conditioning on discrimination tasks. We will discuss these two lines of evidence in turn.

6.15.5.1 Modified Inputs

The organization of the somatosensory cortex can be drastically altered when the inputs from the periphery are modified (Gilbert, C. D. *et al.*, 2001). In a classic study, the inputs to the palm of one hand in monkeys were removed by transection of the median nerve (Merzenich, M. M. *et al.*, 1983a). This removal of inputs induced drastic changes in the topographic map of the corresponding region of S1: single-unit mapping of cortical RFs showed that the representation of adjoining regions of the hand expanded and filled in the space in the deafferented region (Merzenich, M. M. *et al.*, 1983a). Such topographic plasticity has been extensively investigated in the barrel cortex of rats following whisker removal (Fox, K. *et al.*, 2000; Feldman, D. E. and Brecht, M., 2005). For example, when all but two adjacent whiskers were clipped, many neurons in the two corresponding barrels exhibited long-lasting enhanced responses to both whiskers (Diamond, M. E. *et al.*, 1993). Interestingly, a follow-up study showed that when pairs of adjacent whiskers were mechanically costimulated (Erchova, I. A. and Diamond, M. E., 2004), the induction of the two-whisker RF plasticity was seen only when the stimulation was delivered during peaks in synchronous bursts across S1 (Erchova, I. A. and Diamond, M. E., 2004).

While it takes months for cortical maps to stabilize following deafferentation (Merzenich, M. M. *et al.*, 1983a; 1983b), such reorganization is probably initiated by a series of events that takes place immediately after deafferentation (Calford, M. B., 2002). Merzenich M. M. *et al.* (1983a; 1983b) examined RFs of individual neurons in the somatotopic map corresponding to deafferented regions of the hand. Many RFs from other regions of the hand were unmasked, often at a similar location on the digit but on the other side of the hand. Similarly, reversibly interrupting localized inputs from the mystacial pad of the rat with local anesthesia result in immediate unmasking of RFs in the brainstem spinal trigeminal nucleus (SpV), VPM, and S1 (Faggin, B. M. *et al.*, 1997). Such immediate changes, too rapid to be brought about by anatomical reorganization of cortical circuitry, are likely induced via a release from inhibitory effects of interneurons that were previously tonically activated by the anesthetized mystacial region (Moore, C. I. *et al.*, 1999).

The series of steps between deafferentation and stabilization of the new somatotopic map are presently being elucidated with the help of

multielectrode recordings. For instance, in one study, researchers recorded from layers II/III and layer IV neurons in single S1 columns in anesthetized rats before and after the removal of PW of that column (Celikel, T. *et al.*, 2004). They found that after such removal, the number of evoked spikes when all uncut whiskers were stimulated remained unchanged, but the order of firing in layers IV and II/III was reversed, such that layer IV neurons tended to fire after supragranular neurons (Celikel, T. *et al.*, 2004). This suggests that deprivation-induced changes in the topographic map are partly caused by spike-timing-dependent plasticity, a hypothesis that has been supported by subsequent studies (Bender, K. J. *et al.*, 2006; Jacob, V. *et al.*, 2007).

6.15.5.2 Operant Conditioning

Task-dependent plasticity has been observed in multiple modalities and species (Calford, M. B., 2002). In a classic study in monkeys, the area of the somatosensory cortical representation was increased specifically for those fingers the monkey used to perform a flutter-vibration discrimination task, and these neurons had smaller RFs when compared with the neurons in untrained digits (Recanzone, G. H. *et al.*, 1992). This plasticity was not observed in VPM, suggesting a cortical origin (Wang, X. *et al.*, 1995). In a particularly noteworthy study, a 7×7 MEA was chronically implanted in the hand representation in S1 of monkeys (area 3b) such that the electrodes sampled from regions corresponded to the two digits used in the discrimination task (Blake, D. T. *et al.*, 2005). Initially, none of the units' RFs included both digits, but during the initial month of training, 40% of the neurons acquired RFs that included responses to the two digits used to perform the task.

Another study revealed interesting functional consequences of the topographic organization of the representation of the whiskers in S1 (Harris, J. A. *et al.*, 1999; Blake, D. T. *et al.*, 2005). Researchers first trained rats to perform a gap-crossing task with a single intact whisker (in the gap-crossing tasks, rats are trained to leap across a gap between two platforms when they contact the target platform with their whiskers). After that single whisker was cut, the rats were able to relearn the task when researchers attached a prosthetic whisker attached to a single whisker stub. Interestingly, the time the rats took to relearn the task increased with the distance between the prosthetic whisker and the original whisker used to learn the task. In a second group of rats, they recorded from S1 in rats with 100 electrode arrays and found that the relearning speed was highly correlated with the degree of overlap between the cortical representation of the original whisker and the prosthetic whisker (Blake, D. T. *et al.*, 2005).

6.15.6 Behavioral Modulation of Tactile Responses

It is important to note that the localist or the labeled line approach and the distributed approach to somatosensory coding sketched above need not be mutually exclusive, but could reflect different processing strategies appropriate in different behavioral contexts. Previous studies have shown that S1 is not a simple recorder of events that occur on the periphery, but is modulated by the behavioral state of the animal (Nelson, R. J., 1996). This has also been observed in the rat whisker system where different S1 responses are observed in the quiet waking state as compared to the whisking state (Fanselow, E. E. and Nicolelis, M. A., 1999; Moore, C. I. *et al.*, 1999; Nicolelis, M. A. and Fanselow, E. E., 2002a; 2002b; Castro-Alamancos, M. A., 2004; Moore, C. I., 2004).

By measuring neuronal tactile responses during clearly distinguishable behavioral states, Fanselow E. E. *et al.* (2001) showed that the response properties of S1 and VPM neurons depend strongly on a rat's behavioral state (Fanselow, E. E. and Nicolelis, M. A., 1999; Nicolelis, M. A. and Fanselow, E. E., 2002a; 2002b). In one set of experiments, a nerve cuff electrode was used to stimulate the IO nerve. Individual stimuli were delivered to freely behaving rats, and the cortical and thalamic sensory responses produced when the rats were not moving their whiskers were compared to those observed during periods when the animals were engaged in four different types of behaviors (during quiet immobility, large-amplitude low-frequency whisking, and small-amplitude high-frequency whisker twitching). Overall, the magnitudes of the neural responses in S1 and VPM neurons were significantly reduced during whisker movements. This was not the case when there was motor activity that did not include the whiskers (e.g., movement of the head or the body) or during the period of quiet immobility. This corroborates work in cats (Coulter, J. D., 1974) and in humans (Schmidt, R. F. *et al.*, 1990a; 1990b).

Nicolelis M. A. and Fanselow E. E. (2002) proposed that greater response magnitudes during the quiet state could perform a gross detection function, and the decreased adaptation during the whisking state

would allow for better discrimination of stimuli with a dynamic spatiotemporal structure. Based on the finding that the area of the cortex activated by the stimulation of a vibrissa is relatively smaller during whisking than during an isolated passive contact, some authors have further speculated that a more spatially focused sensory representation during whisking could improve tactile discrimination (Moore, C. I. *et al.*, 1999; Castro-Alamancos, M. A., 2004; Moore, C. I., 2004).

Another study recorded the activity of ensembles of S1 neurons when performing a tactile discrimination task (Krupa, D. J. *et al.*, 2004). In this task, rats learned to behaviorally discriminate between a wide and a narrow aperture width using only their whiskers as sensors (Figures 4(a) and 4(b); see also Krupa, D. J. *et al.*, 2001). By recording from populations of S1 neurons at different cortical depths in the whisker representation, they found that populations

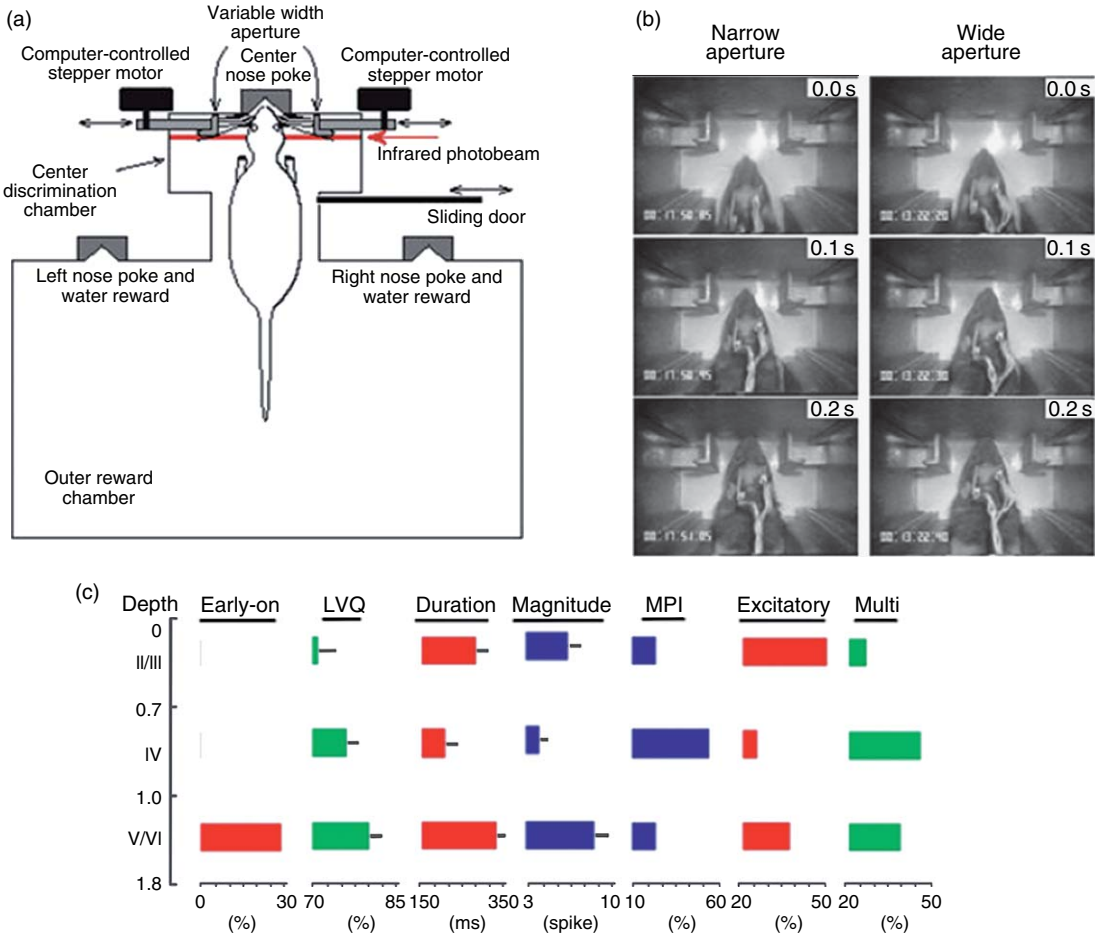

Figure 4 S1 single-unit responses during a freely moving tactile aperture-width discrimination task. (a) Schematic of the behavioral task. Trials begin when a sliding door into the discrimination chamber opens. Rats then sample the variable width aperture with their whiskers and retreat to the left for reward if the aperture was narrow (60 mm) and to the right if the aperture was wide (68 mm). (b) Video frame captures over a 0.2 s period showing a rat approaching and sampling the narrow and wide apertures (left and right panels). (c) Summary diagram showing salient response properties of neurons in different layers of S1. The vertical axis measures recording depth in millimeters. Early-on: percentage of units showing early-onset responses that begin before whisker stimulation; *LVQ:* mean (SEM) wide versus narrow categorization performance of an artificial neural network using population neural activities recorded at different depths. Duration: mean (SEM) excitatory response duration. Magnitude: mean (SEM) magnitude of excitatory responses. MPI: distribution of units with multiphasic responses that began with an inhibitory phase. Excitatory: percentage of units with excitatory responses. Multi: percentage of multiphasic responses. The difference between responses during the active discrimination and responses to passive whisker stimulation (not shown) could not be attributed to differences in the stimuli, suggesting that top-down inputs to S1 sculpt the active discrimination responses. LVQ, learning vector quantization; MPI, multiphasic inhibitory. Adapted from Krupa, D. J., Wiest, M. C., *et al.* 2004. Layer-specific somatosensory cortical activation during active tactile discrimination. Science 304(5679), 1989–1992.

of infragranular neurons encoded aperture width better than the granular and supragranular layers (Figure 4(c), learning vector quantization (LVQ) column), where encoding was quantified using percent correct of a classification algorithm as discussed above in the section on location coding.

In the same study, Krupa D. J. *et al.* (2004) examined the effects of performing the active task on S1 neurons by delivering physically similar stimuli to both anesthetized and awake head-fixed rats. The study demonstrated several differences between S1 responses in the active versus the passive context. First, during active discrimination, S1 neurons produced longer-duration responses (lasting hundreds of milliseconds) of much higher magnitude. Second, a much higher percentage of inhibitory S1 tactile responses was seen when performing the aperture-width discrimination task (49% inhibitory responses vs. 7% during passive stimulation). Third, a novel functional class of S1 neurons was observed during the execution of this task: 30% of infragranular neurons exhibited profound modulation of their firing rate several hundred milliseconds before the animal's whiskers contacted the discriminandum. These anticipatory firing modulations could involve either an increase or a decrease in firing rate, or both. Figure 4(c) summarizes S1 response properties during active tactile discrimination at different cortical depths.

Multiple lines of evidence support the conclusion that these differences between active and passive neural responses are due to top-down modulation of S1 rather than the result of differences in the stimulus itself (see online supplement for Krupa, D. J. *et al.*, 2004). For example, anticipatory firing modulations obviously cannot be accounted for in terms of bottom-up stimulus-driven responses. Similarly, recordings in the peripheral trigeminal ganglion during the active discrimination task show short-duration neural responses (unpublished data), suggesting that long-duration responses at the cortical level are not stimulus-driven. As activity in S1 is modulated by the phase within the whisking cycle and by M1 activity, M1 is a candidate source of top-down inputs (Ahrens, K. F. and Kleinfeld, D., 2004). S2 represents another potential source of contextual modulation of S1 responses (Jackson, M. E. and Cauller, L. J., 1998). The contribution of these and other candidate top-down inputs to S1 may be quantified by combining reversible inactivation of specific candidate areas with multielectrode recordings when performing the tactile discrimination task.

6.15.7 Conclusion and Outlook

We have reviewed recent progress in somatosensory neurophysiology with an emphasis on chronic multielectrode recordings in the rat whisker system. The results suggest that as the typical experimental paradigm shifts from studies of single-whisker stimulus coding in a neutral behavioral context towards more complex stimuli and more active behavioral states, the neural representation of tactile stimuli shifts towards more dynamic and distributed codes. In fact, neural responses within the primary thalamocortical loop, even to simple whisker stimuli, are widely distributed across the two hemispheres. Moreover, the results of reversibly inactivating S1 while recording in VPM showed that thalamic tactile response properties are partly determined by descending feedback from S1, supporting the idea that tactile responses in general reflect the asynchronous convergence of inputs from multiple levels of the somatosensory system. Finally, we found that the importance of the relative timing of responses among neurons tends to increase with the number of whiskers stimulated. Achieving these results was greatly facilitated by multielectrode recording methods – and the last result is currently not attainable in any other way.

The other major shift in our understanding of the somatosensory system came as neurophysiologists found that the functional organization of the somatosensory system was plastic on increasingly fast timescales, down to milliseconds. The evidence that principles of somatosensory coding depend strongly on the behavioral state of the rat, together with observations of task-related plasticity, suggests that the rat's brain adjusts its functional architecture to optimize the performance in different behavioral contexts. This hypothesis provides a framework for interpreting changes in tactile responses in varying contexts and will be most naturally explored and tested using simultaneous recordings of neurons distributed across multiple brain areas involved in somatosensory behavior.

Multielectrode, behavioral, pharmacological, and quantitative methods have evolved to the point where we can now effectively test these ideas about somatosensory coding by neuronal ensembles in the awake-behaving rat. Technical improvements in three directions will facilitate the discovery of the neuronal underpinnings of somatosensory behavior. First, more fine-grained circuit analysis techniques

will reveal specific cell-types, their precise locations, geometry, and channel distributions, leading to refinements of biologically realistic models of the specific transformations being carried out by the somatosensory system. Markram H. (2006) discusses a research program along these lines.

Second, techniques to evoke neuronal activity in precise spatiotemporal patterns will shed light on the effects of such perturbations on downstream networks and behavior. Recent advances in such techniques are discussed in Boyden E. S. *et al.* (2005). Third, as the focus of somatosensory electrophysiology shifts to questions of somatosensory function in awake-behaving animals, behavioral methods will assume increasing importance. For example, advances in whisker sensory physiology will likely follow improvements in our ability to monitor whisker movements using optoelectronic whisker monitoring (Bermejo, R. *et al.*, 1998), video analysis (Knutsen, P. M. *et al.*, 2005), and physical modeling of whisker dynamics (Hartmann, M. J. *et al.*, 2003).

These and related advances will allow experimenters to determine the limits and mechanisms of the fast representational flexibility observed in the mammalian somatosensory system as a result of the past 25 years of multielectrode recordings.

Glossary

endomechanosensory Tactile specializations in certain areas within the skin.

follicle-sinus complex (F-SC) The mechanosensory apparatus found in the follicles at the base of vibrissae and other hairs.

oripulation Working with objects in the environment using lips and other perioral tissues.

ringwulst A dense collar of connective tissue that in many mammals is seen inside the ring sinus portion of the blood sinus around the follicles of vibrissae.

telemechanosensory Apparatus for achieving tactile sensation at some distance from the main body mass.

vibrissa A stiff hair that serves as a tactile organ.

6.16.1 Introduction

By way of introducing the contents of this chapter, a bit of deconstruction of the chapter title will help. Specialized means something is other than the usual, and has a unique character or identity. Somatosensory refers to a group of sensory modalities that are found over wide extensive regions of the body, and is nearly coterminous with general, meaning not special, sensation. So specialized somatosensory is something of a two-word oxymoron. We will take advantage of this inherent self-contradiction to make use of several different meanings of specialized.

The general run of somatosensory modalities respond to mechanical displacement of body tissue, so one kind of specialized somatosensations can be those that respond to stimuli other than mechanical displacement. One of these, the sensation of pain, is sufficiently widespread and important that it is allotted a volume of its own in this series.

Another modality, taste, has long been classified as a special sense since in humans the sensory surface is concentrated in a particular location, as are the organs of the other special senses. Studies of fishes have shown, however, that it could as well be regarded as a general rather than a special sense spread over widespread bodily regions with its receptors intermingled with those of painful and mechanosensory modalities. This topic shares a separate volume in the series with the olfactory sense.

A third traditional somatosensory modality is that of temperature, yielding sensations of heat and cold to stimulation by changing the thermodynamic flow of thermal energy in bodily tissues.

A fourth and newly recognized modality is that of electroreception, which in one of its manifestations in the mammalian monotremes shares receptor locations and neural pathways with the mechanosensory, nociceptive, gustatory, and temperature-sensing systems.

We will begin our treatment of specialized somatosensory systems by reviewing the last two of these widespread receptor modalities, thermoreception and electroreception, which share the somatosensory neural pathways with those of mechanoreceptors, but which are not represented elsewhere in this series of volumes.

Following this we will consider the varieties of unusually organized groups of mechanosensory receptors and pathways that have arisen in the course of chordate evolution. The topic of somatosensation in invertebrates is covered in another volume in this series.

6.16.2 Thermal Sensory Systems

Among the vertebrates, there are two sensory systems that respond to different states of temperature, and particularly, to changes in the temperature of objects in the vicinity of the thermal receptors. One of these systems – that of the cold sensors – responds to loss of heat energy to other objects in the near environment, and to changes in the rate of that loss. The second, less extensive – the warmth-sensing system – responds to the gain of heat from objects that are warmer than the receptive tissues.

The cold and warm systems have different receptors, and activate different pathways within the overall somatosensory pathways to and through the central nervous system. More is known about the cold-sensing system, because it is more widespread in the body and includes several times more cells and fibers than does the warmth-sensing system.

6.16.2.1 Receptor Structure and Function

This account is based mostly on Hensel H. (Hensel, H. *et al.*, 1974; Hensel, H., 1981), with a few later additions cited individually. Both cold and warm receptors are located in unencapsulated free nerve endings, as are the pain and many mechanosensory receptors (Figure 1). The nerve endings are the terminals of small myelinated (A-delta) and unmyelinated (C) fibers. As judged by conduction velocities, all of the warmth-sensitive fibers are believed to be unmyelinated, while there is evidence that cold-sensitive fibers include both myelinated and unmyelinated types.

Some of the cold-sensitive fibers, and possibly some of the warmth-sensitive fibers as well, also respond to painful stimulation with no concurrent change in temperature. Others respond only to changes in temperature. This has led to classifications of receptive endings and fibers as innocuous cold and innocuous warm in contrast to nociceptive cold and nociceptive warm. No innocuous cold and warm endings and fibers have been identified.

In the cellular slime mold amoebas *Dictyostelium discoideum* (Darcy, P. K. *et al.*, 1994), changes in cyclic guanosine monophosphate (cGMP) levels occur in response to thermal stimulation. This finding suggested speculation that transduction processes in thermal receptors may in some ways be analogous to the transduction processes in visual receptors, where a chain of molecular and enzymatic effects brought about by

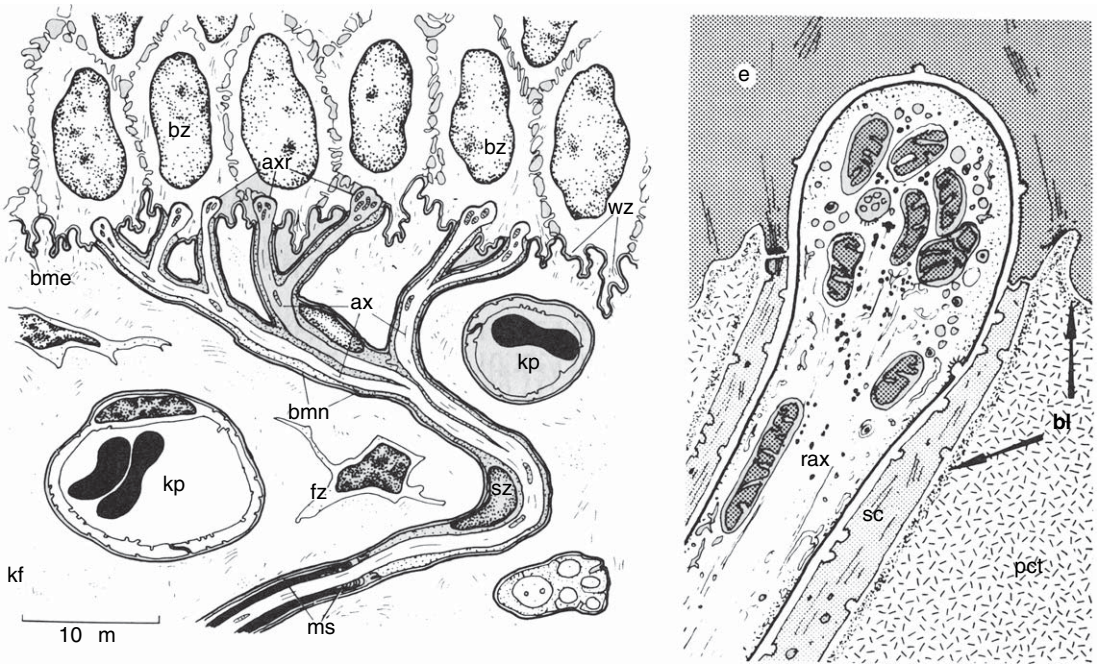

Figure 1 Left: Semischematic diagram of nerve endings at the site of an electrophysiologically identified cold receptor in the hairy skin of the cat nose. ms, myelin sheath of afferent nerve fiber; sz, nonmyelinated Schwann cell accompanying terminal axons (ax) to the basement membrane (bme) of epidermis; bmn, basement membrane of nerve terminals; axr, receptive endings with mitochondria; bz, basal epidermal cells; wz, root feet of basal cells; kp, capillaries; fz, fibrocyte; kf, collagen fibrils of stratum papillare. Right: Schematic representation of a cold receptor axon. The terminal protrudes into a basal epidermal cell. The typical structures of the receptor matrix are present below the receptor membrane. rax, receptor axon;sc, Schwann cell; e, epidermis; pct, papillary connective tissue; bl, basal lamina. Reproduced from Pflügers Arch., Vol. 352, 1974, 1–10, Structure and function of cold receptors, Hensel, H., Andres, K. H. and Düring, M. von., figure 6, with kind permission of Springer Science and Buisness Media. and figure 4.2 in Hensel, H. 1981. Thermoreception and temperature regulation. Monogr. Physiol. Soc. 38, 1–321.

photic stimulation results in changes in cGMP levels that are involved in the initiation of neuronal activity.

More closely related to the actual transduction process, genetic analysis of molecular structure has identified a set of receptor membrane channels known as transient receptor potential (TRP) channels. These channels play a role in the neural activation of receptor cells in a great variety of sensory modalities, and understanding of their function is advanced in the cases of temperature and pain sensation. The subdivision of somatic sensation through free nerve endings may soon be revealed as a graded distribution of the sensitivities of various TRP channels, in the membranes of receptive endings, to restricted ranges of ambient temperatures. These observed ranges fill in the range of perceptible temperature changes, and nociceptive results are obtained by activations beyond these restricted ranges at both the hot and cold ends of the range. Before long we may see a reunification of the separate modalities of heat, cold, pain, and mechanical sensation into a common somatic sensory modality with gradations based on TRP channels of graded sensitivities.

The TRP channels, when activated by their appropriate range of temperature change or other environmental alteration, open to permit the flow of calcium and magnesium through the membrane of the receptive ending. Many contemporary reviews describe the history and details of this developing science of temperature, pain, and mechanical sensation (McKemy, D. D. *et al.*, 2002; Jordt, S.-E. *et al.*, 2003; Patapoutian, A. *et al.*, 2003; Voets, T. *et al.*, 2004; Caterina, M. J. and Montell, C., 2005; Voets, T. *et al.*, 2005; Montell, C., 2006).

6.16.2.2 Location

Based on reaction times to application of cold and warm stimuli, it appears that cold receptive endings in the skin are located immediately below the

epidermis, while warm receptive endings are found deeper, in the upper layers of the corium. In any given region, cold, warm, and nociceptive endings are found, but within a region there are distinct cold and warm spots.

6.16.2.3 Pathways to and through the Central Nervous System

Both cold and warm fibers, along with many nociceptive and mechanosensitive fibers, terminate in the outermost layer of spinal and medullary dorsal horns, in the marginal lamina (Lamina 1 of Rexed). For all of these modalities there are fibers of marginal lamina cells, which project to the ventroposterolateral (VPL) thalamic nucleus in a somatotopic order. In rats there is a distinctive region within VPL that responds only to cold stimulation through a special group of cold-sensory second-order axons of marginal lamina cells (Zhang, X. *et al.*, 2006). Cells of VPL in many and possibly all mammalian species project to parietal regions of the cerebral cortex.

Functional magnetic resonance imaging (fMRI) study has shown the cortex of the superior parietal lobule and other brain regions responding to stimulation by thermal stimuli, which is perceived by human subjects as being warm or cold. These regions include the insular and orbitofrontal regions of the cerebral cortex (Hua, L. H. *et al.*, 2005; Craig, A. D. *et al.*, 2006) (Figure 2).

6.16.2.4 Heat-Sensory Pit Organs of Snakes

Snakes of the subfamily Crotalinae (Viperidae), and others of the family Boidae, possess concentrations of warm receptors in special organs known as pits, depressions between the scales on the face between the eyes,

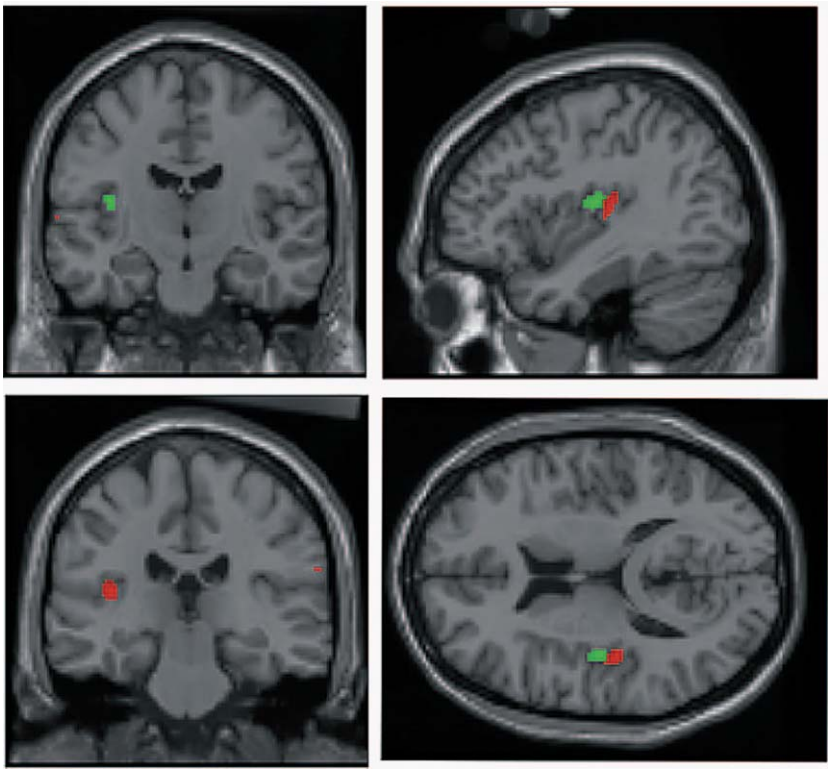

Figure 2 Somatotopographical organization of hand (red) and neck (green) activation foci in the human dorsal posterior insula superimposed on a standard brain anatomic volume. This activation, viewed with functional magnetic resonance imaging (fMRI), was produced by stimulation of the hand or neck with an innocuous cooling stimulus. Reproduced from Figure 5 in Hua, L. H., Strigo, I. A., Baxter, L. C., Johnson, S. C., and Craig, A. D. 2005. Anteroposterior somatotopy of innocuous cooling activation focus in human dorsal posterior insular cortex. Am. J. Physiol. Regul. Integr. Comp. Physiol. 289, R319–R325, used with permission.

nares, and mouth. The boids have several small sensory pits, while the crotalines have a single large pit on each side of the head. This account is based largely on contemporary reviews by Krochmal A. R. and Bakken G. S. (2003) and by Pappas T. C. *et al.* (2004).

6.16.2.4.1 Location, structure, and function of receptors

Within the crotaline pits the receptors are concentrated in a thin membrane that stretches between the edges of the pit, and this membrane is accompanied by a concentration of capillaries that can serve as a drain for removing heat accumulated in the pit, analogous to the role of the pigment epithelium in the visual retina that absorbs light after light has excited the layer of photoreceptors. Evidence now shows that the pit receptors are sensitive to ambient temperatures rather than to photons reporting the location of infrared radiation. The pit organs contain the greatest number and density of heat-sensitive cells known in the animal kingdom. They have the capability of giving the snakes a finely detailed picture of the temperature map of their environment.

The heat receptors are in the endings of neurons in the trigeminal ganglia. The mode of transduction of the dynamic patterns of heat energy into patterns of nerve impulses in the trigeminal nerve is not known, but electrophysiological evidence suggests that it may be similar to that which utilizes TRP channels and cGMP activation in mammalian temperature and nociceptive receptors.

6.16.2.4.2 Pathways to and through the central nervous system

The trigeminal temperature-sensitive cells project to the optic tectum, where the information they supply appears to complement that received from the visual system. Many individual tectal cells receive both visual and thermosensory input.

6.16.2.4.3 Role in behavior

The temperature information appears to supply deficiencies in the visual information due to decrease in ambient light during the dark part of the diurnal cycle, giving the snake a continuous 24 h visual–thermal picture of the environment and events therein. The thermal aspect of the informational input has been put to use by snakes as an aid in locating warm-blooded prey, and also to help find warm places to rest and to nest.

6.16.3 Electrosensory System of Monotremes

The egg-laying monotreme mammals have developed a unique system, within the trigeminal somatic sensory system, that is sensitive to electrical states and currents in the environment (reviewed by Proske, U. *et al.*, 1998; Pettigrew, J. D., 1999).

6.16.3.1 Receptor Structure and Function

The electroreceptors are nerve endings associated with the ducts of large mucus-secreting glands (Gregory, J. E. *et al.*, 1988; Manger, P. R. and Pettigrew, J. D., 1996). They respond to steady DC electrical fields and to rapid potential transients. The neurons with the receptive endings are excited by cathodal (negative) pulses and inhibited by anodal (positive) pulses (Proske, U. *et al.*, 1998). Figure 3 shows the organization of nerve endings around and in the duct of the gland. There are many other mucous glands without the receptor innervation.

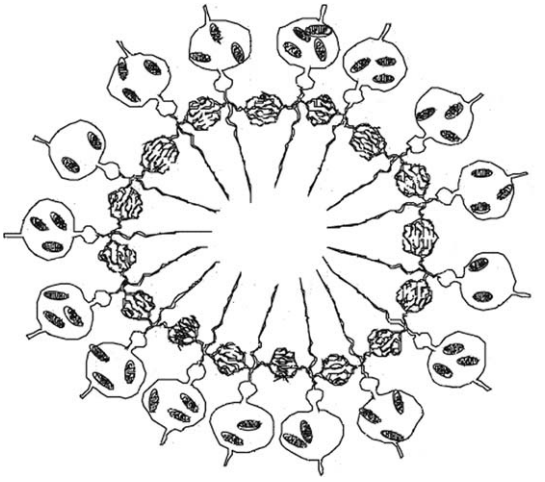

Figure 3 Diagrammatic representation of a monotreme mucous gland electroreceptor showing the tangential arrangement of afferent nerve endings around the pore. The bulbous expansions of each nerve fiber are packed with mitochondria. The terminal naked filaments pierce a high-resistance layer in the epidermis and extend toward the mucous-filled duct. The lateral branches of each fiber extend toward each other. It is not known whether they are electrically coupled. Reproduced from figure 3 in Pettigrew, J. D. 1999. Electroreception in monotremes. J. Exp. Biol. 202, 1447–1454, with permission.

6.16.3.2 Location

In platypus the mucous gland electroreceptors are arranged in a series of rostrocaudal bands with electroreceptor-free bands between them, over almost the whole extent of the inner and outer surfaces of the upper and lower bill (Figure 4; Manger, P. R. and Pettigrew, J. D., 1996; Pettigrew, J. D., 1999). This is in contrast to the distribution of another set of mechanoreceptors peculiar to monotremes, called the push-rod receptors, which are arrangements of stiff rods in the skin of the bill that enhance the mechanical stimulation of sets of Merkel cells and lamellated corpuscles when the bill is touched. (Their structure and function have many features in common with Eimer's organs; see Figure 10.) The push-rod receptors are distributed more evenly across the whole surface of the bill.

Another type of receptor, called serous gland receptors located in the ducts of glands smaller than the mucous receptors, is found along the lateral margins of the bill. It was speculated that the serous gland receptors might be another type of electroreceptor sensitive only to electrical events in close proximity to small regions of the skin of the bill.

These receptor types are also found in the two extant monotreme species of echidnas (spiny anteaters), but are restricted to a small region near the tip of the bill, where the skin is kept moist by nasal secretions (Gregory, J. E. *et al.*, 1989; Manger, P. R. *et al.*, 1997).

6.16.3.3 Pathways to and through the Central Nervous System

In echidnas the electrosensory receptors were found to project through the infraorbital branch of the maxillary division of the trigeminal nerve (Gregory, J. E. *et al.*, 1989).

In platypus electroreceptors were reported to project to the somatosensory region of the cerebral cortex, with some cortical cells activated by either electrosensory or mechanosensory stimulation of bill receptors (Iggo, A. *et al.*, 1992; Proske, U. and Gregory, E., 2003). Pettigrew J. D. (1999) reported alternating electrosensory and mechanosensory modality columns in this cerebral cortical region.

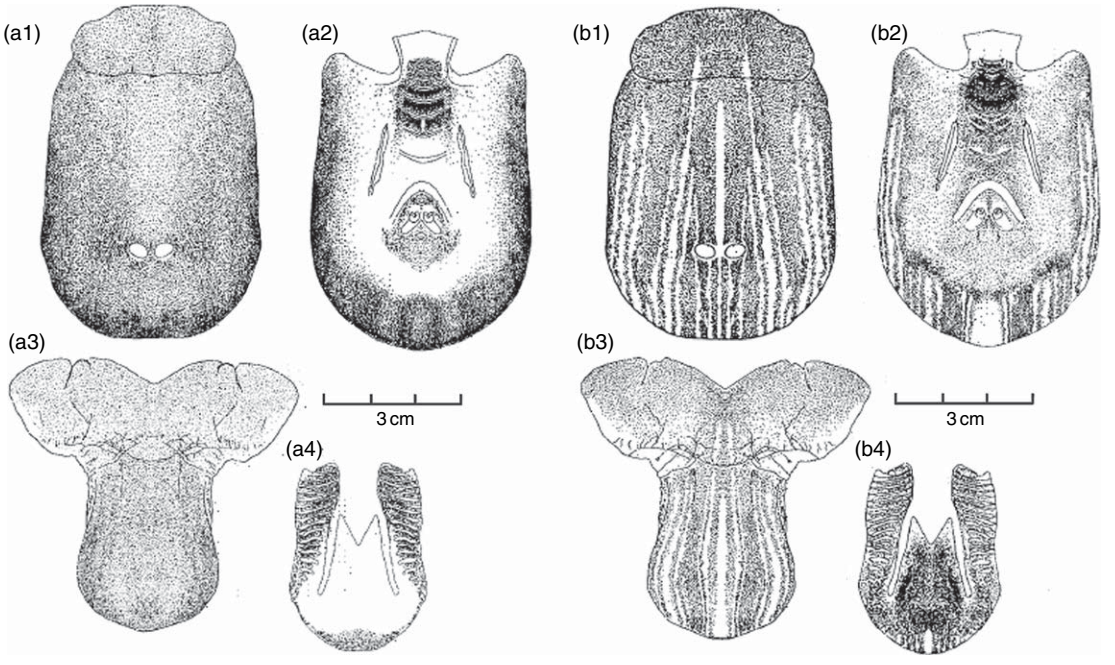

Figure 4 Distribution of push-rod mechanoreceptors (a) (visible as a touch dome in the dissecting microscope) and (b) mucous electroreceptors (visible as a large pit) in platypus. Note the parasagittal arrays of electroreceptors. The total number of electroreceptors, counting both the outside (1,3) and the inside (2,4) surfaces of both the upper (1,2) and lower (3,4) bills, is approximately 40 000. There are approximately 60 000 mechanoreceptors. Reproduced with permission from Manger, P. R. and Pettigrew, J. D. 1996. Ultrastructure, number, distribution and innervation of electroreceptors and mechanoreceptors in the bill skin of the platypus, *Ornithorhynchus anatinus*. Brain Behav. Evol. 48, 27–54 as it appears in figure 2 of Pettigrew, J. D. 1999. Electroreception in monotremes. J. Exp. Biol. 202, 1447–1454.

6.16.3.4 Role of Electrosensation in Specialized Behaviors of Platypus and Echidnas

Pettigrew J. D. (1999) provides an extensive discussion of the possible roles of the striated arrangement of electroreceptors on the platypus bill, and the alternating stripes of electrosensory and mechanosensory projections in the sensory cerebral cortex, in prey localization. These features appear to work optimally in combination with a saccadic side-to-side movement of the bill over the aquatic substrate where voltage-generating prey are found. One interesting feature revealed in behavioral studies is that the whole moving platypus can detect smaller voltage changes than can the individual receptors. It is speculated that echidnas employ their more modest electrosensory endowment in a similar fashion in searching for ants in a sandy environment.

6.16.3.5 Comparison of the Trigeminal Electrosensory System of Monotremes with the Octavolateral Electrosensory Systems of Fishes

Electrosensory systems have arisen convergently and independently at least three times in the evolution of the vertebrate chordates. In two of these cases, both in fishes, electrical sensation takes place through derivatives of the eighth cranial nerve placode; the third case is that in monotremes, where the system derives from the fifth cranial nerve placode (Pettigrew, J. D., 1999). In the octavolateral systems, transduction takes place in specialized epithelial receptive hair cells. In the trigeminal system, transduction takes place in naked nerve endings in ducts of secreting glands, although these naked endings have an elaborate formal arrangement in the daisy chains seen in Figure 3. In the trigeminal monotreme system, most central processing takes place in the cerebral cortex of the forebrain; in the octavolateral fish systems most central processing takes place in the brain stem and cerebellum of the hindbrain. In all three systems receptors are located at the depth of pores in the surface skin.

6.16.4 Specialized Mechanosensory Systems

We have sorted specialized mechanosensory systems into two categories. The first category is that of telemechanosensory specializations, whereby mechanical stimulation is amplified or spatially extended by the use of projections reaching out from the body surface. These are represented by extension of the skin, by sensory endings related to feathers in birds, and most extensively by specialized hairs extending from the skin of mammals. In birds and mammals, these structures embedded in, and projecting out from the skin, function in locomotion, or body heat conservation, or as tools with which to accomplish specific behavioral ends, but in the cases to be described they also add to the animals' sensation of objects and events in the more distant environment.

The second category is that of endomechanosensory specializations, such as touch spots or regions – adaptive groupings of receptors within particular regions of skin, in locations of importance to adaptive behaviors peculiar to particular species or groups of species.

6.16.4.1 Telemechanosensory Specializations

6.16.4.1.1 Structural extensions of the skin in fishes

Among the best-known projections of skin for the purpose of extending sensory surfaces into the environment are the barbels seen around the oral regions of several species of bony fishes. In many species these are outgrowths of the taste system (see references in Zhang, G. *et al.*, 2006). The barbels extend the sensory surface into the surrounding environment. In one species, the Antarctic plunderfish, there is a single midline barbel that has no taste buds and is entirely mechanosensory, which is not used for probing the substrate but rather for gathering information about the presence and activity of prey in the water (Roule, L. *et al.*, 1913; Eastman, J. T. and Lannoo, M. J., 2003) (Figure 5).

6.16.4.1.2 Feathers and bristles in birds

In birds there is a rich network of sensory nerve fibers around the base of feathers (Saxod, R. *et al.*, 1996). This suggests a role of feathers in amplifying tactile sensation of mechanical contact.

Bristles, which are actually modified feathers around the mouth and eyes, appear to have a tactile sensory protective function inducing reflex closure of these openings (Lederer, R. J., 1972; Conover, M. L. and Miller, D. E., 1980).

6.16.4.1.3 Vibrissae in mammals

All mammals possess hair of some kind during at least some phase of their ontogeny. Vibrissae are hairs that are specialized for sensory functions. Terrestrial

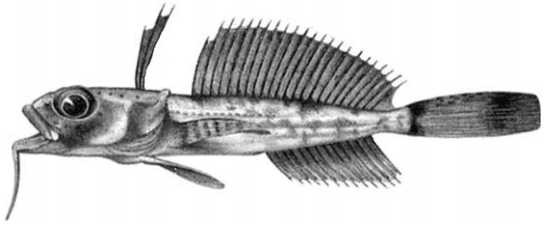

Figure 5 A tactile barbel with no taste function. Antarctic plunderfish *Dolloidraco longedorsalis* (TL = 123 mm) showing overall morphology, barbel, eyes, and location of nasal pore. In life the barbel is usually oriented about 45° above the substrate. Reproduced with permission from Roule, L., Angel, F., and Despax, R. 1913. Poissons. In: Deuxième Expédition Antarctique Française (1908–1910), (*eds.* J. Charcot and L. Joubin), p. 24. Masson as it appears in figure 1 in Eastman, J. T. Lannoo, M. J. 2003. Anatomy and histology of the brain and sense organs of the Antarctic plunderfish *Dolloidraco longedorsalis* (perciformes: notothenioidei: artedidraconidae), with comments on the brain morphology of other artedidraconids and closely related harpagiferids. J. Morphol. 255, 358–377.

mammals possess vibrissae on restricted regions of the body, most notably the face (Pocock, R. I., 1914; Eisenberg, J. F., 1981). However, monotremes, some marsupials, and humans lack vibrissae (Ling, J. K., 1966). Some rodents possess a few carpal, antebrachial, or tarsal vibrissae, and six to eight vibrissae are found on the trunk in two squirrel species (Hyvärinen, H. *et al.*, 1977; Sokolov, V. E. and Kulikov, V. F., 1987). Rock hyraxes (*Procavia capensis*) have vibrissae on the trunk (Sale, J. B., 1970; Sokolov, V. E., 1982). Among aquatic mammals, pinnipeds and cetaceans have vibrissae on the face only (Ling, J. K., 1977). Baleen whales have ~100 thin vibrissae on the upper and lower jaws. In most odontocete cetaceans, hair is present only as prenatal vibrissae, which atrophy, leading to a completely hairless condition postnatally. An important exception is the freshwater river dolphins, with well-developed vibrissae along the upper and lower jaws. Sirenians possess vibrissae over the entire body (Reep, R. L. *et al.*, 2001; 2002).

Vibrissae are known to convey detailed information about shapes and textures of objects in the immediate environment through direct tactile contact (Dykes, R. W., 1975; Brecht, M. *et al.*, 1997), and they enable detection of hydrodynamic stimuli in some aquatic mammals (Dehnhardt, G. *et al.*, 1998a; 2001). The use of mystacial vibrissae by terrestrial mammals is well documented, and includes the findings that rodents use rhythmic whisking motions (Welker, W. I., 1964) and that each row of mystacial vibrissae operates as a functional unit by sampling highly overlapping spatial information perpendicular to the rostrocaudal axis (Brecht, M. *et al.*, 1997). Sokolov V. E. and Kulikov V. F. (1987) performed vibrissae ablation experiments indicating that nocturnal and crepuscular rodents, which possess relatively long mystacial vibrissae, rely primarily on touch for orientation whereas diurnal species, which have short vibrissae, rely principally on vision. Vibrissal follicles are referred to as follicle-sinus complexes (F-SCs) because of their specialized structural features, including a well-defined circumferential blood sinus, dense connective tissue capsule, and substantial innervation (Andres, K. H., 1966; Stephens, R. J. *et al.*, 1973; Rice, F. L. *et al.*, 1986; 1997; Ebara, S. *et al.*, 2002). Furthermore, in many taxa, specializations exist in the brain stem, thalamic, and cortical regions that process information from F-SC afferents (Van der Loos, H., 1976; Jones, E. G., 1983; Ladygina, T. F. *et al.*, 1985; Land, P. W. and Simons, D. J., 1985; Nomura, S. and Mizuno, N., 1986; Florence, S. L. and Lakshman, S., 1995; Rice, F. L., 1995).

All the major hair types possess innervated mechanoreceptors. Vibrissae are the most extensively innervated and have numerous mechanoreceptors, including Merkel cells, lanceolate endings, and free nerve endings (Zelena, J., 1994). Receptor types and innervation patterns have been studied in a variety of mammals including rodents (Munger, B. L. and Rice, F. L., 1986; Rice, F. L. *et al.*, 1986; Mosconi, T. M. *et al.*, 1993; Rice, F. L., 1993; Rice, F. L. *et al.*, 1993; 1997; Ebara, S. *et al.*, 2002), rabbits and cats (Rice, F. L. *et al.*, 1986; Rice, F. L., 1993; Ebara, S. *et al.*, 2002), primates (Halata, Z. and Munger, B. L., 1980), tammar wallabies (Marotte, L. R. *et al.*, 1992), hippopotamuses (Bachteler, D. *et al.*, 1998), manatees (Reep, R. L. *et al.*, 2001; 2002; Sarko, D. K. *et al.*, 2007), sea lions (Stephens, R. J. *et al.*, 1973), ringed seals (Hyvärinen, H., 1995), and bearded seals (Marshall, C. D. *et al.*, 2006). A deep vibrissal nerve contains 100–200 axons that terminate in receptors located in the outer root sheath and mesenchymal sheath. Some aquatic mammals possess far greater numbers of axons per follicle (Hyvärinen, H., 1995; Dehnhardt, G. *et al.*, 1999; Marshall, C. D. *et al.*, 2006).

It is not known exactly how vibrissae work. However, integrity of the sinus capsule is necessary for normal function (Gottschaldt, K.-M. *et al.*, 1973). Rapidly adapting vibrissal afferent axons code stimulus onset and appear to be associated with encapsulated endings (Ebara, S. *et al.*, 2002). Slowly adapting units code aspects of stimulus intensity, and are associated with Merkel cells and possibly lanceolate and club-like endings (Gottschaldt, K.-M. *et al.*, 1973; Dykes, R. W., 1975; Ebara, S. *et al.*, 2002). Reticular and spiny endings

are candidates for transducing directionally selective responses seen in some slowly adapting units (Dykes, R. W., 1975; Ebara, S. *et al.*, 2002). Blood pressure may set the mechanical tension (and thus response sensitivity) of the tissue in which lanceolate endings and Merkel cells are located (Woolsey T. A. *et al.*, 1981; Rice, F. L. *et al.*, 1986). Therefore, the neural response properties of individual vibrissa follicles would depend on at least the following attributes at the microanatomical level: (1) hair length, diameter, and stiffness, both external to the skin surface and within the follicle; (2) follicle geometry, especially follicle length and diameter, capsule wall thickness, and ring sinus size and shape; (3) innervation density and types and distributions of nerve endings; (4) Merkel cell density and distribution.

6.16.4.1.3.(i) Nonmystacial vibrissae in terrestrial mammals The intense focus on mystacial vibrissae as a neurobiological model system has tended to obscure the fact that many mammals also possess vibrissae in other body locations. Among rodents, collectively, vibrissae are found in nine other regions of the face and eight other regions of the postfacial body (Sokolov, V. E. and Kulikov, V. F., 1987), with individual species exhibiting various subsets of these. In a morphological study of squirrel carpal and abdominal vibrissae, Hyvärinen H. *et al.* (1977) found that these have structural features similar to mystacial vibrissae, including the same types of receptors. Fox squirrels exhibit a wide expanse of somatosensory projections to the dorsolateral medulla oblongata from the outer hairs of the forelimb (Ostapoff, E.-M. *et al.*, 1983). Jerboas hang their longest mystacial vibrissae on the ground in front of where their feet will land, apparently sampling the substrate prior to landing (Sokolov, V. E. and Kulikov, V. F., 1987). This is especially apparent during jumping. The ventral abdominal vibrissae in squirrels may perform a similar function (Hyvärinen, H. *et al.*, 1977; Sokolov, V. E. and Kulikov, V. F., 1987).

In microchiropteran bats, touch domes along the wings are heavily invested with Merkel cells and free nerve endings that appear to detect air flow and aid in navigation and maneuvering (Zook, J. M., 2007).

Hyraxes are unusual in having vibrissae scattered over the entire body, intermingled with dense pelage fur. Sale J. B. (1970) based this conclusion upon external morphological features including the greater length and thickness of these hairs, and their relatively sparse distribution, and suggested that this array of vibrissae may be used for tactile exploration and orientation within rock crevices and tunnels under low-light conditions. Sokolov V. E. (1982) also reported that three species of hyraxes have vibrissae on the trunk as well as the face. Diana Sarko (unpublished observations) has used histological criteria to confirm the identification of these hairs as vibrissae (Figure 6). Thus, hyraxes are apparently unique among extant terrestrial mammals in having vibrissae distributed over the entire body surface. Naked mole rats may represent a case of convergent evolution in this regard. They possess sparsely distributed, evenly spaced vibrissae-like body hairs on their otherwise unfurred bodies, and these hairs are densely innervated though they lack blood sinuses (Park, T. J. *et al.*, 2003). This system of tactile hairs is used in behavioral orientation (Crish, S. D. *et al.*, 2003).

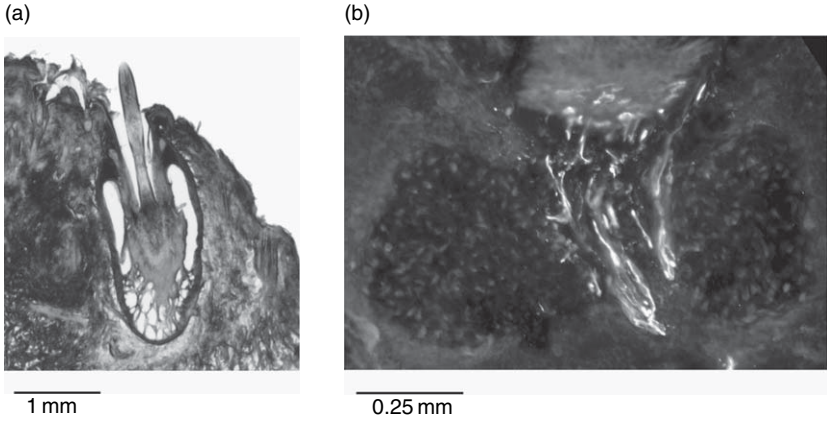

Figure 6 Follicle-sinus complexes (F-SCs) from the dorsal body region of the rock hyrax (*Procavia capensis*). As shown in (a), the blood sinus is surrounded by a dense capsule, and its lower portion is trabeculated. (b) Illustrates nerve endings positive for protein gene product 9.5 in the mesenchymal sheath, flanked by the sinus to the left and right. Photo courtesy of Dr. Diana Sarko.

6.16.4.1.3.(ii) Functions of vibrissae in aquatic mammals The aquatic medium presents two features that have a significant impact on somatosensory processes. First, the greater density of water compared to air changes the dynamics of interaction between a moving vibrissa and the follicle wall containing mechanoreceptors. Some pinniped vibrissae are oval and stiff (Marshall, C. D. *et al.*, 2006); others are flattened and exhibit a wavy, beaded edge (Hyvärinen, H. and Katajisto, H., 1984; Watkins, W. A. and Wartzok, D., 1985; Hyvärinen, H., 1989; Dehnhardt, G. and Kaminski, A., 1995), features that may reduce vibratory movements generated by swimming (Hanke, W., personal communication). Second, many aquatic environments are turbid, which reduces the usefulness of visual cues. Although odontocete cetaceans have developed high-frequency echolocation in order to locate prey and navigate underwater, other aquatic mammals have not.

Hydrodynamic stimuli occur when there is motion in a fluid medium. Hydrodynamic reception is intermediate between touch and hearing and it has been suggested that mammalian vibrissae may serve a function complementary to audition at low frequencies (Griffin, D. R., 1959; Marler, P. and Hamilton, W. J., 1966; Yohro, T., 1977; Gerstein, E. R. *et al.*, 1999; Reep, R. L. *et al.*, 2002). In nonmammals hydrodynamic receptors act as low-pass filters that respond proportional to velocity or acceleration of stimuli, in the frequency range of 1–150 Hz (Bleckmann, H., 1994). Fishes and some amphibians possess a lateral line system that detects hydrodynamic stimuli with frequencies in the range of <100 Hz. Evidence suggests that pinnipeds, sirenians, and some aquatic rodents possess vibrissal specializations that represent adaptations for direct tactile contact and for the detection of low-frequency hydrodynamic stimuli in the aquatic environment. In the latter context they may be considered mammalian analogs of the lateral line system.

Psychophysical studies and behavioral observations suggest that vibrissae are very important in the lives of aquatic mammals. Harbor seals can discriminate objects using their facial vibrissae as effectively as monkeys do when using their hands (Weber fraction of ~9%; Dehnhardt, G. and Kaminski, A., 1995). Manatees perform tactile discriminations using their facial vibrissae as well, as do elephants when using their trunks (Weber fraction of ~14%; Bachteler, D. and Dehnhardt, G., 1999), and much better than sea lions do when using their facial vibrissae (Weber fraction of ~20%; Dehnhardt, G. and Ducker, G., 1996). Walruses can distinguish shapes with surface areas as low as 0.4 cm^2 (Kastelein, R. A. and van Gaalen, M. A., 1988). Pinnipeds wave their long vibrissae in the air during display behaviors and tactile exploration (Peterson, R. S. and Bartholomew, G. A., 1967; Miller, E. H., 1975; Kastelein, R. A. and van Gaalen, M. A., 1988; Dehnhardt, G., 1994; Dehnhardt, G. and Kaminski, A., 1995; Dehnhardt, G. and Ducker, G., 1996). Freshwater river dolphins (Platanistidae) have reduced visual systems but relatively well-developed bristle-like vibrissae on the upper and lower jaws. These nonmobile vibrissae are likely used to detect fishes and crustacean prey along river bottoms (Norman, J. R. and Fraser, F. C., 1948; Layne, J. N. and Caldwell, D. K., 1964, cited in Ling, J. K., 1977). The Australian water rat is an aquatically adapted murid rodent that uses its long mystacial vibrissae to locate prey underwater. It also dips its vibrissae in the water while the remainder of its body is on land, presumably to sample the hydrodynamic environment prior to diving after prey with its eyes closed (Woollard, P. *et al.*, 1978; Dehnhardt, G. *et al.*, 1999). Marshall C. D. *et al.* (2006) have drawn attention to the relationship between feeding strategy and vibrissae elaboration. Bearded seals and walruses are benthic foragers and they possess more numerous vibrissae arranged on a broad, flat muzzle compared to the lateral placement of fewer vibrissae in pinnipeds that are nonbenthic foragers. Walruses and sirenians use their perioral vibrissae not only for tactile investigation, but also to move food and inanimate objects (Fay, F. H., 1982; Marshall, C. D. *et al.*, 1998a; 1998b; 2003).

In manatees the perioral bristles are located in six regions. A subset of these perioral vibrissae engages in true grasping to gather and ingest plants during feeding (Marshall, C. D. *et al.*, 1998a; 1998b; Reep, R. L. *et al.*, 1998). We have named this unique behavior oripulation. (Oripulation is a term we use to denote grasping or handling behavior using the vibrissae and associated perioral musculature (Reep, R. L. *et al.*, 2001). This distinguishes it from the term manipulation, which connotes the use of the manus or hand.) The oral disk, the expanded mystacial region of the sirenian face, contains a dense array of thin vibrissae intermediate in stiffness and innervation between perioral bristles and postcranial body hairs. These thinner vibrissae are used during tactile investigation of novel objects or food items (Hartman, D. S., 1979; Marshall, C. D. *et al.*, 1998b; Bachteler, D. and Dehnhardt, G., 1999). About 3000 vibrissae are distributed on the postfacial body, each with a relatively independent field of movement (Reep, R. L. *et al.*, 2002). Each postcranial follicle is supplied by 20–50

axons, compared to 50–250 axons innervating follicles of the perioral bristles and oral disk (Reep, R. L. *et al.*, 2001; 2002). This widespread postfacial distribution of vibrissae is unique among mammals. In nonmammals, hydrodynamic sensors spread over the body surface record the spatial distribution of a stimulus, and thus extract important 3D information (Teyke, T., 1989; Bleckmann, H., 1994). For example, many fishes use the lateral line for discrimination and avoidance of objects in the aquatic environment (Hassan, E. S., 1986). Stationary underwater objects create distortions in the flow fields generated by animals moving through water, and unequivocal information about object size and distance can be obtained by analyzing the velocity distribution of the flow field over the body (Hassan, E. S., 1989). These capacities may be enhanced in manatees due to the widespread distribution of vibrissae and large body size.

Vibrissae of nonsirenian aquatic mammals appear to be used not only in direct tactile contact, but also to detect water movements, often caused by other animals. Harbor seals can use their facial vibrissae to detect controlled low-frequency underwater vibratory stimuli (Mills, F. H. J. and Renouf, D., 1986) and hydrodynamic trails like those produced by swimming fishes (Dehnhardt, G. *et al.*, 1998a; 2001). The Australian water rat preys on fishes and is able to detect constant velocity but not oscillatory hydrodynamic stimuli (Hanke, W., personal communication).

6.16.4.1.3.(iii) Follicle structure and follicle-sinus complexes in aquatic mammals Vibrissae follicles in aquatic mammals exhibit several structural differences from those in terrestrial mammals, likely reflecting the different functional requirements of operating in the aquatic medium. Mystacial vibrissae of terrestrial rodents exhibit a circumferential ring sinus with a ringwulst (ring body), as well as a ventrally adjacent trabeculated cavernous sinus (Vincent, S., 1913; Melaragno, H. P. and Montagna, W., 1953; Wineski, L. E., 1985; Rice, F. L. *et al.*, 1986; 1997; Dehnhardt, G. *et al.*, 1999). Facial vibrissae in pinnipeds and manatees exhibit elongated F-SCs with a ring sinus flanked by upper and lower cavernous sinuses (Ling, J. K., 1966; 1972; Stephens, R. J. *et al.*, 1973; Hyvärinen, H. and Katajisto, H., 1984; Reep, R. L. *et al.*, 2001; 2002; Marshall, C. D. *et al.*, 2006), and trabeculae found in the cavernous sinuses of manatees are innervated by a novel type of nerve ending (Sarko, D. K. *et al.*, 2007). Ling J. K. (1977) noted a variety of sinus configurations among cetaceans. One effect of increased F-SC size and the addition of an upper cavernous sinus is to increase thermal compensation. Low temperature reduces the sensitivity of mechanoreceptors, but at least some taxa (harbor seals) exhibit selective heating in F-SCs (Mauck, B. *et al.*, 2000), which preserves tactile sensitivity under conditions of low ambient water temperature (Dehnhardt, G. *et al.*, 1998b).

Pinniped F-SCs possess a ringwulst, but sirenian follicles do not. The ringwulst in southern elephant seals is relatively small compared to the ringwulst in rats (Ling, J. K., 1966). The largest F-SCs of manatees exhibit rigidly attached appendages rather than a suspended ringwulst, whereas smaller manatee F-SCs have no appendages and reduced ring sinuses (Reep, R. L. *et al.*, 2001; 2002). Stephens R. J. *et al.* (1973) suggested that the ringwulst may transmit vibratory energy from the hair shaft to the ring sinus, and this conjecture may also apply with some modification to the appendages in manatee F-SCs. Postfacial F-SCs in manatees are smaller than the facial F-SCs, lack a ring sinus and ringwulst, and have only cavernous tissue with a widened region where one would expect to find the ring sinus (Reep, R. L. *et al.*, 2002). This condition is also seen in F-SCs of rhesus monkeys (Van Horn, R. N., 1970), tammar wallabies (Marotte, L. R. *et al.*, 1992), and brush-tailed possums (Hollis, D. E. and Lyne, A. G., 1974). Hippopotamus facial F-SCs have a similar configuration, in which the sinus contains umbrella-like appendages invested with Merkel cells (Bachteler, D. *et al.*, 1998).

In the Australian water rat, mystacial F-SCs exhibit an asymmetrical ring sinus that is larger rostrally than caudally (Dehnhardt, G. *et al.*, 1999), and this may bias each follicle toward directionally selective responding. Water rat follicles also exhibit specialized sandwich nerve endings that may be adaptations for low-frequency detection of hydrodynamic stimuli.

6.16.4.1.3.(iv) Innervation density Several variables undoubtedly influence the functional responses of F-SCs. These include follicle size; hair shaft size, shape, and composition; sinus geometry and blood pressure; receptor types and their distribution; and innervation density. The last factor is somewhat difficult to quantify because one first needs to know the effective region of contact when the hair shaft is deflected. Although this parameter is not usually known, it can be approximated by the perimeter or area of the ring sinus around which most receptors are located.

Some aquatic mammals possess more axons and mechanoreceptors per follicle than terrestrial taxa, perhaps suggesting that vibrissae in aquatic mammals have

greater discriminative power than those of terrestrial taxa. Facial vibrissae in rodents, rabbits, cats, and monkeys are innervated by 80–200 axons originating from the deep vibrissal nerves (Halata, Z. and Munger, B. L., 1980; Rice, F. L. *et al.*, 1986; 1997). However, in the Australian water rat, each caudal mystacial F-SC receives over 500 myelinated axons (Dehnhardt, G. *et al.*, 1999). As many as 1300 axons innervate single F-SCs in ringed seals (Hyvärinen, H., 1995) and bearded seals (Marshall, C. D. *et al.*, 2006). Nerve estimates in cetacean F-SCs range from 40 to 290 axons per F-SC (Ling, J. K., 1977). Manatee caudal mystacial vibrissae (U2 field) are innervated by ~200 axons (Reep, R. L. *et al.*, 2001). Hyvärinen H. (1995) estimated that individual follicles in ringed seals possess 10 000–20 000 Merkel cell–neurite complexes compared to 500–2000 for terrestrial taxa, and 1000–4000 lanceolate endings versus 20–100 for terrestrials.

Implicit in the conjecture that these data suggest higher acuity for aquatic follicles is the assumption that higher numbers of axons and receptors equate with higher innervation density, a major determinant of acuity. However, this assumption is complicated by the fact that follicles tend to be larger in aquatic species. Larger follicles have ring sinuses that are longer and of greater circumference than those in smaller follicles. Consequently, the area to be innervated is greater, requiring a greater number of mechanoreceptors in order to preserve the same innervation density found in smaller follicles. Therefore, it may be that more axons are required in aquatic follicles to match the same innervation density seen in terrestrial follicles. To what extent do axon numbers in aquatic taxa exceed this expected increase? The Australian water rat exhibits ~500 axons per follicle of ~6.3 mm length, whereas terrestrial rats exhibit ~200 axons per follicle of ~4.0 mm, suggesting a surplus in water rats of ~185 axons per follicle beyond the number required to meet expected linear scaling to preserve innervation density. Ringed seals and bearded seals possess a surplus of ~950 axons when scaled to terrestrial rats, and somewhat fewer axons than predicted by scaling to water rats. Therefore, these admittedly crude estimates support the claim that at least some aquatic taxa possess relatively high innervation density. One confounding factor is that the most relevant size variable is likely to be area innervated rather than the total follicle length. Thus, this issue cannot be resolved fully until sufficient quantitative data exist.

In manatees there are significant linear correlations between number of axons and ring sinus perimeter and area for facial follicles, suggesting that larger follicles have more axons simply because the ring sinus is larger (Reep, R. L. *et al.*, 2001). Thus, innervation density may be relatively similar in small and large manatee follicles. This would suggest that differently sized follicles are specialized to respond to different types of stimuli. We know that manatees utilize vibrissae of the oral disk for tactile investigation whereas perioral vibrissae are used in oripulation (Marshall, C. D. *et al.*, 1998a; 1998b), and we have hypothesized that the postfacial vibrissae are used in hydrodynamic reception (Reep, R. L. *et al.*, 2002). Each of these groups of vibrissae exhibits characteristic attributes, not only of follicle size, but also of sinus geometry, hair shaft geometry, and receptor types and distribution (Reep, R. L. *et al.*, 2001; 2002; Sarko, D. K. *et al.*, 2007). Interestingly, Marshall C. D. *et al.* (2006) found no such relationship between the number of axons and the perimeter of the mesenchymal sheath in bearded seals.

Another factor that is significant in considerations of innervation density is axon branching. Because the extent and geometry of branching among the axons supplying mechanoreceptors has not generally been quantified, it is not known whether these parameters influence innervation density and the types of information processed by single axons. Different types of mechanoreceptive endings are likely to be associated with differing degrees of branching. The simplest assumption is that the overall degree of branching is conserved across taxa. If so, it follows that an increase in axon number would be required in aquatic taxa to match the innervation density seen in terrestrial taxa.

6.16.4.1.3.(v) Evolution and vibrissae Species-level variation in the distribution of vibrissae on the body raises interesting questions concerning the evolution and development of these patterns of variation. Sirenians and at least some hyraxes possess vibrissae over the entire body. Interestingly, these groups are both members of the Afrotheria (Waddell, P. J. and Shelley, S., 2003; Reyes, A. *et al.*, 2004) and their extant taxa represent closest living relatives. This relatively close relationship suggests that a body-wide distribution of vibrissae may have been present in the common ancestor of sirenians and hyraxes. Evidence that postfacial vibrissae in manatees and hyraxes have similar molecular pathways of development would provide support for this conjecture. The body-wide distribution of tactile hairs in naked mole rats suggests at least two possible scenarios: first, a body-wide distribution of vibrissae may be a plesiomorphic trait in

mammals generally, and naked mole rats have evolved a modified type of vibrissa; second, naked mole rats may have evolved their peculiar type of tactile hairs independently. In the absence of relevant fossil evidence, molecular developmental studies would be of particular importance in generating strong inferences to resolve these possibilities. (It is also significant that we have no data on the status of these traits in many living taxa, including tenrecs, hippopotamuses, and elephants.) As reviewed above, many terrestrial mammals have retained some nonfacial vibrissae, raising the issue of whether these arose via sculpting of an ancestral body-wide distribution pattern or by addition to an ancestral facial-only distribution. It is possible that pelage hair could transform rather easily into vibrissae through alterations in developmental pathways, but not enough is known about the relevant molecular events to address this possibility.

6.16.4.2 Endomechanosensory Specializations

Another form of mechanosensory specialization is in the relatively high density of receptors in particular locations in the skin, accompanied by expanded connections in the central nervous system, which are related to distinctive behavioral needs. Several examples have been documented.

6.16.4.2.1 The dome pressure receptor systems of crocodilian reptiles

This account of a reptilian specialized mechanosensory system derives from that of Soares D. (2007). Tactile papillas are found in all reptiles. Those in lizards have bristles that indicate sensitive areas of skin, which contain a variety of sensory terminals such as Merkel cells, discoid terminals, and free nerve endings in dermal layers. All reptilian touch papillas have a modified keratin layer, where a more flexible region is located over the sensory organ.

Dome pressure receptor organs are a specialized form of tactile papilla found in the crocodilian reptiles: families Alligatoridae, Crocodylidae, and Gavialidae. The alligatorids have dome pressure receptors around the face and mouth; in the other two families they are found on the caudal portions of most scales over the whole body surface, including the belly, legs, tail, and cloaca. They possess a pigmented epidermal evagination, with thinner epidermis and a more compact keratin layer, which contains highly branched nerve bundles. The secondary and tertiary branches lie directly under the epidermis. In alligatorids there are some, more distal, unmyelinated branches issuing from more proximal myelinated branches; they project, via foramina in the maxillary and mandibular bones, which can be recognized in fossils, to the trigeminal sensory nuclei of the brain stem. These nuclei are greatly enlarged, forming lateral lobes visible on the surface of the brain stem.

The dome receptors in alligators have been shown experimentally to be used to detect the precise locations of the sources of perturbations in the air–water interface where alligators habitually lurk. Their natural stimulation by such disturbances provokes instantaneous coordinated predatory attack on the locus of the source of the disturbance. These receptor organs may also participate in courtship rituals of alligators, which include bellowing by both sexes, which produces informative patterns of disturbances in the air–water interface.

6.16.4.2.2 Specialized relatively hairless regions of skin in mammals

Like the alligators, most mammals (and probably most vertebrates, and even most members of the animal kingdom) have an extraordinary density of receptors, including mechanoreceptors, around the face and mouth. One extreme of this is seen in sheep, where thalamic and cerebral cortical projections from lips and oral structures occupy the major portion of these cerebral parts of the somatic sensory system (Figure 7), particularly the glabrous region between hairy skin of the face and the mucous lining of the mouth, along with the glabrous rhinarium between hairy skin and the mucous lining of the nasal cavity. Sheep, like most of the grazing artiodactyls, show facility in oripulation using perioral tissues, but without the involvement of long vibrissae as seen in manatee oripulation.

In raccoons, a striking expansion of medullary, thalamic, and cortical projections from sensory surfaces on the digits and palm of the forelimb result in separate lobules and gyruses in the brain regions to which they project (Welker, W. I. and Seidenstein, S., 1959; Welker W. I. and Johnson, J. I., 1965; Johnson, J. I. *et al.*, 1968) (Figure 8). Parallel subdivisions resembling these are seen in medullary and thalamic forelimb, and some hindlimb, projections in primates (Florence, S. L. *et al.*, 1989; 1991).

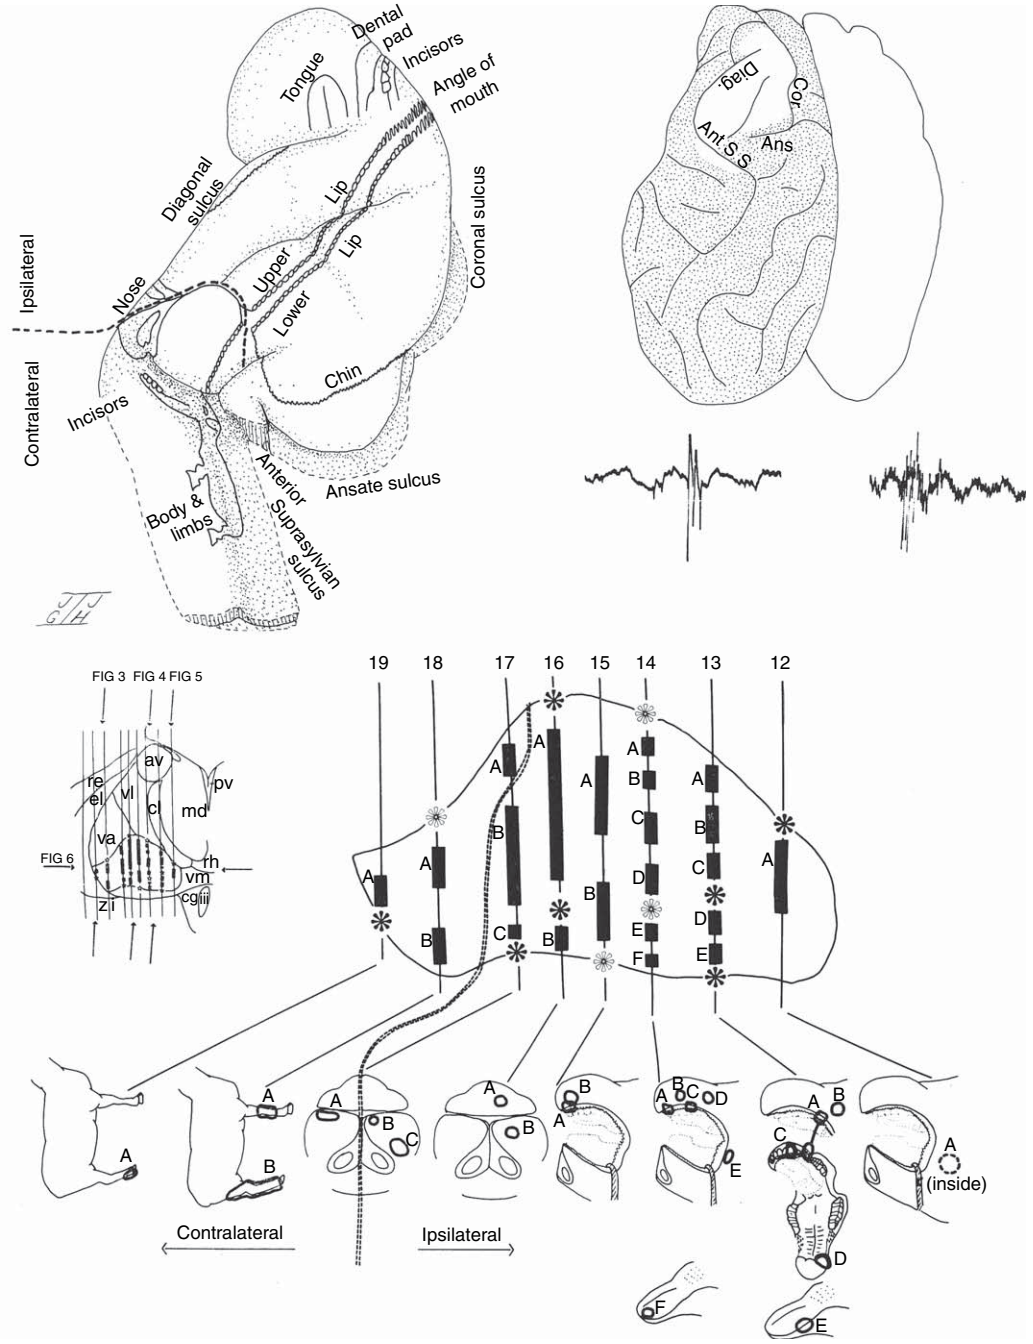
In raccoons this density of projections results in more than simple discriminative sensation: there is a positive motivational component for the animal in stimulation of this system.

The scientific name of raccoons is *Procyon lotor*, owing to their presumed habit of washing, often

thought of as a food-cleaning behavior. In fact, all objects, particularly smooth or metallic ones, are washed in any available water as a rewarding leisure time activity, which may have evolutionary significance for training animals to discriminate submerged food items that cannot be readily seen.

Similar expansions of central nervous projections, from the snout, are seen in marsupial wombats (Johnson, J. I., 1980), carnivore coatimundis (Welker, W. I. and Campos, G. B., 1963), and artiodactyl pigs (Woolsey, C. N. and Fairman, D., 1946; Craner, S. L. and Ray, R. H., 1991), where the location of the nostril in the cerebral cortical body representation is marked by a constant sulcus (Figure 9).

The receptive surface contributing to these specialized arrangements in brain structures is different



in different groups of species where the tactile skin surface has been well investigated. Those common to the extremities in primates, tree shrews, and arboreal marsupials have been summarized by Preuss T. M. (2006) as follows. Mechanosensorily (tactile, haptic) specialized surfaces on the extremities consist of dermatoglyphic glabrous (hairless) skin with complex patterns of epidermal ridges. In some platyrrhine New World monkeys such as in the genera Cebus and Ateles (e.g., spider monkeys) and Cebus (e.g., capuchin monkeys) there is an additional patch of such dermatoglyphic skin near the distal end of a fifth extremity – a prehensile tail. A special internal neural feature of this skin is a population of distinctive Meissner corpuscles, a nerve ending ensheathed in a capsule of nonneural cells, making them hypersensitive to deformation of the skin. In raccoon hands, in contrast, there are no Meissner corpuscles or epidermal ridges (Rice, F. L. and Rasmusson, D. D., 2000).

All of these skin regions specialized for touch, on the extremities of the forelimbs, hindlimbs, and in some cases the tail, have greatly enlarged representations in the various regions of the brain somatic sensory system to which they project.

6.16.4.3 Combined Endo- and Telomechanosensory Specializations

There are two other examples, from mammals, of elaborate specializations in the immediate vicinity of the olfactory portal and the opening of the mouth, like the perioral–nasal skin of pigs, sheep, and wombats. But unlike the ones that we have described, in these two examples the skin itself is carried out for a distance to extend the reach: the trunks of elephants and the stars of the star-nosed moles. These can be considered both telemechanosensory and endomechanosensory in that they extend the spatial reach of tactile surfaces, but possess the entire sensory apparatus within the skin.

6.16.4.3.1 Elephant trunks

A mechanosensorily specialized patch of skin in elephants is situated at the end of greatly elongated and motile nostrils, the well-known trunk, with which the animal can reach into, over, and under objects in the environment in a range of the same order as that of vibrissae in other mammals. Furthermore, the trunk contains sufficient musculature to act as a grasping organ and is the chief means through which elephants can manipulate objects in their local environment, in ways similar to the ways primates and raccoons both sense and manipulate using their hands, and many herbivores use prehensile lips. At the distal end of the trunk, above the narial openings, there is a distinctive finger, a flexible, pointed, but more rigid structure that is used for detailed exploration, grasping, fine manipulation, and enhanced tactile sensation. The skin of the finger contains epidermal ridges, multiple clusters of peripheral nerve endings, and what are described as Meissner-like endings, but no true Meissner corpuscles. The finger also has an olfactory role in that it can be used to insert samples of items of interest into the openings of the vomeronasal organ to obtain an increased level of discriminatory stimulation (Rasmussen, L. E. L. and Munger, B. L., 1996; Hoffman, J. N. *et al*., 2004). Stone J. and Halasz P. (1989) speculated that a peculiar distribution of retinal ganglion cells might have developed in elephants to provide fine visual monitoring of movements of the finger of the trunk.

6.16.4.3.2 Stars of star-nosed moles

The skin around the nares in talpid moles contains specialized assemblies of mechanoreceptors, known as Eimer's organs (Figure 10). In star-nosed moles the

Figure 7 Approximate locations of projections from peripheral receptors to somatosensory cerebral cortex and thalamus in sheep. The diagram at upper right shows the location of the somatosensory cortex (the unstippled region) on the left cerebral hemisphere between or along the ansate (Ans.), anterior suprasylvian (Ant. s. s.), coronal (Cor.), and diagonal (Diag.) sulci. Rostral is toward the top. The diagram at the upper left shows the somatosensory region as dissected free from the rest of the hemisphere, and with the anterior suprasylvian sulcus spread open. The locations of projections forming sensory representations of major body parts are indicated. Particularly prominent are projections from the glabrous, papillated lips, and the neighboring hairy skin. At the center right are examples of activity of neuronal units in response to mechanical stimulation. The diagram at lower right represents a section through the somatosensory thalamus and shows the paths of recording electrodes through the thalamus. Black bars illustrate the location of neural responses to stimulation of receptive fields whose locations are depicted on drawings of the body surface. Most of the sensory thalamus and cortex of sheep is devoted to processing information from very small receptive fields in and around the ipsilateral mouth and rhinarium. Reproduced from: upper diagrams Johnson, J. I., Rubel, E. W., Hatton, G. I. 1975. Mechanosensory projections to cerebral cortex of sheep. J. Comp. Neurol. 158, 81–108, with permission and lower diagrams Cabral, R. J. and Johnson, J. I. 1971. The organization of mechanoreceptive projections in the ventrobasal thalamus of sheep. J. Comp. Neurol. 141, 17–36, with permission.

skin is shaped into a star-shaped assemblage of skin extensions or rays around the nares (Catania, K. C., 1999; 2000; 2005).

Skin of all the rays contains Eimer's organs and those of two central foveal rays have a much greater density of these organs and smaller receptive fields (Catania, K. C. and Remple, F. E., 2004). The rays are motile and objects of interest are moved from other rays on to the foveal rays for closer mechanosensory examination. There is a central nervous elaboration related to projections from the rays, particularly the foveal rays: using appropriate histological markers the pattern of the rays and the much larger region containing projections from the foveal rays form a distorted somatotopic image of the star in the cerebral isocortex (Figure 10).

There is an olfactory role for the star as well, animals underwater will exhale air past objects of potential olfactory interest, then the rays act as a scoop to gather up the olfactant-filled air and direct it into the nares (Catania, K. C., 2006).

6.16.5 Overview

This account has been a survey of multiple ways in which a particular somatosensory system can be special. Most somatic sensory systems have been considered to be mechanosensory; so other bodily ubiquitous forms of energy transduction into neural signals can be considered special. The familiar triad of energy transductions that occur in free nerve endings would, in this view, constitute the basis of one general sensory modality, mechanosensory, and two special modalities, nociceptive and thermosensory (thermosensory is often divided into two submodalities, sensation of warmth and of cold).

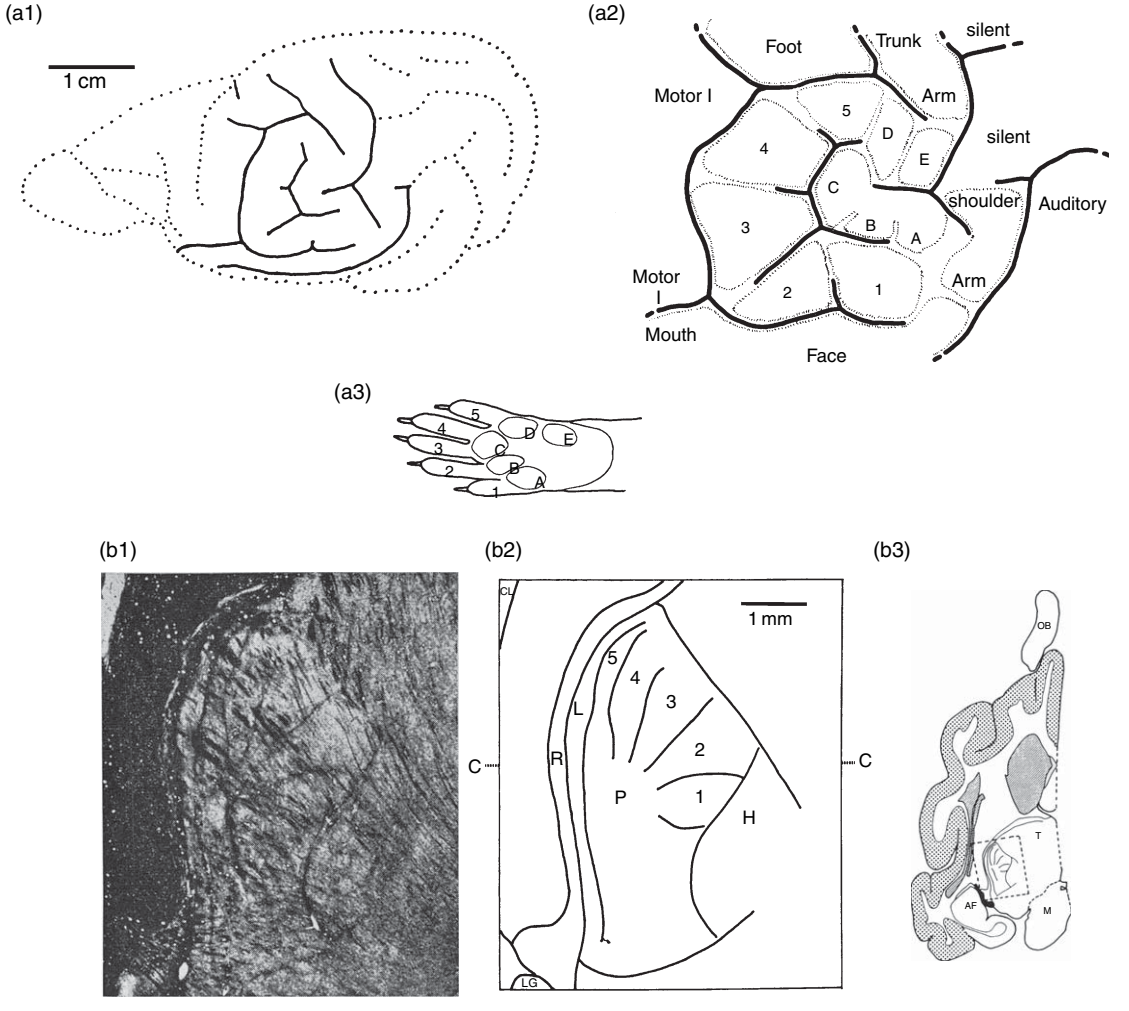


Figure 8 (*Continued*)

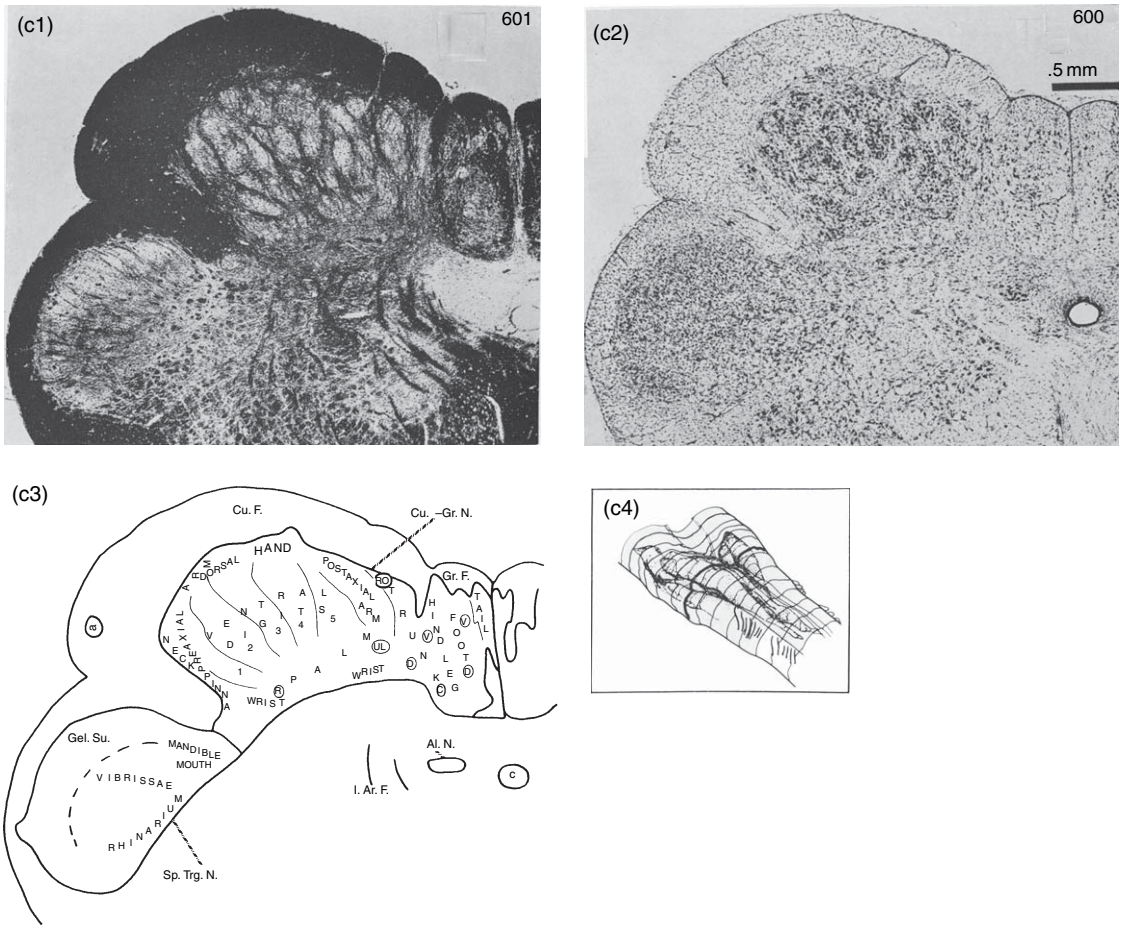

Figure 8 Mechanosensory projections from the volar hand in cerebral cortex, thalamus, and cuneate nucleus of raccoon. (a1) Outline drawing of left cerebral hemisphere with solid lines showing gyral formations in the somatic sensory region. Anterior is to the left. (a2) Projections from hand digits and palm pads, and other body parts and their relation to gyri and sulci. (a3) Positions of volar digital and palm pads on the skin of the hand. (b1) Section through the somatosensory thalamus stained for myelin, showing fiber bundles segregating the nucleus into lobules. (b2) Outline drawing of lobules showing the projection regions of head h, volar surfaces of digits 1, 2, 3, 4, 5, hind limb l, palm p, head, thalamic reticular nucleus r. (b3) Location of b2 in a horizontal section through the brain. Anterior is toward the top. (c1) Section 601 through a dorsal caudal medulla oblongata stained for myelin, showing fiber bundles segregating the cuneate nucleus into lobules containing projections from volar surfaces of individual digits of the hand. (c2) Neighboring section 600 stained with thionin for ribonucleic acid (Nissl method) showing the location of neuronal cell bodies organized into clumps forming the digit lobules. (c3) Outline diagram of the sections identifying the receptive fields projecting to the different parts of the cuneate, gracile, and spinal trigeminal nuclei. (c4) A 3D reconstruction showing the location of the sections and the dorsal column and spinal trigeminal nuclei in the medulla oblongata. C, caudal; D, dorsal; R, radial; RO, rostral; UL ulnar; V, ventral; an external cuneate nucleus; Al. N., alar nucleus; c, central canal; Cu. F., cuneate fasciculus; Cu.–Gr. N., cuneate–gracile nuclear complex; Gel. Su., substantia gelatinosa; Gr. F., gracile fasciculus; I. Ar. F., internal arcuate fibers; Sp. Trg. N., spinal trigeminal nucleus. (a1–a3) Reproduced from Welker, W. I. and Seidenstein, S. 1959. Somatic sensory representation in the cerebral cortex of the racoon (*Procyon lotor*). J. Comp. Neurol. 111, 469–501. (b1–3) Reproduced from Welker, W. I. and Johnson, J. I. 1965. Correlation between nuclear morphology and somatotopic organization in ventrobasal complex of the raccoon's thalamus. J. Anat. 99, 761–790, with permission from Blackwell publishing Ltd. (c1–4) Reproduced from Johnson, J. I., Welker, W. I., Pubols, B. H. 1968. Somatotopic organization of raccoon dorsal column nuclei. J. Comp. Neurol. 132, 1–44.

We have seen in Section 6.16.2.1 that current work on the role of TRP channels in thermal and nociceptive transduction in free nerve endings suggests a common cellular mechanism for touch, heat, cold, and painful sensation and that the distinction between these modalities is based on distinctive ranges of sensitivities that overlap and together comprise a continuous spectrum of sensed energy

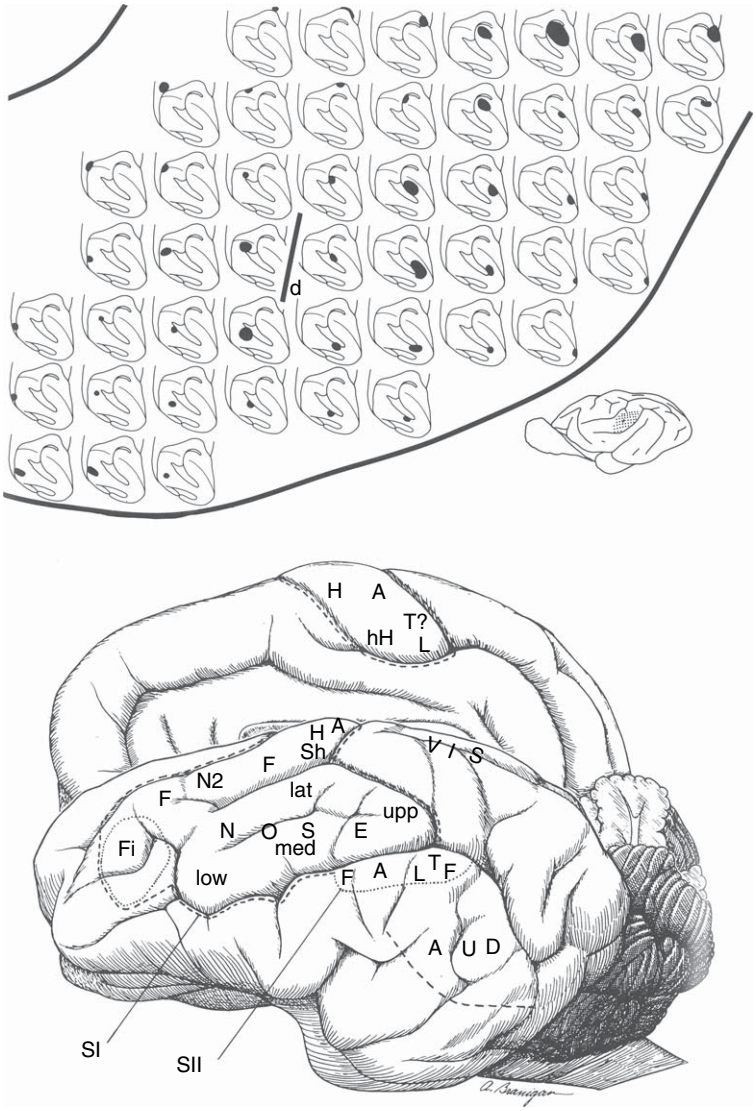

Figure 9 Top: Map of the relatively large somatosensory representation of the contralateral rhinarium on the crown of the coronal gyrus in the coatimundi (*Nasua narica*). A small dimple (solid line: d) commonly appears within the coati's rhinarial representation at a location (indicated in brain diagram at lower right) that is surrounded by a slightly elevated gyral formation that contains peripheral projections from the ring of highly innervated rhinarium that surrounds the nostril. Bottom: Locations of somatic sensory projections to primary (SI) and secondary (SII) cortical regions of pigs (*Sus scrofa*) as described in Adrian E. D. (1943), Woolsey C. N. and Fairman D. (1946), and Craner S. L. and Ray R. H. (1991). The left cerebral hemisphere is depicted, showing both the lateral surface and the mesial surface as it would be reflected in a mirror. Anterior is to the left. A, arm or foreleg; F, face; Fi, ipsilateral face; H, forehoof; hH, hindhoof; L, hind leg; lat, lateral; low, lower; med, median; upp, upper, aspects of the large representation of the flat rostrum of the rhinarium (NOSE), which occupies a large elliptical gyrus around a sulcus that occurs where the nostril is located in the cortical representation (a giant narial sulcus, Johnson, J. I., 1980); N2, a second complete representation of the nose in SI; Sh, shoulder; T?, site of occasional few and inconsistent responses to stimulation of the trunk. The face (F) is represented twice in SII, at its anterior and posterior poles. (Top) Adapted from Welker, W. I. 1990. Why Does Cerebral Cortex Fissure and Fold? A Review of Determinants of Gyri and Sulci. In Cerebral Cortex: Vol. 8B: Comparative Structure and Evolution of Cerebral Cortex, Part II (*eds*. E. G. Jones and A. Peters), pp. 3–136. Plenum; and Welker, W. I. and Campos, G. B. 1963. Physiological significance of sulci in somatic sensory cerebral cortex in mammals of the family procyonidae. J. Comp. Figure 10 Top: The glabrous rhinarium of three species of talpid moles covered with thousands of mechanosensory organs called Eimer's organs. The elaborate rhinarium of the star-nosed mole, consisting of 22 nasal appendages is covered with 25,000 Eimer's organs. Below, left: Drawings of sections through individual Eimer's organs from each of the three species. Each organ consists of a small swelling in the epidermis, and contains a circular configuration of free nerve endings, one or more Merkel cell-neurite complexes, and an encapsulated corpuscle in the underlying dermis. Below, right: A section through the flattened neocortex processed for the metabolic enzyme cytochrome oxidase, showing the area to where touch information from the star projects. The 11 modules in the cortex each represent one of the 11 appendages of the contralateral side of the star. Note the greatly expanded representation of the tactile fovea (appendage 11). Adapted with permission from Catania K. C. (2005a, b).

alterations. This in turn points the way toward considering these various modalities as a single modality that is present in most body tissues of animals and perhaps plants and other life forms as well. The nociceptive modality is at least as ubiquitous as the mechanosensory, such that pain is allotted a volume of its own in this series of handbook volumes.

We have included the generally distributed thermosensitive systems here as specialized somatosensory systems largely because they are not treated elsewhere in the series. Within the thermal modality there is at least one truly specialized apparatus – that of the heat-sensitive pit organs found in crotaline and some boid snakes, described in Section 6.16.2.4.3

Another form of specialization is represented by the electrosensory apparatus of the monotreme mammals, discussed in Section 6.16.3.5. In this case, in a restricted taxonomic grouping, a truly specialized system has evolved, but it works in concert with the general mechanoreceptive system with which it shares the same trigeminal-to-cerebral-cortical pathway and associated brain processing regions.

The remainder of the specialized systems we described were elaborations and variations in mechanosensory capabilities. One set of these specialties are those that take advantage of peripheral structures, in many cases developed to serve other vital functions such as alimentation and locomotion, to increase the range of mechanical recognition of environmental features and events. This was done by attaching mechanoreceptive nerve endings to such structures as lips, limbs, barbels of fishes, feathers of birds, and hairs of mammals. A great deal of scientific attention has been paid to vibrissae, mammalian hairs that have become specialized for mechanoreceptive functions. We classify these spatial range-extending specialties as telemechanosensory – touching at a distance.

An alternative type of specializations we call endoreceptive. They consist of unusual concentrations of receptors within certain regions of skin, such as lips of the oral cavity.

Both telemechanoreceptive and endomechanoreceptive specialties include brain elaborations and expansions to process the increased amount of information delivered by the specialized receptive interfaces with the environment.

Many systems incorporate both telemechanoreceptive and endomechanoreceptive properties. Among these we have considered the hands of raccoons, the tails of some New World monkeys, the trunks of elephants, and the stars of star-nosed moles. Significantly, all of these enhanced sensory surfaces are also mechanically prehensile, revealing the collaborative nature of motor and sensory specialization of particular body parts.

Our selection, and that of science in general, of specialized somatosensory systems is in no way exhaustive. Those presented here are certain instances of sensory system evolution that have caught the attention of astute observers. They constitute an instructive exhibit of the evolutionary possibilities that have been realized in variations and additions to basic sensory equipment.

Glossary

cercal system In insects, the cercal system consists of a bilateral pair of tapered spike-shaped structures (cerci) extending posteriorly from the last abdominal segment. Each cercus has several hundred mechanoreceptive hairs, organized into regular rows and columns, and each hair is mechanically coupled to a single afferent neuron. This system is responsible for the detection and monitoring of wind currents on the body surface.

campaniform sensillae Campaniform sensillae are sensory receptors located in the cuticle and respond to stress on the cuticle. Associated with the flexible ovoid cuticular dome is a single sensory neuron which inserts into the surrounding tissue. Compression of the cuticle perpendicular to the length axis of the sensillum excites the sensory neuron.

hair sensillae Hair sensillae are sensory receptors located in the cuticle on various parts of the body. Based on their detailed morphology and function two kinds of hair sensillae are distinguished: trichoid senillae and basiconic sensillae. The dendrite of a sensory neuron extends into the shaft of the hair and transduces movements of the hair into spike discharges. While trichoid sensillae serve exclusively as mechanoreceptors with one single mechanoreceptive sensory neuron innervating at the base of the hair, basiconic sensillae act in addition as chemoreceptors with chemoreceptive sensory neurons located at their work base and connected by the shaft to the pore at the tip.

6.17.1 Introduction

The somatosensory system is often considered to be an exclusive organizational feature of vertebrate central nervous systems (CNSs), although the sensory modalities and (equivalent) receptors involved are found in invertebrates as well. The somatosensory system encompasses receptors, modalities, and pathways that underlie the representation of sensory stimuli from the surface of the organism as well as the relative positioning of body appendages relative to each other and in space. The primary sensory modality associated with somatosensation is tactile input from the surface of an organism. As such, discriminative touch is the sensory modality that many textbooks refer to first when introducing somatosensation. Additional secondary modalities included in the somatosensory system are the senses for pain and temperature and proprioceptive

sensation. In addition to the types of receptors involved, the most prominent architectural feature of the somatosensory system in vertebrate nervous systems is the mapping of the body surface to a spatially coherent internal map in a designated cortical (neuronal) space.

It is this latter aspect that has probably limited the use of somatosensation in invertebrate neuroscience more widely, which can easily be tested by running a search for this term together with the term invertebrate. This is true despite the fact that (1) representation of all three aspects of body sensations, that is, touch, temperature, and proprioception, exist in invertebrate phylae; (2) mapping of sensory signals according to their origin or function is widely found in the invertebrate CNS; and (3) a variety of invertebrate directional motor behaviors have contributed substantially to our current understanding of how animal nervous systems operate.

The distributed and decentralized nature of invertebrate nervous systems precludes the strict application of the term somatosensation, as the vertebrate definition does not readily apply to this neural architecture. As the CNS of invertebrates is largely distributed along the body axis, there is no single central cortical structure with a global representation of the body surface as found in the sensory cortex of mammals. Instead, invertebrate nervous systems are subdivided into segments and ganglia that have a substantial degree of independence with respect to the organization of local sensory and motor processing. Secondly, although a highly centralized representation of the body surface does not exist in invertebrates, sensory information processing on a local level possesses numerous features that appear similar to, or functionally parallel with, the characteristics of vertebrate somatosensory systems. We will introduce several examples in order to illustrate similarities, functional parallels, and also differences.

We first list the sensors that report somatosensory information from the surface of the body, and then describe the principles of sensory mapping found in invertebrates, as well as the neural substrates and present two different examples of somatosensation in invertebrates.

6.17.2 Sensors Reporting Discriminative Touch, Temperature, and Proprioception

Invertebrates with a soft cuticle, like annelids, have sensory cells in each of their homologous segmental ganglia that respond to touch and pressure, and to noxious stimuli. One annelid model system that has contributed to our present understanding of decision making in CNSs in general is the medical leech, *Hirudo medicinalis* (Muller, K. J. *et al*, 1981; Kristan, W. B. and Shaw, B. K., 1997; Kristan, W. B., Jr., 2000). Three major groups of sensory neurons, named for their specific modality, are the T (touch), P (pressure), and N (nocioceptive) neurons. The T and P cells each have specific receptive fields that cover part of the body surface in each segment. For example, the four P cells per segment divide up the circumference of the body wall into dorsal left and right and ventral left and right quadrants with overlapping receptive fields (Nicholls, J. G. and Baylor, D. A., 1968). These sensory neurons provide the sensory inputs to the CNS underlying a variety of motor functions such as directionally specific avoidance reflexes (Lewis, J. E. and Kristan, W. B., 1998).

Invertebrates with a tough cuticle made from chitin, that is, arthropods, have a variety of sensory cells that can report discriminative touch and proprioception from the body surface. Among those are three major receptor types: two types of hair sensillae and cuticular stress receptors, the campaniform sensillae.

6.17.2.1 Trichoid Sensillae

Trichoid sensillae are typical mechanosensory hair sensillae that possess a single sensory neuron at their base, just below the socket in which the hair shaft is articulated, that is sensitive to displacement of the tactile hair (e.g., Klee, S. and Thurm, U., 1986). Trichoid hairs can vary in length from as short as 60 μm to more than 750 μm (Newland, P. L., 1991a; 1991b). The thickness of the hair shaft can vary in different regions of the body. Filiform hairs are long and thin while bristle hairs are short and thick. Correlated with these changes in thickness are changes in stiffness of the socket of the hairs, which determines whether a trichoid hair can be very sensitive to small forces exerted by sound pressure or small air currents (e.g., Pflüger, H. J. and Tautz, J., 1982; Shimozawa, T. and Kanou, M., 1984) or sensitive only to stronger mechanosensory stimuli, like touch, as in case of the bristle hairs. In many cases trichoid sensillae also exhibit directional sensitivity (e.g., Newland, P. L., 1991a; 1991b). A case study illustrating the role of these receptors in sensing air currents and predator avoidance is the insect cercal system (see below).

6.17.2.2 Basiconic Sensillae

Basiconic sensillae are peg-like structures with a shaft that is generally much shorter than trichoid hair sensillae, often in the range of 30–50 µm (Newland, P. L. and Burrows, M., 1994). Most often basiconic sensillae exhibit directional sensitivity (ibid). The sensitivity of the basiconic sensillae to displacement is very high, and is on the order of a few degrees. These sensillae are much more sensitive than the trichoid sensillae. In addition, the shaft of the basiconic sensilae has a pore at its tip that allows access for chemicals to the dendrites of chemosensory neurons inside the hair. Each basiconic sensillum is innervated by five to ten sensory neurons, with one of them being a chemoreceptive sensory neuron (e.g., Newland, P. L. *et al.*, 2000). Together with the trichoid receptors, these sensillae are the relevant input elements for several simple targeted movement patterns in insects (Berkowitz, A. and Laurent, G., 1996; Matheson, T., 1997; Page, K. L. and Matheson, T., 2005).

6.17.2.3 Campaniform Sensillae

Campaniform sensillae reside in the cuticle and respond to stress and torsion of the cuticle. Their outer appearance is best described as an ovoid depression of the cuticle. Underneath the flexible central cuticular dome, a single sensory neuron inserts into the surrounding tissue. Compression of the cuticle perpendicular to the length axis of the ovoid sensillum excites the sensory neuron (Spinola, S. M. and Chapman, K. M., 1975). Individual campaniform sensillae are found on the insect leg (Burrows, M. and Pflüger, H. J., 1995; Hustert, R. *et al.*, 1981; Zill, S. N. and Moran, D. T., 1981; Zill, S. N. *et al.*, 2004) or they may be arranged in groups, most often close to the joints (Hustert, R. *et al.*, 1981; Bässler, U. and Hofmann, T., 1986; Mücke, A., 1991; Akay, T. *et al.*, 2001). The mechanics of the campaniform sensillae also make this receptor directionally sensitive. Torsion of the cuticle, and excitation of the receptor, may arise either from active muscle contractions or from passive externally imposed stress (Delcomyn, F., 1991). Considering the first kind of activation of the campaniform sensillae, that is, torsion of the cuticle upon muscle activity, the campaniform sensillae serve a function in motor control that parallels closely the role of group Ib afferents, that is, the Golgi tendon organs in vertebrates (cf. Pearson, K. G., 2000; Zill, S. N. *et al.*, 2004; Büschges, A., 2005).

6.17.3 Mapping in Invertebrates

A characteristic feature of CNSs is that sensory information is represented as neural maps at one or more levels of their processing. These maps may be organized with respect to the location of the sensory neuron or organized with respect to the parameter space encoded by the sensory signals. As such, the projections of mechanosensory neurons on the limbs of invertebrates form somatotopic maps in which the spatial location of each signal is maintained (e.g., Zill, S. N. *et al.*, 1980; Murphey, R. K., 1981; Pflüger, H. J. *et al.*, 1981; Levine, R. B. *et al.*, 1985; Newland, P. L., 1991a; 1991b). Maps of the other sensory modalities can be organized differently, for example, for the eyes by forming retinotopic maps in the visual pathway (Strausfeld, N. S., 1976) or for auditory signals by forming tonotopic maps (Oldfield, B. P., 1982; Römer, H., 1983; Römer, H. *et al.*, 1988). In invertebrates, these maps are formed at a given morphological level where information processing takes place and they are not dependent on, or attributed to, any hierarchical level of the nervous system. Somatotopic mechanosensory maps are found in the segmental ganglia, retinotopical maps in the invertebrate brain and tonotopic maps in thoracic ganglia.

6.17.4 Case Studies Illustrating Principles of Somatosensory Organization and Processing in Invertebrates

The sensory processing in somatosensation is related to the representation of the body surface on a higher order level in sensory processing. Therefore, somatosensation can only be present in invertebrates that have a CNS, that is, in organisms from articulates, like annelids, onwards. Several arthropod systems have been investigated in detail that exhibit features related to vertebrate somatosensation. In the following section we will introduce two different examples for somatosensation in invertebrates (insects) where they have most thoroughly been studied.

6.17.4.1 The Insect Cercal System

The cercal system of insects is responsible for the detection and monitoring of wind currents on the body surface. This system consists of a bilateral pair of cerci which are tapered spike-shaped structures

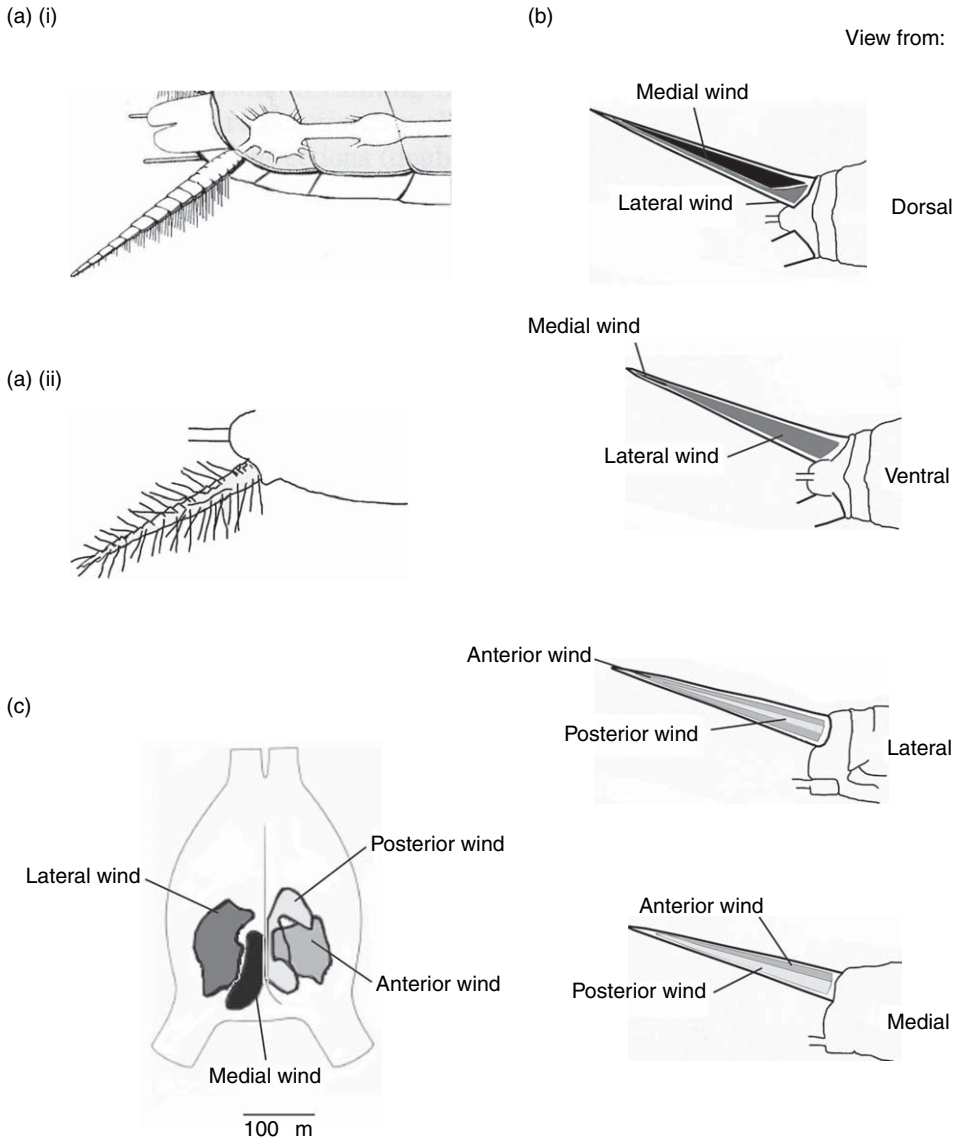

Figure 1 Mapping of cercal hair receptors in the cockroach and cricket. (a) (i) Schematic drawing of a single cercus and the last abdominal ganglion in the cockroach, (ii) schematic drawing of a circus and filiform hairs in the cricket. (b) Mapping of the directional sensitivity of the hairs on the surface (dorsal, ventral, lateral, and medial) of the cricket cercus. (c) The functional organization of the cereal glomerulus in the ganglionic neuropil. There are four almost entirely nonoverlapping neuropil regions corresponding to different wind from four quadrants.

extending posteriorly from the last abdominal segment of the animal. Each cercus has several hundred filiform mechanoreceptive hairs that are organized into regular rows and columns and each hair is mechanically coupled to a single afferent neuron. In the cockroach (Figure 1(a)(i)) these hairs are arranged in rows of nine long (0.5–1.0 mm) hairs on each of the 19 cercal segments except for the basal and tip segments. The homologous hairs at a given position along the segment are organized in columns of similarly oriented hairs that are aligned along the length of the cercus. The hairs in a given column are functionally equivalent in that they are all oriented with respect their axis of (easiest) mechanical deflection (Nicklaus, R., 1965). This precise arrangement of sensory hairs is also seen in the cricket cercal system (Figure 1(a)(ii)), where the circumferential location of the hair is precisely correlated with the directional tuning of the hairs (Palka, J. *et al.*, 1977; Bacon, J. P. and Murphey, R. K., 1984).

The afferent neurons are tonicly active and deflection in the preferred direction depolarizes and hence increases the firing rate of the afferent, while deflection in the opposite direction (−180°) inhibits the neuron and decreases the firing rate. The orientation of the optimal deflection axis is different for each of the columns and the angular orientation of the deflection is shifted sequentially from column to column in a given row. The response tuning curves to wind stimulation are rather broad, but are generally restricted to wind input from a single spatial quadrant (Westin, J., 1979). The different mechanical properties of the hairs results in different coding properties. In the cricket, long hairs are more flexible, respond to low-frequency air currents and code for wind velocity, while short hairs are stiffer, respond only to high frequencies, and code for wind acceleration (Shimozawa, T. and Kanou, M., 1984). The cercal hairs therefore constitute a receptor system that encode wind direction information and dynamics and the ensemble of receptors can completely map air currents on the body surface and hence in space around the animal.

Multiple inputs from cercal afferents are processed by interneurons in the terminal abdominal ganglion of the CNS in order to construct higher order maps of the sensory space. These convergent inputs have been extensively described in the cricket and cockroach CNS. There are seven giant interneurons (GI 1–7) in the cockroach that integrate cercial afferent inputs (Westin, J. *et al.*, 1977). The interneuronal tuning curves are generally broader than the individual afferent tuning curves and the distribution of afferent inputs and their synaptic strengths determine the directional tuning of the individual GIs. The interneurons also appear to receive inputs of differing sign from specific receptors that serves to sculpt their response properties.

6.17.4.1.1 Central processing of cercal afferent information

A feature of the central organization of somatosensory systems is the relatively strict topographic organization of sensory space in the CNS. For example in the mammalian somatosensory system, touch or pressure receptors that innervate an area on the body surface are mapped to similar adjacent higher-order neurons in somatosensory cortex, resulting from a projection of adjacent sensory neurons to adjacent cortical cells. This somatotopic mapping produces the classical homunculus representation of the body surface in the cortex. However, in many systems such as the visual and auditory systems, maps of sensory features in the cortex are often computational maps (Konishi, M., 1986; Knudsen, E. I., 1987) that are not organized on a topological basis, but rather serve to map the variation of some derived parameter of sensory input to higher-order neurons. A simple variant of a computational map appears to be present in the interneurons that receive inputs from cercial primary afferents in the cricket.

As in the cockroach, the cercal hairs of the cricket are arranged circumferentially along the cercus and each hair has a preferred stimulus direction of stimulation (Figure 1(b); Palka, J. *et al.*, 1977; Bacon, J. P. and Murphey, R. K., 1984). However, unlike the arrangement in the cockroach, the hairs are more randomly arranged on the cercus with respect to their preferred direction (Figure 1(b); Walthall, W. W. and Murphey, R. K., 1986) although they are clustered with respect to their preferred direction. The hairs therefore are not continuously mapped topographically on the surface of the cercus. However, the presynaptic arborization of individual afferent terminals in the abdominal ganglion project to specific regions in the ganglionic neuropil that are correlated with the directional specificity of the individual hair, thus establishing a map of the sensory array in the CNS (Murphey, R. K., 1981; Bacon, J. P. and Murphey, R. K., 1984; Jacobs, G. A. and Nevin, R., 1991).

Cercal afferents can be grouped into four major classes based on their directional sensitivity (Figure 1; Bacon, J. P. and Murphey, R. K., 1984.) The afferent terminals of these four classes have been shown to terminate in specific regions of the neuropil of the terminal abdominal ganglion that define four corresponding regions of directional sensitivity in the second-order sensory interneurons in the ganglion (Figure 1(c)). Centrally, the circumferential position of each hair on the cercus, and its longitudinal position, is associated with a specific terminal arborization (Thompson, K. S. *et al.*, 1992).

A simple model of the directional sensitivity of the interneurons based on their monosynaptic inputs from the cercal afferents can account for the major features of the directional sensitivity of the interneurons (Bacon, J. P. and Murphey, R. K., 1984; Shephard, D. and Murphey, R. K., 1986). In a more detailed study of the central processing of cercal input, Jacobs G. A. *et al.* (1986) demonstrated that for one interneuron (10-3) there are distinct dendritic branches of this interneuron that receive afferent

input and these regions have different receptive fields. Summation of the individual receptive fields could account for the interneuron's total receptive field, but the precise directional sensitivity could not be predicted by simple linear summation. Specific afferents were identified that inhibited interneuron 10-3 via polysynaptic connections and the electrotonic structure of the interneuron was also found to play an important role in this overall computation.

A detailed analysis of the neuroanatomical organization of the projections of wind-sensitive afferents in the CNS revealed that the central map of wind direction was formed by projections of afferents with similar direction aborizing adjacent to each other, thus composing a global map of wind direction in the CNS (Jacobs, G. A. and Theunissen, F. E., 1996). The projections of the afferents form a spiral shape with stimulus direction mapped continuously along the spiral. The conclusion was that there was not a topographic projection of the sensory epithelium to the CNS, but rather that the continuous central representation of wind direction was synthesized by the anatomic organization of the afferent terminals, that were independent of the location of the specific afferent on the cercus.

6.17.4.1.2 Mapping of the surface of the insect leg by mechanosensory signals in the locust nervous system

The surface of an insect leg (Figure 2(a)) is covered by exteroceptors, the most prominent ones being hair sensillae and campaniform sensillae. These sensors provide information from the surface of the leg and can monitor contact of an object with the cuticle. In addition to these receptors, proprioceptors are located on and in the leg that provide information about movement and position of the joints. In his detailed account of the neurobiology of the locust, Burrows M. (1996) estimated that there are a few hundred proprioceptive afferent axons in locust leg nerves, while the majority of the approximately 10 000 sensory axons from the leg arise from exteroceptors, including the hair sensillae. The mechanosensory trichoid and basiconic hair sensillae send their afferent axons into the segmental ganglion, with the latter being accompanied by chemoreceptive afferents (Newland, P. L. and Burrows, M., 1994; 1997). The afferents from the trichoid sensillae all project to a common region in the most ventral portion of the neuropil of the thoracic ganglia, that is, the ventral, anterior, and lateral ventral association center (VAC; Figure 2(b)). In this region of the ganglion almost exclusively arborizations of interneurons are present, while almost no arborizations of leg motorneurons are present. The arborizations of the hair sensillae in the segmental ganglion are arranged in a way that represents their origin on the surface of the segmental appendage (Newland, P. L. and Burrows, M., 1997; Newland, P. L. *et al*., 2000). Clear topographical maps reflecting the legs surface can be found for the arborizations of afferents of hair sensors in the locust (Figure 2(b)). Afferents from the leg arborize so that the surface of the leg is closely represented in the internal neural map of the leg (Figure 2(c)). Afferents from the tarsus project to more lateral regions as compared to afferents from the trochanter and coxa, and the opposite is the case for afferents from more centrally located afferents (Newland, P. L. *et al*., 2000). Similarly, arborizations of hair sensillae are different for hairs on the ventral, dorsal, anterior, and posterior surface of the leg. The subsequent neural levels of processing mirror this mapping so that interneurons exhibit receptive fields that result from their specific dendritic branching pattern in the area of the VAC (Newland, P. L., 1991a; 1991b; Burrows, M. and Newland, P. L., 1993). These interneurons are the neural elements in a variety of local reflex circuits that are generated in response to touch stimuli of the leg. These reflexes act to ensure posture and maintain the mobility of the leg by moving the leg away from the assumed origin of stimulation. For example, when the dorsal femur is touched the trochater is depressed, the tibia flexed, and the tarsus levated and when the ventral tibiae is touched the trochanter is levated the tibia extended and the tarsus depressed (summary in Burrows, M., 1996).

It appears that the somatosensory mapping of the locust leg within the CNS not only reflects a topological organization, but also bears some relation to the sensorimotor transformations involving individual afferents. In that respect the somatotopic mapping of the locust leg in the CNS may share similarities to findings on cutaneous somatotopy in the spinal cord of vertebrates (Willis, W. D. and Coggeshall, R. E., 1991; Woodbury, C. J. and Scott, S. A., 1991; Levinsson, A. *et al*., 2002). However, although current data suggest that somatotopic disruption is common in the vertebrate spinal cord (Molander, C. and Grant, G., 1985; Florence, S. L. *et al*., 1991), it does not appear to exist for somatosensory projections of leg afferents in the insect CNS.

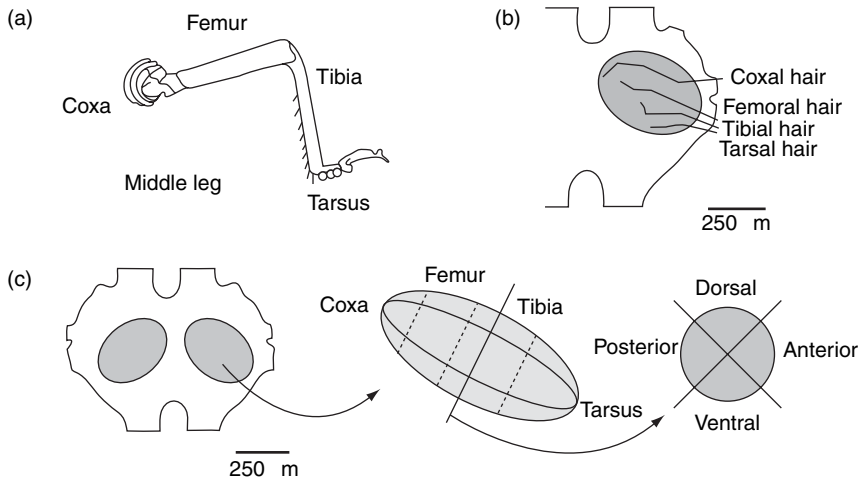

Figure 2 Mapping of exteroreceptive afferents in the mesothoracic ganglion of the locust. (a) Schematic drawing of the locust middle leg and its four main partitions (see also Burrows, M., 1996). (b) Schematic representation of the branching of the primary neurites of trichoid hairs from coxa, femur, tibia, and tarsus of the locust middle leg. (c) Schematic drawing of the main arborization area of leg exteroceptors in the mesothoracic ganglion in the ventral association center (VAC). The first inset in the middle shows a top view of the spatial mapping of afferents from the leg segments in that area. The second inset to the right gives a transection of the VAC showing the order of topographical mapping of leg afferents with respect to their location in three-dimensional space on a given segment.

Acknowledgments

We are grateful to Dr. Tim Mentel for his suggestions on the manuscript and Sharon Meyen-Southard for technical support in editing the text and preparing the figures.

Glossary

BOLD Blood oxygen level-dependent (BOLD) responses are the measured signals in functional magnetic imaging studies. BOLD indicates brain regions, especially in the cortex, where blood flows have increased due to heightened neural activity in the underlying tissue. The blood flows are greater than the metabolism needed to support the activity, which leads to greater oxygenation in the affected site. As oxygenated blood is less paramagnetic, there is lower suppression of the magnetic fields and hence, larger measured local magnetic signals in the region of increased neural activity.

compensatory processing An eighteenth-century concept that described substitution of heightened acuity in retained sensory capacities in response to severe sensory deprivation such as blindness or deafness.

dot-gap densities An aspect of braille cell patterns involves the location of raised dots within a standard two column by three row array. Adjacent braille cells that spell words vary as to whether comparably positioned dots are raised in adjoining series of letters. These differences create variations in the size and frequency of spaces between dots in any given row within a word and between adjacent words.

dot numerosity An aspect of braille cell patterns involves the number of raised dots. More raised dots for a particular braille letter indicate greater dot numerosity.

event-related potentials (ERPs) A technique that measures synchronized electrical responses in the brain through electrodes attached to the scalp. Usually some external stimulus is used to elicit these stereotypical responses. ERPs are seen only after averaging recordings from dozens or hundreds of synchronized events. The timing of recorded negative and positive potentials reflects ongoing brain activity, including possible cognitive processes such as attention.

GABA Gamma-aminobutyric acid is an inhibitory neurotransmitter found throughout the vertebrate central nervous system.

global–holistic An entire object is perceived as a single entity.

haptics An object's properties are perceived through touch by actively moving a portion of skin, usually a fingertip, over the object.

isomorphic response patterns See spatial response profiles.

odd-ball targets A paradigm in which a repeated series of similar stimuli is interrupted by presentation of a stimulus with different parameters. Detecting these unusual and infrequent events often requires attention.

oxygen extraction fraction (OEF) A measure of brain activity related to the ratio of fractional changes in cerebral blood flow (CBF) and cerebral metabolic rate of oxygen consumption ($CMRO_2$): $CBF/CMRO_2$.

PET Positron emission tomography is a nuclear medicine imaging technique that is based on scanning the brain (or other organ) after intravenously injecting (or inhaling) a short-lived radioactive tracer isotope, which decays by emitting a positron. Detection occurs when a burst of light is produced where positrons encounter and annihilate with an electron to produce a pair of photons. Coincident detection of photon pairs by arrays of photodetectors and back-projection algorithms localize the source of the positrons.

phosphene A sensation of seeing light is caused by nonvisual stimulation of the retina or visual cortex.

retinopathy of prematurity A potentially blinding disease of the retina that mainly affects prematurely born babies. The condition develops as a consequence of abnormal retinal vessel growth in areas where normal retinal vascularization has not yet occurred. Normally retinal blood vessel growth is mostly complete in full-term babies. In premature infants, before normal blood vessels reach the edges of the retina, normal vessel growth is replaced. The abnormal blood vessels are fragile, can leak, and consequently can scar the retina and even lead to retinal detachment.

S1 First or primary somatosensory cortex is located along the postcentral gyrus of parietal cortex in primates. Historically, it was the first cortical region identified that responded to stimulation of peripheral mechanoreceptors which are responsible for the sense of touch.

S2 Second somatosensory cortex is located lateral to S1 and along the parietal operculum in primates. Historically, it was the second cortical region identified that responded to stimulation of peripheral mechanoreceptors.

SA-I afferent activity A type of peripheral mechanoreceptor that shows persistent, slowly adapting responses to constant pressure.

spatial response profiles A topographically distributed representation of neural responses evoked by sequential, spatially iterated stimulation, usually across a tactile object. The spatially represented responses are directly triggered by the structure of the touched object. The response pattern is said to be isomorphic where it faithfully maps an object's shape.

transcranial magnetic stimulation (TMS) A noninvasive technique through which neurons in the brain can be excited. Short duration, rapidly changing magnetic pulses are passed through to the underlying brain from a coil placed on a section of skull. Cortical activity in the affected region is excited by induced electric currents momentarily induced by the magnetic fields. Pulse application is most effective when applied repetitively.

two-point threshold A measurement of the minimum detectable distance between two points simultaneously applied to the skin.

vibrissae Elongated hairs used as tactile sensing organs and mostly concentrated on the faces of furry animals.

von Frey filament von Frey, a nineteenth-century psychophysicist, first described using fine wires or hairs of varying diameter to study the sense of contact force against the skin. His studies utilized Hook's principle that a constant force is delivered and proportional to the extent of recoverable inwards bends. Filaments of different diameters have different spring constants and therefore produce a constant force proportional to the filament diameter. von Frey calibrated the forces produced by different diameter filaments (cat's vibrissal hairs) at the first bend and used these to determine the minimum detectable tactile contact force on different regions of skin.

6.18.1 Reading by Touch

6.18.1.1 Somatosensory Aspects of Braille Reading

Braille reading involves pattern recognition of mechanical stimulation arising from small scale, 2D coded, embossed dot arrays (Millar, S., 1997; Mountcastle, V. B., 2005). Each braille cell is based on a six-dot pattern arranged into two columns of three each (Figure 1), which provides 64 different dot patterns. In the standard braille matrix, dots are ~1 mm in diameter and ~0.45 mm high. Interdot spacing within a cell is 2.28 mm and between cells is 6.35 mm. Dot spacing is above human thresholds of 0.7–0.9 mm on the fingertip (Mountcastle, V. B., 2005). Braille letter patterns are more distinguishable, and therefore easier to read than embossed letters or even letters made with braille-like dots (Loomis, J. M., 1981). It is the patterns rather than the dots *per se* that makes braille more legible. Braille patterns lack multiple distinctive features since the presence or absence of any dot changes the character. Each dot arrangement defines a unique letter or a word in contracted braille (Figure 1).

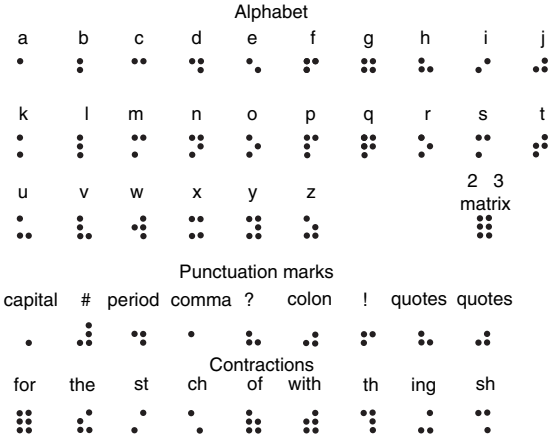

Figure 1 American braille cell patterns for alphabet, punctuation marks, and some braille II contractions.

The lateral scanning movements of skilled braillists evoke distinct tactile stimulation from each braille cell and a rapid, complex stream of intermittent stimulation from every word and line of text. These scanning movements across the dots effectively activate afferent nerve endings found in the glabrous skin finger tip (Mountcastle, V. B., 2005). The slowly adapting Merkel cell-associated afferents (SA-I) especially resolve individual dots in typical braille cells (Johnson, K. O. and Lamb, G. D., 1981). Reconstructed population spatial response profiles from various peripheral afferents showed that only SA-I afferents coded the spatial structure of braille cell dot patterns (Phillips, J. *et al.*, 1990). SA-I spatial response profiles persist with scanning at 20–120 mm s^{-1}, speeds that span the typical range of braille reading rates of 60–175 words per minute. Other low-threshold peripheral afferents are also activated by braille dot arrays (Johnson, K. O. and Lamb, G. D., 1981), but their contribution to braille reading is less certain because the spatial response profiles are less distinctive for different braille patterns.

A nearly isomorphic transformation of the peripheral SA-I activity reaches area 3b and some area 1 cells in the primary somatosensory cortex (Phillips, J. R. *et al.*, 1988). These faithful replications of peripheral responses transmit information to the cortex where subsequent decoding and linkage to linguistics support tactile reading. Mountcastle V. B. (2005) lists several hypotheses plausibly underlying observed isomorphic cortical responses:

1. Each synaptic stage between periphery and cortex must respond nearly simultaneously.
2. Temporal dispersion between peripheral receptor to cortical responses must be minimal despite conduction times and synaptic delays.

3. Transient responses are most critical at each synapse because only 75–100 ms is available for perceptual processing of a braille cell in skilled braillists.
4. Activation from successive braille cells is independent of each other.
5. Isomorphic transmission of braille cell patterns relies on spatially distributed activity from peripheral receptors and the population of activated cortical neurons.

6.18.1.2 Shape or Texture Processing

The possible braille cell physical attributes perceived during reading are dot numerosity, texture, and spatial shape (Millar, S., 1985). Additionally, a tactile feature produced by fluent braille reading is sensing lateral shearing produced by the density of dot gaps within individual braille cells (Millar, S., 1987; Pring, L., 1994). Thus, flowing lateral movements of the reading finger across the text transform braille cell static spatial shapes into a dynamically changing spatial–temporal pattern. These patterns vary with braille letters and characters due to differences in dot-gap densities, a texture feature, which the SA-I afferent nerve endings also excel at coding (Connor, C. E. *et al.*, 1990; Connor, C. E. and Johnson, K. O., 1992). Thus, fluid hand movements in fluent reading highlight the possibility of temporally extended dynamic patterns (Millar, S., 1997).

Good readers presumably do not use global–holistic letter or word shape coding (Nolan, C. and Kederis, C., 1969; Millar, S., 1984a; Pring, L., 1985; Millar, S., 1987; Pring, L., 1994). In contrast, a global shape hypothesis receives strong buttressing from neurophysiological findings that braille spatial patterns are coded isomorphically. However, many S1 (primary somatosensory cortex) cells and all other activated cortical areas do not show isomorphic response patterns that are tied to the global shapes of braille cells. Whether nonisomorphic response patterns solely derive from input projected by SA-I afferent activity or indicate input from other activated peripheral afferents is unknown. Decoding nonisomorphic response patterns remains an important unresolved issue. Current physiology also does not adequately encompass the actual events in fluent text reading in which top-down linguistic content drives perceptual processing (Millar, S., 1997). Thus, detection of the spatial structure of individual braille cells probably becomes subservient to content-driven discrimination of the text.

6.18.1.3 One- or Two-Handed Braille Reading

A critical aspect of reading braille is simultaneously processing both spatial and verbal components of the text (Millar, S., 1997). The resulting integration of the spatial and verbal domains is often shared across two hands, especially in more proficient readers (Davidson, P. W. *et al.*, 1992). Nevertheless, there is discrepant evidence on the cerebral lateralization of braille reading (Semenza, C. *et al.*, 1996), which, as a linguistic task dominated by left hemisphere processing (Burton, H. *et al.*, 2002a), might predict a right-hand preference. Consistent with left linguistic lateralization, one study demonstrated a right-hand advantage when a matching task required processing name identities (e.g., a verbal code) as opposed to the physical identities of letters (Semenza, C. *et al.*, 1996). However, according to Millar, there is no best hand for braille reading (Millar, S., 1984b) because proficient reading depends on simultaneous verbal and spatial information processing that commonly involves two-handed reading. In addition, reading proficiency appears related to task demands and an individual's proclivities as opposed to any left hemisphere specialization for linguistic factors in braille reading (Millar, S., 1997).

Most readers prefer to use two hands, and bimanual reading is faster (Davidson, P. W. *et al.*, 1992). Reading strategies also vary widely wherein the first segment of a line might be explored by the left hand, a second segment conjointly and a third by the right hand (Bertelson, P. *et al.*, 1985). Analyses of braille reading based on photographing the hands from below transparent braille text showed no evidence for simultaneous, parallel text reading even with conjoint hand movements across the text (Millar, S., 1997). One finger reads while the other marks spatial features of the text (e.g., spaces, line position). Two fingers never show simultaneous skin compression over textual dots that characterize reading even when both fingers are simultaneously over different text (Millar, S., 1997). One fingertip pressed against the dots while the other sequentially was pushed into spaces between braille cells or adjacent words in instances of apparently tandem and juxtaposed reading (Millar, S., 1997). Thus, one finger reads while the other simultaneously tracks the layout of the text.

6.18.2 Tactile Acuity Following Visual Deprivation

6.18.2.1 Heightened Tactile Acuity

Blind people are traditionally believed to be better at perceiving tactile stimuli that go unnoticed by sighted individuals possibly because of obligatory expanded experience with haptics. In 1749, Diderot proposed the concept of compensatory processing in remaining senses after the loss of one sensory system. In 1890, William James suggested that compensation led to acquiring superior acuity in the intact senses (cited in Röder, B. and Rösler, F., 2004). However, in blind and sighted people, equivalent tactile receptor sensitivity thresholds are found over approximately a six-decade age range (Stevens, J. *et al.*, 1996), and tactile acuity thresholds on the fingers rise at nearly identical rates with age (Stevens, J. *et al.*, 1996; Goldreich, D. and Kanics, I. M., 2003). Threshold increases with age presumably reflect decreases in peripheral receptor densities and/or central neuron populations that are not affected by blindness. Thus, it is doubtful that peripheral receptor sensitivity changes in blind people. The one exception to these findings is peripheral neuropathy in individuals whose blindness arises from diabetic retinopathy (Hollins, M., 1989). In contrast are reports of enlarged and elongated facial vibrissae (e.g., peripheral tactile organs) in cats and mice visually deprived at birth (Rauschecker, J. P. *et al.*, 1992). Altered vibrissae anatomy possibly was a consequence of increased haptic usage (Rauschecker, J. P. *et al.*, 1992). As noted below, learned skills are a more probable explanation for superior tactile acuity in blind humans because age of blindness onset, extent of visual experience, and level of retained light sensitivity did not affect the uniformity of tactile acuity findings across blind subgroups (Stevens, J. *et al.*, 1996).

No differences in tactile thresholds between blind and sighted people have been reported for tactile tasks that are based on detecting probable differences in the magnitude of peripheral receptor activity. For example, blind people show no superiority in von Frey filament force detection thresholds (Axelrod, S., 1959; Pascual-Leone, A. and Torres, F., 1993; Sterr, A. *et al.*, 2003). No group threshold differences were reported even with servo-controlled application of contact force that was distributed over a fingertip (Goldreich, D. and Kanics, I. M., 2003). Blind and sighted individuals are also equally adept at distinguishing the lengths of thin bars pressed against the finger (Stevens, J. *et al.*, 1996). Both groups comparably discern tactile roughness differences between horizontal gratings with variable ridge widths (Grant, A. C. *et al.*, 2000) or textures such as sandpaper or abrasive stones, whether actively or passively touched (Heller, M. A., 1989a). Each of these tasks involves detecting stimulus magnitude differences, which reflect response vigor in activated peripheral receptors and/or the number and types of activated receptors.

Distinctions in tactile acuity between blind and sighted people have been mixed when using the classic test of the minimum detectable distance between two, passively applied points. The ambiguity arises because traditional two-point assessments are prone to intensity differences from stimulating more or less skin with, respectively, two or one point (Johnson, K. O. and Phillips, J. R., 1981). Study protocols that ignored this confound reported no two-point threshold differences between blind and sighted persons (Axelrod, S., 1959; Pascual-Leone, A. and Torres, F., 1993). In contrast, Stevens J. *et al.* (1996) reported that people with early- and late-onset blindness, and some with residual light perception, similarly detected ~15% shorter gap distances than sighted. Stevens and co-workers' study utilized a two-alternative forced choice task in which the intensity confound based on perceived stimulation length was balanced. The task involved discriminating between a two-point gap versus an uninterrupted narrow bar whose length equaled the distance between the two points. Blind people also differentiated transverse compared to longitudinal orientation of two-point stimulation with ~40% shorter distances between points compared to sighted people (Stevens, J. *et al.*, 1996). All blind participants were braille literate, and the test results were obtained from the preferred braille reading index finger.

Greater acuity on these tests possibly reflected practice in attending to features of braille dot displays. For example, learning to distinguish braille dot patterns that differ by dot numerosity (Figure 1, e.g., f vs. p) possibly provides practice with detecting two points as in the test used by Stevens and co-workers. Similarly, learning to read braille letters based on the angle of dots across the first and second column (Figure 1, e.g., e vs. i) might provide practice in noting the orientation of two-point stimulation. Another consequence of these developed skills is that blind braillists recognize braille-like tactile patterns better than sighted, but only for dot pattern

arrays whose size (3×3 and 4×4) resembled standard braille (e.g., 2×3) (Foulke, E. and Warm, J. S., 1967). Cognitive guidance subsequent to extensive practice is also relatively specific to the task and learned tactile patterns, because blind and sighted performance differences did not occur when participants discriminated patterns created from unfamiliar, larger embossed dot matrices (e.g., 5×5 or 6×6), even when using the practiced braille reading finger (Foulke, E. and Warm, J. S., 1967).

Heightened sensitivity in blind people is also observed with tactile stimuli unrelated to braille. A grating orientation task involves discriminating between transverse and longitudinal orientations of passively applied square-wave gratings (e.g., equal groove and ridge widths), where the variable parameter is groove width (Van Boven, R. W. and Johnson, K. O., 1994). The minimal groove width is an index of tactile spatial acuity. However, the orientation task involves a fine tactile spatial discrimination for which groove width contributes to the perceptions. Two studies found that blind people detected orientation differences for gratings with smaller groove widths (Van Boven, R. W. *et al.*, 2000; Goldreich, D. and Kanics, I. M., 2003). All blind subgroups had lower groove width thresholds than the sighted group when gratings were applied with calibrated force levels, using a servo-controlled device (Goldreich, D. and Kanics, I. M., 2003), or were applied manually (Van Boven, R. W. *et al.*, 2000). Superior tactile spatial acuity did not correlate with braille reading factors (e.g., years reading, daily usage, age when learned) (Goldreich, D. and Kanics, I. M., 2003). However, tactile acuity on the reading finger was superior to the other fingers; although all fingers were superior compared to sighted individuals (Van Boven, R. W. *et al.*, 2000). Group differences were not found in another study that used the same grating orientation task and manual stimulation (Grant, A. C. *et al.*, 2000). The divergent findings might involve procedural differences.

6.18.2.2 The Effects of Practice and Enhanced Attentive Skills

Superior tactile acuity plausibly ensues from learned sensorimotor skills (Hollins, M., 1989; Davidson, P. W. *et al.*, 1992; Millar, S., 1997; Morgan, M., 1999; Grant, A. C. *et al.*, 2000; D'Angiulli, A. and Waraich, P., 2002) and attention strategies (Millar, S., 1974; Röder, B. and Rösler, F., 2003; Collignon, O. *et al.*, 2006). A real-life example is that reading comprehension persists relatively unchanged in older braillists despite significant declines in braille reading speeds. Age-related structural changes possibly do not affect fluent braillists because they attend to contextual, linguistic content to guide perceptual processing (Millar, S., 1997). In the absence of age-associated cognitive impairments, such lexical skills are probably less affected by age. However, training that leads to superior acuity tends to be confined to the practiced skin surface. For example, late-onset blind individuals have >20% lower thresholds in the grating orientation task on the dominant compared with the nondominant hand (Sathian, K., 2000). In contrast, skin surfaces that normally are not exposed to extensive experience in haptic exploration or tactile literacy, such as the lips, show no tactile discrimination differences between blind and sighted persons (Stevens, J. *et al.*, 1996).

Another study explicitly evaluated the effects of practice and learning to attend tactile differences in a more refined embossed dot detection paradigm (Grant, A. C. *et al.*, 2000). Multiple blind subgroups and sighted individuals detected whether a central dot in a three-dot linear array was offset (Grant, A. C. *et al.*, 2000). On the first assessment, early blind were 50% and late-onset blind were 33% more sensitive than sighted participants. They detected offsets of less than 1 mm, which is considered an example of hyperacuity because the differences are below the limits of tactile spatial acuity. However, there were no group differences after practice. Thresholds declined nearly 50% in sighted, >20% decrease in early blind, and 0% in late-onset blind participants. Irrespective of the tested hand, early- and late-onset subgroups were also not significantly different. Amongst the early blind participants, there were no threshold differences between preferred and nonpreferred braille reading hands. These results indicate that practice rapidly improves performance on a tactile task involving braille-like embossed dots, but only in individuals who have little or no prior experience with attending to tactile distinctions. Smaller or no threshold improvements in the blind participants and an absence of threshold differences between the hands suggest that prior braille literacy had already optimized and generalized cognitive skills affecting tactile perceptual acuity.

Practice effects on tactile acuity are not limited to blind people. Adult professional pianists, who have practiced daily from early childhood, have lower

two-point spatial discrimination thresholds than age-matched nonmusicians and, for the musicians, more hours of daily practice inversely correlated with the magnitudes of lower discrimination thresholds (Ragert, P. *et al.*, 2004).

6.18.2.3 Visual Deprivation and Enhanced Attentive Skills

Superior tactile acuity in blindness might not solely rely on expanded haptic experience because visual deprivation alone possibly induces cognitive changes that contribute to heightened acuity (Goldreich, D. and Kanics, I. M., 2003). Permanent visual deprivation during some critical developmental period is not necessary to demonstrate behaviorally enhanced tactile acuity because sighted individuals improved performance on tactile tasks after blindfolding. In one study (Kauffman, T. *et al.*, 2002), two groups of sighted individuals wore blindfolds for 5 days. One subgroup additionally received 4 h of daily practice learning braille and 2 h of intense tactile stimulation. Two control groups were not blindfolded, and one of these was also exposed to enhanced tactile stimulation. Performance was assessed at days 1, 3, and 5 using two-alternative forced choice identification of whether stimulation was with the same or different braille cell patterns. Blindfolded participants made significantly fewer errors than both groups without visual deprivation. Surprisingly, the blindfolded subgroup that did not receive tactile training performed significantly better than the stimulated group (Théoret, H. *et al.*, 2004), which contradicts reports of heightened acuity following practice on the dot-offset task (Grant, A. C. *et al.*, 2000) and evidence of greater skill in braillists in recognizing braille-like patterns (Foulke, E. and Warm, J. S., 1967). Additionally, shorter-term visual deprivations of 90 min lowered thresholds on a grating orientation task (Facchini, S. and Aglioti, S. M., 2003) and 120 min of blindfolding enhanced accuracy in identifying tactile shapes (Weisser, V. *et al.*, 2005). Awareness of somatosensory and auditory sensations probably increased during blindfolding, which possibly enhanced resource allocations to tactile stimulation during threshold testing.

Tactile encoding might be enhanced by practice-induced improvement in memory recognition of haptically explored objects. For example, blind were faster, but less accurate in recalling tactile nonsense shapes than sighted participants (Millar, S., 1974). The speed–accuracy trade-off might reflect a behavioral strategy rather than recognition recall differences in blind people. Early- and late-onset blind are also better than sighted participants at recalling tangible letters. However, letters presented in a practiced modality (braille for blind and visually for sighted) were remembered with equivalent accuracy by blind and sighted participants (Bliss, I. *et al.*, 2004). However, it is more probable that blind people are superior at directing attention toward selected targeted stimulation (Hötting, K. *et al.*, 2004; Collignon, O. *et al.*, 2006) and at dividing or switching attention between targets (Kujala, T. *et al.*, 1997a). Thus, congenitally blind process the spatial location of attended tactile or auditory stimuli faster in both selective and divided attention conditions (Collignon, O. *et al.*, 2006) and ignore irrelevant stimulation better (Hötting, K. *et al.*, 2004). These differences indicate that in the absence of vision, congenitally/early blind people are qualitatively less distracted by nontarget stimuli and are better at processing target stimuli within intact modalities. Without visual deprivation, sighted people have difficulty dissociating visual and tactile information even when performing tactile tasks (Hollins, M., 1989).

A possible consequence of extensive practice with tactile skills is "a higher-order plasticity" that "alters somatosensory information processing and sensory perception beyond training-specific constraints" (Ragert, P. *et al.*, 2004, p. 477). However, several findings indicate that such metaplastic phenomena might not be universal. For example, equivalent tactile reading speeds occur in blind and sighted people following practice with the Optacon device (Craig, J., 1988), a vibrator-based tactile reading device. Blind people do not show any advantage in learning to read with the Optacon device despite prior developed tactile skills for braille literacy. In addition, those who had the least prior tactile learning showed greater improvement in tactile acuity with practice, as noted above by performance of sighted individuals on the dot-offset task following practice (Grant, A. C. *et al.*, 2000) and on the braille pattern detection task in blindfolded participants who received no extra tactile practice (Théoret, H. *et al.*, 2004).

6.18.2.4 The Blind Artist

A traditional view is that congenitally/early blind people have limited competence to create pictures because they fail to incorporate perceptions of outlines and perspective that are not readily perceived through touch (Hollins, M., 1989). Haptic

perceptions are necessarily atomistic, which possibly makes it difficult to relate parts to an overview of a complex display (Heller, M. A. *et al.*, 2003). Generally, haptic exploration places greater emphasis on substance properties, successive integration of inputs, and the manipulative complexity of hand movements (Klatzky, R. L. *et al.*, 1989). Because of the successive nature of touch, even extensive practice with haptics might not compensate for the structural compartmentalization of form experienced by blind individuals. A possible consequence is that congenitally/early blind people are unable to understand such structural linkages as interposition or covering and perspective. In contrast, Révész G. (1950) hypothesized that late-onset blind people probably retain visual imagery, which directs manual dexterity and helps fuse haptic inputs. Prior visual experience and greater haptic skills possibly allow late-onset blind to perform better on a haptic-embedded figures test (Heller, M. A. *et al.*, 2003) and on identifying tangible drawings (Heller, M. A., 1989b). A contrary view is that congenitally/early blind people can appreciate perspective, overlapping objects, and structural relationships across 3D objects and can interpret external scenes. Examples of these skills are the ability to identify objects in tangible drawings (Kennedy, J., 1993), to perceive separate objects within complex backgrounds (Heller, M. A. *et al.*, 2003), and to draw pictures (Kennedy, J., 1993; 2003; Kennedy, J. M. and Igor, J., 2003; Kennedy, J. and Juricevic, I., 2006).

Spatial perception might not be inherently visual but depends on familiarity and practice to learn rules like linear perspective, convergence, vantage point and depth in pictorial representation (Heller, M. A., 1989b; Heller, M. A. and Kennedy, J. M., 1990; Heller, M. A. *et al.*, 2002; Kennedy, J. M., 2003; Kennedy, J. M. and Igor, J., 2003; Kennedy, J. and Juricevic, I., 2006). Greater superiority in picture naming observed in late-onset blind participants might indicate that the translational rules in pictorial representation were learned from prior visual experience (Heller, M. A., 1989b; Kennedy, J. M. and Igor, J., 2003). A consequence of no familiarity or practice with these rules is that raised outline drawings produced by congenitally/early blind individuals often appear distorted and unrealistic (Figures 2(a)–2(e)). However, even blindfolded sighted participants, who relied only on tactile feedback, produced unrepresentative perspectives in their raised outline drawings of angled stimulus objects (Heller, M. A. *et al.*, 2002), which indicate the need to practice drawing correct perspectives irrespective of visual status.

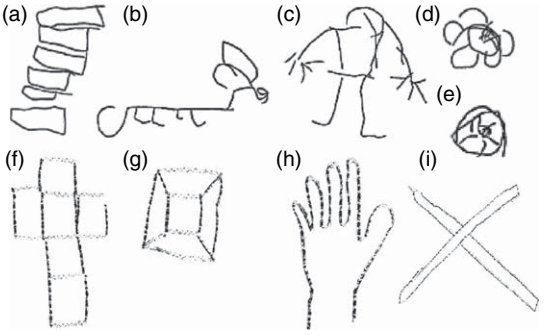

Figure 2 Tangible, raised line drawings produced by early blind individuals. (a)–(e) Drawings made by a 10-year-old blinded at age 21/2. (a) Hexagonal box drawn as six rectangular sides. (b) Stick figure of a dog. (c) Stick figure of a man. (d) Spinning wheel shown with extra loops around the edge for movement. (e) Static wheel drawn with spokes arranged around the center. (f)–(i) Drawings made by a 12–13-year-old blind since birth. (f) A foldout drawing of a cube with all six sides. (g) A cube drawn with vertical sides. (h) A hand. (i) Overlapping pencils showing one on top of the other, note the bottom pencil has its sides occluded. Reproduced from Kennedy, J. 1993. Drawing and the Blind: Pictures to Touch. Yale University Press; Kennedy, J. M. 2003. Drawings from Gaia, a blind girl. Perception 32, 321–340, with permission from Yale University Press.

Because raised outline, tactile drawings predominantly portray visual perceptions as opposed to those obtained through touch, they present a somewhat arbitrary depiction to blind people. As a consequence, tangible drawings produced by congenitally/early blind individuals can appear distorted, especially when the attempt is to show features with a possible haptic provenance (Kennedy, J., 1993). The drawing might incorporate some metaphorical device like a spinning wheel (Figure 2(d)) or an individual running that is not visually representative in 2D drawings (Kennedy, J., 1993). However, blind people can identify objects represented with 3D perspective in tactile pictures (Kennedy, J., 1993; Heller, M. A. *et al.*, 2002) and can recognize raised outline shapes with accuracy comparable to sighted (Heller, M. A. and Kennedy, J. M., 1990). Blind individuals can also create drawings that employ perspective (Figures 2(f)–2(i)) including object overlap (Figure 2(i)) and other visual conventions (Kennedy, J., 1993; Kennedy, J. M., 2003; Kennedy, J. M. and Igor, J., 2003; Kennedy, J. and Juricevic, I., 2006). With practice and feedback that teaches the representational rules, tangible drawings produced by congenitally/early blind individuals can be reasonable

Figure 3 Photograph and self-portrait of Ernesto Masuelli. Reproduced by permission from Révész, G. 1950. Psychology and Art of the Blind. Longmans, Green and Co.

depictions (Kennedy, J., 1993; Kennedy, J. M., 2003; Kennedy, J. M. and Igor, J., 2003) that even indicate foreshortening and convergence (Kennedy, J. and Juricevic, I., 2006). However, the ability to understand perspective is more variable in congenitally/early compared to late-onset blind people (Heller, M. A. *et al.*, 2002).

Révész G. (1950) evaluated whether sculpture produced by congenitally/early blind and late blind individuals had aesthetic qualities. Truly aesthetic accomplishments were noted only in creative and technically trained people with late-onset blindness (Révész, G., 1950). Révész G. concluded that congenitally blind individuals are incapable of creating truly aesthetic sculptures because they lack a unifying sense of form and space. He hypothesized that in a late-blind individual, previous visual world experiences presumably provide a guiding spatial, symmetrical conception that suffuses true aesthetics.

An example of art produced by a late-onset blind person is shown in Figure 3. Masuelli was an artist who first began sculpting 14 years after losing sight through a shell splinter in World War I (Révész, G., 1950). His remarkable artistic ability is highlighted by a comparison between a photograph of the artist and a particularly captivating self-portrait (Figure 3). The aesthetics revealed in Masuelli's sculpture relies on 3D spatial skills.

6.18.2.5 Spatial Cognition and Blindness

Individuals with congenital/early compared to late-onset blindness have diminished processing abilities for spatial information mainly because of difficulties in encoding external cues, frames of reference or configurations (Millar, S., 1994; Gaunet, F. *et al.*, 1997). Absence of early visual experience is especially deleterious to appreciating metrical information obtained through haptic exploration of space even when topological positions are accurately retained (Gaunet, F. *et al.*, 1997). Most congenitally and early-onset blind individuals, even subsequent to improved performance learned through feedback guidance, were unable to learn with comparable accuracy the spatial representations of complex 3D haptic arrays. Late-onset blind and trained blindfolded sighted individuals were similar in performing with greater accuracy (Gaunet, F. *et al.*, 1997). However, contrary findings indicated that a true spatial metric probably is available to even congenitally blind people if they are given more time to establish a representation of space (Heller, M. A. and Kennedy, J. M., 1990). For example, congenitally blind participants had smaller absolute displacement errors in the raised outline drawings they created to represent a top-down perspective of a haptically explored, multiobject scene. Additionally, blind participants had lower absolute distance errors compared to blindfolded sighted participants in a pointing task to memorized proprioceptive targets (Gaunet, F. and Rossetti, Y., 2006).

The role early visual experience plays in integrating and mapping somatosensory stimuli into external spatial coordinates is especially demonstrated by the effects that crossing the hands over the body midline has on tactile perceptions. When sighted, blindfolded sighted, and late-onset blind people detected the temporal order between two tactile stimuli, they required longer interstimulus intervals with the hands held crossed compared to resting in a normal uncrossed position. In contrast, congenitally blind individuals have better temporal resolution of two successive tactile stimuli compared to sighted and late-onset blind for the crossed and uncrossed posture (Röder, B. *et al.*, 2004). In sighted people, for whom vision dominates other sensory modalities, the localization of external tactile events is subjugated to a visual spatial reference frame (Eimer, M., 2004). Crossing the hands creates a conflict between left and right visual space and anatomical left and right hands. Computations are slowed when body-centered proprioceptive and externally referenced tactile coordinates are in conflict (Röder, B. *et al.*, 2004). Visual instruction to the somatosensory system never occurs in congenitally blind. Consequently, these people do not perceive a conflict between

body-centered and externally referenced tactile coordinates because the latter never develops. Therefore, they do not experience computation differences when the hands are crossed. Finding that late-onset blind individuals have delayed perceptions similar to those observed in sighted people with crossed hands posture suggests that early visual experience permanently instructs the somatosensory system with a visually established external coordinate reference frame. These effects persist for life and are probable contributors to the work of blind artists such as Masuelli.

6.18.3 Somatosensory Cortex Changes in Response to Visual Deprivation

6.18.3.1 Evidence for Reorganized Somatosensory Cortex

Extensive sensorimotor experiences involving isolated body regions (e.g., fingers) causes the S1 representation for the affected peripheral anatomy to expand in animals and humans (Jenkins, W. M. *et al.*, 1990; Recanzone, G. H. *et al.*, 1992b; Merzenich, M. M. and Jenkins, W. M., 1993; Elbert, T. *et al.*, 1995; Buonomano, D. V. and Merzenich, M. M., 1998, Ramachandran, V. S. and Hirstein, W., 1998; Pleger, B. *et al.*, 2003). S1 reorganization revealed in animal studies is mostly subsequent to repetitive and stereotypical tactile stimulation protocols. An important feature is neuroplasticity in adult animals, long after any critical developmental period. S1 reorganization in adult animals predict similar S1 changes in both congenitally/early-onset and late-onset blind people. Additionally, in animal studies, a reorganized cortical representation correlated with enhanced tactile discrimination performance (Jenkins, W. M. *et al.*, 1990; Recanzone, G. H. *et al.*, 1992a; 1992c; Xerri, C. *et al.*, 2005), which suggests heightened tactile acuity in blind people might similarly involve S1 reorganization. Neuroplasticity in S1 of congenital/early blind proficient braillists was suggested by a larger distribution of contralateral parietal cortex surface potentials to braille-like stimulation compared to sighted individuals (Pascual-Leone, A. and Torres, F., 1993). Responses were evoked by stimulating the index finger on the reading hand while participants judged whether braille patterns in a pair matched or differed. Two correlative findings involved the application of repetitive transcranial magnetic stimulation (rTMS) to the contralateral sensorimotor cortex. Normally, rTMS to parietal cortex disrupts perception of tactile stimulation (Cohen, L. G. *et al.*, 1991). In blind participants, tactile perceptions were disturbed by rTMS applied over a larger number of contralateral parietal cortex sites (Pascual-Leone, A. and Torres, F., 1993). Supporting evidence for an expanded S1 representation for the right index fingertip also was obtained using vibrotactile stimulation to elicit functional magnetic imaging (fMRI) responses (Burton, H. *et al.*, 2004). Only early-onset blind participants showed an expanded activity distribution across the contralateral S1.

S1 reorganization in blind people was not found in an event-related potential (ERP) study (Röder, B. *et al.*, 1996) that reported similar topographic distributions of the somatosensory evoked N1 component in blind and sighted individuals. (The very short latency early negative component of the ERP (N1 component) reaches maximum amplitude over primary sensory areas and is hypothesized to be a reflection of primary, low-level sensory processing (Röder, B. *et al.*, 1996).) Participants tracked the frequency of odd-ball tactile dot-pattern stimulation. Attention was additionally manipulated by presenting stimulation patterns that were easy or difficult to discriminate. One potential basis for the contrasting results concerns the reading styles of the blind participants. In the study by Pascual-Leone A. and Torres F. (1993), the cortical distribution of ERPs in the blind participants was greater for the preferred reading hand compared to the ERP extent for the opposite homologous finger, which suggests that these participants might have been predominantly one-handed braillists. Reading preference was not specified in the study by Röder B. and co-workers. However, because most fluent braillists read with two hands (see Section 6.18.1.3), S1 reorganization might plausibly be bilateral. Consequently, no hemispheric differences in ERP distributions might occur in two-handed braillists.

S1 reorganization can also involve changes other than selective expanded representations. For example, in a magnetoencephalography study involving multifinger and single-finger braillists (Sterr, A. *et al.*, 1998a), the S1 neuromagnetic dipole distribution in the multifinger braillists was disorganized and enlarged. In contrast, dipole distance was unchanged in single-finger blind braillists compared to sighted individuals. A behavioral correlate of these distinguishable S1 organizations was that multifinger

braillists made more errors when asked to identify the finger on the reading hand that was focally touched (Sterr, A. *et al.*, 1998a; 1998b; 2003). Tactile thresholds were either lower or equal to those in sighted participants (Sterr, A. *et al.*, 1998a; 2003). Currently, these are the only results that link S1 reorganization to tactile acuity in blindness.

Adult animals and humans showed S1 reorganization when they were forced to rely on tactile experience from a restricted limb. However, no S1 reorganization was found in late-onset blind people in one ERP study (Röder, B. *et al.*, 1996) and in several fMRI studies that involved tactile stimulation (Burton, H. *et al.*, 2002a; 2004; 2006). The evidence for S1 expansions has only been obtained in early-onset blind people who are haptically experienced from infancy (Pascual-Leone, A. and Torres, F., 1993; Burton, H. *et al.*, 2004). The absence of S1 expansion in late-onset blind people was neither attributable to differences in extent of tactile stimulation nor to the duration of blindness. The demographic data indicated that early- and late-onset blind participants had similar sensorimotor experiences such as reading braille daily and depending on tactile information in everyday life (Burton, H. *et al.*, 2002a; 2004; 2006).

Transient reorganization of S1 in normally sighted individuals potentially explains the negative findings in late-onset blind people. S1 representation for stimulated fingers reversibly changes when sighted people attend to tasks that involve processing somatosensory stimulation on the hands and fingers (Buchner, H. *et al.*, 1995; Noppeney, U. *et al.*, 1999; Braun, C. *et al.*, 2002; Iguchi, Y. *et al.*, 2005; Schaefer, M. *et al.*, 2005; 2006). In these studies, the distance between neuromagnetic dipoles or ERPs associated with selected fingers expands when attention is directed toward a particular finger. These short-term neuroplasticity effects arise without protracted practice or visual deprivation but depend on the attended focus. Dynamic switching in S1 organization has been hypothesized as cognitive influences on an existing and earlier established stable representation (Braun, C. *et al.*, 2002). Importantly, these rapid transient changes in somatosensory cortex have been observed in cognitive tasks that last less than 10 min (Schaefer, M. *et al.*, 2005) and when tactile stimulation is synchronized with seen touch attributed to the stimulated finger (Schaefer, M. *et al.*, 2006). A key question is whether S1 reorganization observed in congenitally/early-onset blind individuals involves similar attention-based mechanisms and, as such, is plausibly the result of prolonged transient effects. As noted in Section 6.18.2, heightened tactile acuity in blind people is best explained by practice in attending to touch. It is therefore possible that reorganized S1 maps in blind people indicate improved attention skills that are invoked whenever a blind person addresses a tactile task. Consequently, inconsistent evidence regarding S1 expansions might plausibly depend on the attentive demands associated with the stimulation protocols used in different studies and on the tactile attention skills of early- compared to late-onset blind people.

Tactile stimulation also activates lateral parietal cortex bilaterally in blind and sighted people. The affected cortex includes the parietal operculum, adjoining inferior supramarginal gyrus (SMGi), parietal cortex medial to the intraparietal sulcus, and the superior aspect of the supramarginal gyrus (SMGs), which involves previously identified second somatosensory cortex (S2) (Burton, H. *et al.*, 1993; Ledberg, A. *et al.*, 1995; Burton, H., 2001; Eickhoff, S. B. *et al.*, 2006a; 2006b) and an SMGi region possibly analogous to monkey area 7b (Eidelberg, D. and Galaburda, A. M., 1984; Burton, H., 2001). Blind and sighted people show similar distributions of bilateral parietal opercular activity during vibrotactile (Burton, H. *et al.*, 2004), embossed letter (Burton, H. *et al.*, 2006), and braille stimulation (Sadato, N. *et al.*, 2002). Early- and late-onset blind people also showed similar activity distributions in S2 during braille reading (Burton, H. *et al.*, 2002a). These results suggest that blindness or the age of blindness onset does not differentially induce reorganization in lateral parietal somatosensory regions.

6.18.3.2 Does Reorganization Follow a Hebbian Model?

A Hebbian learning model for increased synaptic efficacy has been proposed as a mechanism responsible for cortical reorganization following extensive use or training (Buonomano, D. V. and Merzenich, M. M., 1998; Ramachandran, V. S. and Hirstein, W., 1998). Key features are that repetitive and synchronized neural activity enhances plasticity. In an attempt to implement such synchronization, passive, long duration (3 h) punctate tactile stimulation was applied through small solenoids worn on the right index fingerpad. Participants did not explicitly attend or discriminate the stimulation but engaged in unrelated activity. Tactile stimulation was presented with pulse durations of 10 ms, at an average frequency of 1 Hz, and with pseudorandomized intervals of 100–3000 ms. Stimulation was applied in one group using a probe tip of 50 mm^2 and to a

second group using a smaller 0.8 mm^2 tip (Pleger, B. *et al.*, 2003). The larger probe tip coactivated a greater number of receptors. S1 and S2 finger representation expanded only in the group that was stimulated over the larger skin surface. In the affected group and in the stimulated skin region, two-point spatial discrimination thresholds were lower and single-point localization was disturbed immediately following the stimulation interval. Several issues challenge whether the results based on coactivated stimulation apply to somatosensory cortex reorganization in blindness. In contrast to the stereotypical protocols used by Pleger B. *et al.* (2003), haptic exploration and tactile reading in blind people is tactilely diverse and less sustained. Braille reading also does not produce spatially and temporally correlated tactile stimulation. Neural activation during braille reading is probably not synchronous, although a temporally dynamic signal distributes tactile stimulation across most of the reading fingerpad (Millar, S., 1997). Stimulation timing changes with dot density differences; any possible stimulation synchrony is interrupted as the finger moves across lines and as reading shifts between hands with two-handed reading. Few braillists read continuously for several uninterrupted hours. Thus, tactile reading implausibly replicates the intensity, synchrony and duration of stimulation used to demonstrate S1 and S2 changes immediately following coactive tactile stimulation (Pleger, B. *et al.*, 2003). Despite these differences in stimulation, careful assessments find that blind people also have lower two-point spatial discrimination thresholds (see Section 6.18.2.1). One possibility is that the multiyear training to learn braille and to develop tactile attention skills provides sufficient repetition to satisfy a Hebbian model for somatosensory cortex neuroplasticity. However, supporting evidence for differences in the organization in S1 is contradictory in congenitally/early-onset blind, negative in late-onset blind people, and absent for S2. Potentially, expanded maps in late-blind and sighted individuals are the same as those maps in early-blind. Thus, top-down cognitive effects from attention provide a more probable mechanism for mobilizing resources in tactile tasks. As noted, blind people are more skilled in attending, and attention focused on selected fingers can transiently reorganize S1. It is unknown whether these transient changes can be long lasting and permanent. Consequently, current results do not support a Hebbian mechanism in somatosensory cortex of blind people.

6.18.3.3 Response Dynamics in S1 and S2

Extended exposure to vibrotactile stimulation changes the temporal patterns of S1 single neuron responses in animals (Recanzone, G. H. *et al.*, 1992c). The question is whether similar dynamic changes in brain activity occur in blind people. In imaging studies, some global indices of brain physiology are response magnitude and time course. Response magnitude is expressed as greater regional cerebral blood flow (rCBF) with positron emission tomography (PET), as amplitudes of regional blood oxygen level-dependent (BOLD) signals in fMRI, and as greater voltage of component waveforms in ERPs. For fMRI or ERPs, response time courses are expressed as component latencies and durations. Selective changes in these measures possibly suggest enhanced processing of information.

Evidence of response magnitude distinctions between blind and sighted persons is contradictory. Tactile stimulation did not evoke larger evoked potentials over parietal cortex in blind compared to sighted people in an ERP study where both groups were equally accurate in detecting rare target stimuli (Röder, B. *et al.*, 1996). Blind and sighted individuals showed no BOLD magnitude differences in S1 or S2 when discriminating vibrotactile stimuli (Burton, H. *et al.*, 2004) or embossed capital letters (Burton, H. *et al.*, 2006). In both fMRI studies, performance accuracy was >75% in all groups. In a PET study, only early blind showed greater rCBF in sensorimotor cortex contralateral to the preferred braille reading finger when discriminating braille cell patterns (Sadato, N. *et al.*, 2002). In the latter study, however, late-onset blind and sighted individuals performed at chance, while early-onset blind participants correctly discriminated the braille patterns. These discrepant findings on response magnitudes in S1 are best explained by behavioral performance differences between groups (Burton, H. *et al.*, 2004) and suggest that response magnitudes in S1 do not correlate with blindness.

Congenitally blind have shorter reaction times than sighted individuals when detecting odd-ball tactile or auditory targets (Röder, B. *et al.*, 1996; Kujala, T. *et al.*, 1997b), identifying embossed block capital letters (Burton, H. *et al.*, 2006), recalling tactile nonsense shapes (Millar, S., 1974), and encoding and transforming the spatial orientation of haptic images (Röder, B. *et al.*, 1997). Blind people, and especially those with late-onset blindness, identify tangible drawings faster (Heller, M. A., 2002; Heller, M. A. *et al.*, 2002; 2003). Shorter latency cortical responses possibly underly

speeded responses. Blind exhibit shortened N1 component latencies over parietal cortex to tactile stimulation (Feinsod, M. *et al.*, 1973; Röder, B. *et al.*, 1996). In addition, earlier time-to-peak were noted in S1 and S2 BOLD responses during an embossed letter identification task from early-onset blind compared to late-onset and sighted individuals (Figure 4). An inference from these results is that speeded performance in early-onset blind is causally linked to more efficient processing, and hence, earlier response latencies to tactile stimulation in somatosensory cortex. Greater skill in attending to tactile stimulation possibly accounts for such speeded neural responses.

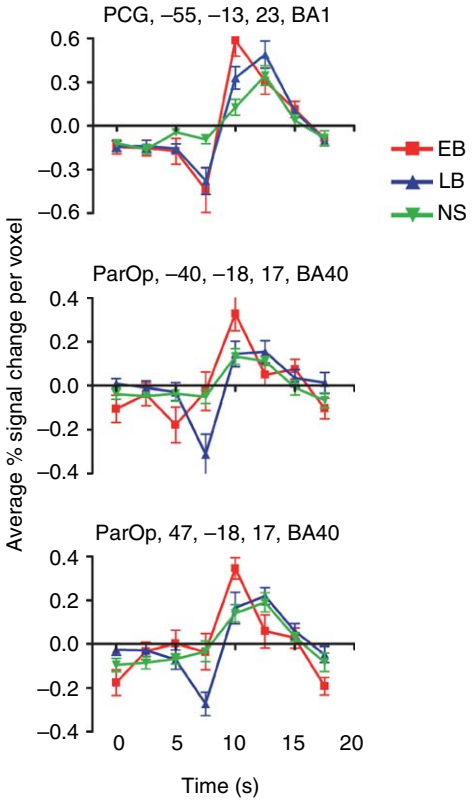

Figure 4 Regional S1 (PCG) and S2 (ParOp) BOLD response time courses during identification of an embossed capital letter with the right index finger in early- (EB), late-onset blind (LB), and sighted (NS) participants. S1 and S2 parietal cortex regions included significant voxels from the time-by-event-type factor in a random effect ANOVA analysis. Repeated measures MANOVA-assessed group differences in the time course profiles from these regions (as described in Burton, H. *et al.*, 2006). Responses in EB differed significantly from those noted in both other groups in left S1 ($p < 0.001$ vs. NS; $p = 0.024$ vs. LB; $p = 0.034$ LB vs. NS), from LB in left S2 ($p = 0.05$; $p = 0.01$ LB vs. NS), and from NS in the right S2 ($p = 0.006$; $p = 0.041$ LB vs. NS). In a *post hoc* analysis, a gamma function was fitted to the estimated hemodynamic response per event type for each participant and region (Liu, H. L. *et al.*, 2004; de Zwart, J. A. *et al.*, 2005). Time-to-peak of the gamma function, taken as the latency to the BOLD response peak, showed significantly earlier time-to-peak in BOLD responses from EB compared to NS. BA, Brodmann area; BOLD, blood oxygen level dependent; PCG, postcentral gyrus; ParOp, parietal operculum.

6.18.4 Visual Cortex Adjustments in Response to Visual Deprivation

6.18.4.1 Metabolic Changes

Metabolism and cerebral blood flow measurements address the important question of whether visual cortex remains active in blindness. Congenitally/early blind individuals show elevated glucose metabolism (Wanet-Defalque, M. C. *et al.*, 1988; Veraart, C. *et al.*, 1990), oxygen utilization and lower oxygen extraction fractions (OEFs) (De Volder, A. G. *et al.*, 1997) and heightened cerebral blood flow (CBF) (Uhl, F. *et al.*, 1993; De Volder, A. G. *et al.*, 1997; Mishina, M. *et al.*, 2003; Wittenberg, G. F. *et al.*, 2004). Studies that found similar glucose (Veraart, C. *et al.*, 1990) and CBF measurements (De Volder, A. G. *et al.*, 1997; Mishina, M. *et al.*, 2003; Wittenberg, G. F. *et al.*, 2004) in sighted people at rest, but with open eyes (e.g., an activated state) support the notion of an active visual cortex in blindness. The metabolic differences noted in these studies were generally identified in visual areas that included Brodmann areas 17–19.

By contrast, late-onset, totally blind have slightly lower glucose utilization compared to sighted individuals with eyes closed (Veraart, C. *et al.*, 1990) and lower resting CBF in visual areas (Wittenberg, G. F. *et al.*, 2004). The depressed glucose and CBF levels might indicate reduced visual cortex activity in late-onset blindness. Visual cortex glucose metabolism differences between early- and late-onset blindness and the relation to results in sighted people indicate that the potential for functional adaptations to visual deprivation possibly decreases with age of blindness onset.

From studies in adult animals, glucose metabolism in late-onset blind people might be expected to be normal or minimally elevated, but not depressed after several years of blindness. Visual cortex metabolic markers were transiently depressed in adult animals following visual deprivation. For example, glucose metabolism in visual cortex decreased and then recovered to normal levels within 16–17 days in monocular enucleated adult rats (Cooper, R. M. and Thurlow, G. A., 1985). Similarly, CBF decreased and then recovered within 45 days in monocular

enucleated adult mice (Madar, I. *et al.*, 1994). Consistent with an expected normal activity level is evidence that late-onset blind and sighted individuals have comparable occipital cortex TMS excitability thresholds for evoked phosphenes (Gothe, J. *et al.*, 2002). Clearly, additional studies of visual cortex in late-onset blind people are needed to confirm or refute findings of lower glucose metabolism (Veraart, C. *et al.*, 1990) or CBF (Wittenberg, G. F. *et al.*, 2004).

Changes in gamma-aminobutyric acid (GABA)ergic, inhibitory circuits are possibly responsible for enhanced excitability in visual cortex despite blindness. In support of this notion are findings of decreased GABA and glutamate decarboxylase (GAD) immunoreactivity in adult monkey's visual cortex following monocular visual deprivation (Hendry, S. H. C. and Jones, E. G., 1988). Presumably regional deafferentation yields decreased synaptic inhibition, which associates with increased regional cortical excitability. Visual cortex excitability also increased in sighted participants within a few hours of complete visual deprivation (Boroojerdi, B. *et al.*, 2000). The excitability changes from short-term blindfolding were blocked when participants received a benzodiazepine agonist, *N*-methyl-D-aspartic acid (NMDA) antagonist, or a muscarinic acetylcholine antagonist (Boroojerdi, B. *et al.*, 2001). These results are comparable to evidence of heightened cortical neuron excitability from reversibly blocking GABA inhibitory synapses in animals (Sillito, A. M., 1975; Alloway, K. D. *et al.*, 1989). However, visual deprivation probably has only a transient effect on cortical activity via inhibitory circuits because even early blind individuals show a normal distribution of $GABA_A$ receptors in visual cortex (Mishina, M. *et al.*, 2003). Consequently, because inhibitory circuits might not be permanently altered by visual deafferentation, alternative mechanisms possibly foster visual cortex activity in blindness (see Section 6.18.6).

6.18.4.2 Studies in Animals

Several animal models have demonstrated that peripherally induced blindness fostered cross-modal responses in normally visually activated cortex (Hyvärinen, J. *et al.*, 1981; Rauschecker, J. P. and Korte, M., 1993; Toldi, J. *et al.*, 1996; Kahn, D. M. and Krubitzer, L., 2002; Newton, J. R. *et al.*, 2002). The possible source for cross-modal reorganization must be evaluated relative to the neurodevelopment stage when blindness occurred. The critical factor is whether blindness was instantiated before or after completion of cell migrations to visual cortex because novel connections might only be possible while cortical and subcortical development is in progress. In monkeys, there was little alteration in the cellular and synaptic structure of visual cortex area 17 following binocular enucleations *in utero* after the gestational stage for cortical cell proliferation and migration (Rakic, P., 1988). Thus, any observed cross-modal adjustments noted after postmigrational development are presumably based on adjustments within extant circuitry. The demographic data on most blind human participants in metabolic, recording, or brain imaging studies cite loss of sight subsequent to peripheral eye structure pathology that primarily occurred late in gestation (e.g., retinopathy of prematurity in congenitally/early-onset blind) and well past postnatal sensitive periods in late-onset blind people. Therefore, human visual cortex connections and structure are probably minimally altered by peripheral eye pathology in most early- and all late-onset blind people.

In a study with monkeys, eyelids were sutured throughout the first year of life and then opened just prior to recording neuronal activity from occipital cortex (Hyvärinen, J. *et al.*, 1981). The model of induced blindness in the monkeys resembles some instances of human early-onset blindness. Somatosensory activity was recorded in extrastriate, Brodmann area 19, a visual association region normally selective for visual inputs (Hyvärinen, J. *et al.*, 1981). After year-long visual deprivation, 20% of multineuron responses were exclusively activated by tactile and 40% were driven by visual stimulation (Hyvärinen, J. *et al.*, 1981). Another study examined the effects of monocular enucleation in adult rabbits. The rabbit's striate visual cortex primarily receives crossed monocular inputs. Consequently, functional adjustments in the deprived contralateral visual cortex in rabbits plausibly correlate with total blindness effects in human late-onset blind people. The proportion of tactile responsive neurons in the rabbit primary visual cortex (V1) increased from 0% to 31%, although generally there were fewer responsive neurons (Newton, J. R. *et al.*, 2002).

Animal studies where visual deprivation was imposed prior to maturation of subcortical connections (Toldi, J. *et al.*, 1996; Kahn, D. M. and Krubitzer, L., 2002) also reported cross-modal activity in normally visual cortical regions. However, it is theoretically possible that in the aforementioned

animal studies, subcortical somatosensory and auditory relay nuclei project to the lateral geniculate nucleus to convey nonvisual information to visual cortex. An equivalent result has been demonstrated in the auditory system of ferrets following peripheral auditory deafferentation prior to maturation of subthalamic and thalamocortical connections. New projections developed from retained subcortical visual nuclei (e.g., superior colliculus), and these connected through the deafferented medial geniculate nucleus to convey visual information to auditory cortex (e.g., Sur, M. *et al.*, 1990; Sur, M. and Leamey, C. A., 2001). New subcortical projections probably do not explain most instances of cross-modal visual cortex activity in human early-onset and no cases of late-onset blindness, but such connections might arise in some cases of congenital anophthalmia.

6.18.4.3 Studies in Humans

6.18.4.3.1 Cross-modal visual cortex activation: event-related potential/ magnetoencephalography recordings

ERP recordings were the first to reveal occipital cortex activation to nonvisual stimulation in blind humans. A prominent sustained negativity was topographically recorded from occipital leads in early-onset blind participants during braille reading compared to passive stimulation with embossed dots. Tactile reading of embossed text did not evoke similar slow negativity from occipital sites in sighted participants (Uhl, F. *et al.*, 1991). The same experimenters also found occipital negativities in early-onset blind and sighted participants while they imagined feeling textured surfaces with the fingertips (Uhl, F. *et al.*, 1994). The authors suggested that the mechanisms in visual cortex responsible for visual imagery were similarly responsible for tactile imagery even in the blind participants who had no prior visual perceptions. This was the first suggestion that visual cortex activity in blind humans serves cognitive processes that were similar to those in sighted people.

Cross-modal auditory responses in occipital cortex were also demonstrated using a detection task involving rare deviant target tones. Evoked short latency, fast ERP components were recorded from posterior-occipital leads in early- and late-onset blind people (Kujala, T. *et al.*, 1995a; 1997a). Observing similar activity irrespective of age at blindness onset suggests that even mature brains can reorganize (Kujala, T. *et al.*, 1997a). Magnetoencephlography (MEG) more explicitly localized these auditory-evoked responses to visual cortex (Kujala, T. *et al.*, 1995b).

The specificity of cross-modal activation of visual cortex was examined by comparing the distribution of slow negative potentials during low-level perceptual or high-level cognitive processing and by determining whether task difficulty affected response distributions. In perceptual tasks, participants detected rare tactile display patterns or tone frequencies (Röder, B. *et al.*, 1996) or perceived and stored in working memory a standard tactile display (Röder, B. *et al.*, 1997). In the cognitive processing task, participants were required to mentally rotate a test tactile display and compare it to a recalled standard (Röder, B. *et al.*, 1997). Extended perceptual detection of both tactile and auditory target stimuli evoked sustained negative ERP potentials from occipital-posterior leads in early-onset blind but not sighted participants. ERP topographies were coincident for tactile and auditory stimulation (Röder, B. *et al.*, 1996). Similar occipital-posterior ERP response distributions were obtained during cognitive perceptual encoding and subsequent mental rotation of tactile stimulus orientations (Röder, B. *et al.*, 1997). Thus, ERP topographies were similar for low- and high-level processes. Task difficulty directly affected ERP magnitudes, but not distributions. In contrast, the topography and magnitudes of negative slow potentials recorded from nonoccipital sites were similar between the groups during the same tasks and difficulty levels. Activated nonoccipital sites especially respected modality specific topographies associated with the tasks – parietal for somatosensory and temporal for auditory.

6.18.4.3.2 Disrupted tactile processing: effects of repetitive transcranial magnetic stimulation and stroke

An important question is whether visual deprivation induces functionally diverse and yet behaviorally relevant cross-modal plasticity in visual cortex that contributes to adaptive adjustments. Behavioral relevance was shown by findings that rTMS applied to occipital cortex in blind people can transiently disrupt performance on various tasks. rTMS is known to disrupt task performance if the stimulated region contributes to task pertinent processing (Cohen, L. G. *et al.*, 1997; 1999). rTMS over a mid-occipital site causes congenitally/early-onset blind participants to make more errors when identifying braille or embossed Roman letters (Cohen, L. G. *et al.*, 1997; 1999). The rTMS caused distorted tactile

sensations that involved noting absent, extra, or confusing dots. However, neither blind nor sighted participants detected any tactile stimulation when single pulse TMS was applied to parietal cortex 20–40 ms after presentation of real or nonsense braille patterns (Hamilton, R. H. and Pascual-Leone, A., 1998; Pascual-Leone, A. *et al.*, 2005). When single pulse TMS was applied to occipital cortex 50–80 ms after peripheral stimulation, blind, but not sighted participants, were unable to identify braille patterns or distinguish them from nonsense dot patterns (Hamilton, R. H. and Pascual-Leone, A., 1998; Pascual-Leone, A. *et al.*, 2005). Both groups detected when they were touched by the embossed dots. These timing differences indicate that initial tactile detection still occurs in dedicated somatosensory–parietal cortex. After a delay, presumably needed for output from parietal cortex to reach occipital cortex, cognitive processing critical to letter identification utilizes posterior occipital cortex in blind people.

Occipital rTMS had no effect on tactile reading in late-onset blind and sighted participants. According to Cohen L. G. *et al.* (1999), the negative findings in late-onset blind participants indicated that cross-modal reorganization of visual cortex is possibly limited by the age of blindness onset. However, the mid-occipital rTMS site studied previously possibly spared a critical occipital region in late-onset blind people. When these individuals read braille, activity primarily was found in lower tier visual areas ipsilateral to the reading hand and mostly in inferior occipital cortex (Burton, H. *et al.*, 2002a). More importantly, occipital rTMS disrupts braille letter discrimination in sighted individuals after 5 days of visual deprivation (Pascual-Leone, A. and Hamilton, R., 2001). Additionally, occipital rTMS in sighted participants not subjected to blindfolding transiently disrupted judgments of the relative distance between raised dot patterns (Merabet, L. *et al.*, 2004). These findings strongly suggest that there is no critical period for the reorganization of visual cortex following blindness and that visual cortex normally contributes to macrogeometric tactile discriminations of spatial distance (Merabet, L. *et al.*, 2004).

Clinical evidence further indicates that visual cortex contributes to tactile perceptions when a blind person reads braille. Specifically, a congenitally blind individual developed alexia for braille without tactile agnosia or aphasia for heard language following a bilateral posterior occipital ischemic stroke (Hamilton, R. *et al.*, 2000). The patient had been a highly fluent braille reader. Her touch sensations were unimpaired and she recognized touched braille, but was nevertheless unable to read. Her microgeometric judgments of roughness were intact, while detection of tactile spatial distances was severely depressed (Merabet, L. *et al.*, 2004). Magnetic resonance (MR) structural images revealed no parietal sensorimotor or frontal language area lesions. Overall the rTMS results and clinical case show that reading by touch, a cognitive language function, depends on reorganized visual cortex in blindness. Whether a visual cortex contribution to tactile spatial discriminations relates to braille reading remains to be investigated.

6.18.4.3.3 Regional distribution of visual cortex activity – perceptual processing

Brain imaging studies in blind people provide numerous examples of visual cortex activation during tactile stimulation (Figure 5(c) and Sadato, N. *et al.*, 1996; 1998; 2002; Gizewski, E. R. *et al.*, 2003; Burton, H. *et al.*, 2004; 2006). However, several studies did not distinguish between regional activity for perceptual processing of tactile stimulation from cognitive language processing when participants read braille words, an explicit language task (Uhl, F. *et al.*, 1991; 1993; Sadato, N. *et al.*, 1996; 1998; Melzer, P. *et al.*, 2001; Burton, H. *et al.*, 2002a; Amedi, A. *et al.*, 2003; Gizewski, E. R. *et al.*, 2003). A similar language confound is present in tasks that required discriminating between successive braille letter displays (Büchel, C. *et al.*, 1998; Sadato, N. *et al.*, 2002) because fluent braillists indirectly incorporate linguistic processes when they recognize letter patterns. Consequently, in these studies activity due to cognition cannot be dissociated from that due to processing tactile stimulation. Generally, less visual cortex activity was elicited by tactile stimulation when discriminating angles, groove widths, or Roman letters compared to tactile inputs when distinguishing between braille words and nonwords (Sadato, N. *et al.*, 1996; 1998). These pioneering PET studies reported widespread, bilateral activation of medial occipital cortex, including striate and extrastriate cortex (Sadato, N. *et al.*, 1996; 1998), but did not differentiate regional activation differences between tasks. However, significant visual cortex responses consistently occurred only when blind people attended to sensory inputs (Sadato, N. *et al.*, 1996; Gizewski, E. R. *et al.*, 2003; Kujala, T. *et al.*, 2005), which suggests a task-relevant contribution

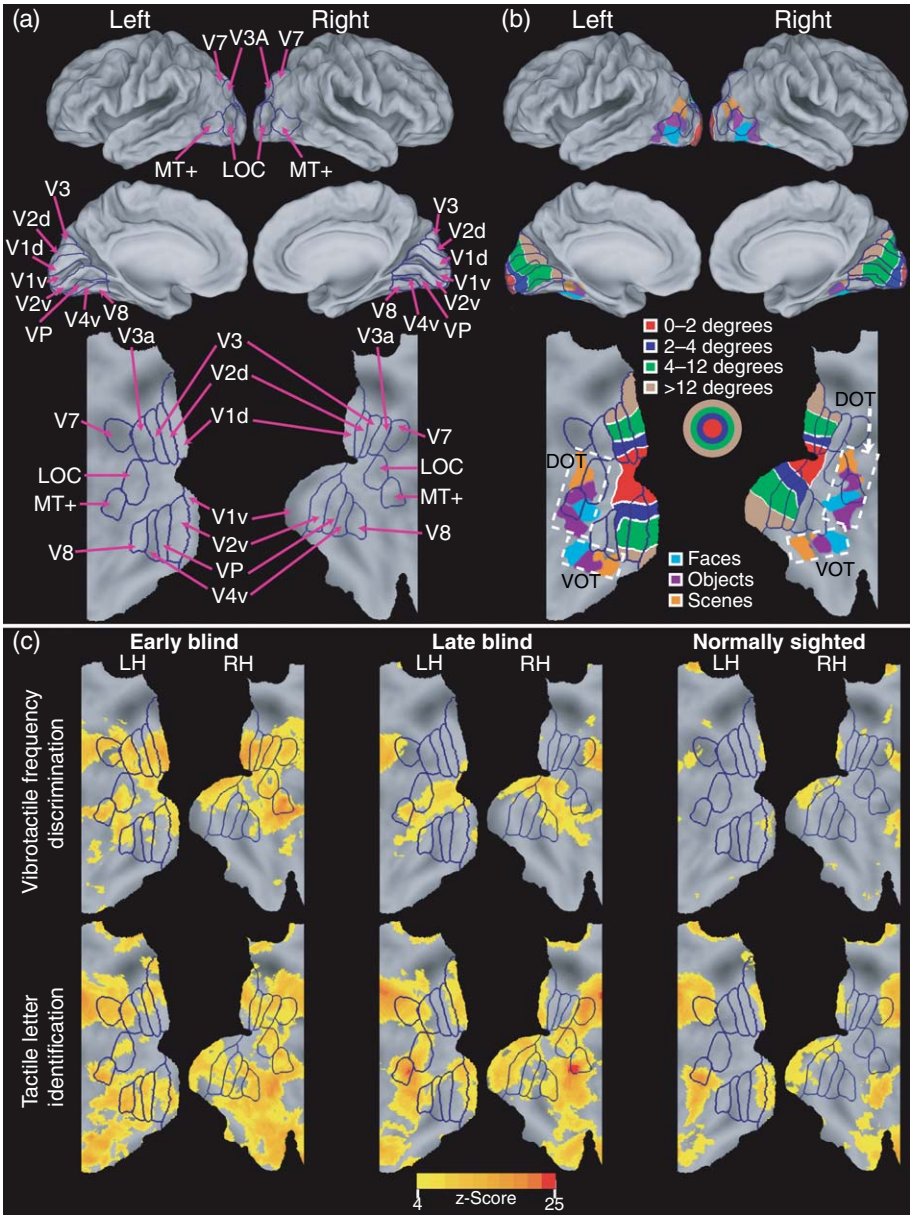

Figure 5 (a) Projection of visual areas onto a standard surface-based cerebral cortex reconstruction (VAN ESSEN, D. C., 2005). Top and middle: Fiducial reconstructions show lateral and medial hemisphere views, respectively. Bottom: Flattened reconstructions of the occipital lobe show visual area borders that are from prior identifications in sighted people (Hadjikhani, N. *et al.*, 1998; Van Essen, D. C., 2004). LOC, lateral occipital complex; MT+, medial temporal area; V1d and V1v, dorsal and ventral primary visual areas; V2d and V2v, dorsal and ventral second visual areas; V3 and V3a, third visual areas; V4v, ventral fourth visual area; VP, ventral posterior visual area; V7, seventh visual area; V8, eighth visual area. (b) Projection of receptive field eccentricity bands for lower tier visual areas onto a standard surface-based reconstruction. Concentric colored circles indicate different degrees of eccentricity. In the fiducial views, foveal to peripheral ordering of eccentricity bands occupies, respectively, posterior to anterior Talairach atlas coordinates (Talairach, J. and Tournoux, P., 1988). In the flattened view, foveal to peripheral eccentricity bands align from bottom to top in dorsal visual areas and from top to bottom in ventral visual areas. In addition, item selective regions in ventral and dorsal occipito-temporal partitions (VOT and DOT) were projected onto the standard surface reconstruction using spheres centered on previously reported centers-of-mass coordinates (Hasson, U. *et al.*, 2003). Colored boxes indicate regions activated when viewing faces, objects, or scenes (Hasson, U. *et al.*, 2003). (c) Distribution of increased activity in the occipital lobe for two tactile tasks. Maps show results by group during a vibrotactile frequency discrimination task (Burton, H. *et al.*, 2004) and a tactile letter identification task (Burton, H. *et al.*, 2006). Scale is for group average cross correlation magnitude *z*-scores greater than 4. LH, left hemisphere; RH, right hemisphere.

to performance as opposed to reactive stimulus–response effects.

Perceptual processing occurred during tactile stimulation in a task that involved vibrotactile stimulation passively applied to the right index finger. Early- and late-onset blind and blindfolded sighted participants attended paired vibrations (25 and 100 Hz) to detect when they differed in frequency. No activity was found in traditional language areas during this frequency discrimination task (Burton, H. *et al.*, 2004). Thus, verbal tagging was absent and long-term recognition/recall was not required because the interval between stimuli was 300 ms. The vibrotactile discrimination task evoked some bilateral visual cortex activity in all groups. Early blind participants showed the greatest activation of visual cortex including portions of all lower tier retinotopic areas, that is, V1–VP (Figures 5(a) and 5(c)). These areas additionally show an orthogonal regional representation of different eccentricity axes (e.g., center–periphery maps) (Figure 5(b) and Hasson, U. *et al.*, 2002; 2003; Grill-Spector, K. and Malach, R., 2004). Within the eccentricity representation, the vibrotactile task activated the most significant responses in foveal and parafoveal eccentricity bands (Figures 5(b) and 5(c)). No lower tier visual areas selectively responded except for activation along the upper bank of the calcarine sulcal cortex, which in sighted people normally represents lower visual space. Similar lower tier visual subdivisions were activated in late-onset blind participants in whom, however, responses principally affected foveal eccentricity band cortex (Figure 5(c)).

Higher tier visual areas in the inferior and middle occipital gyri and posterior inferior temporal sulcus and gyrus were also bilaterally activated in early blind participants during a vibrotactile task. The same regions had smaller responses that were less extensively distributed in late-onset blind participants (Burton, H. *et al.*, 2004). The affected higher tier regions included V7, V8, LOC, and MT+ (Figures 5(a) and 5(c) and Tootell, R. B. *et al.*, 1996; Amedi, A. *et al.*, 2002; Grill-Spector, K. and Malach, R., 2004; Van Essen, D. C., 2004). Included within, but extending beyond these higher visual areas is a second tier organization that involves dorsal occipito-temporal (DOT) and ventral occipito-temporal (VOT) partitions (Figure 5(b)). In sighted people, activity associated with these partitions selectively deal with visual images of faces, objects, and scenes compared to textures (Figure 5(b) and Malach, R. *et al.*, 1995; Kanwisher, N. *et al.*, 1997; Levy, I. *et al.*, 2001; Hasson, U. *et al.*, 2002; Malach, R. *et al.*, 2002; Hasson, U. *et al.*, 2003; Levy, I. *et al.*, 2004; Yovel, G. and Kanwisher, N., 2004). Within these partitions, visual information from faces or letters activates cortex just anterior to foveal eccentricities; cortex associated with parafoveal eccentricities selectively process pictures of objects; and cortex associated with peripheral eccentricities are preferentially activated by views of buildings or scenes (Figure 5(b)). Activity evoked by the vibrotactile stimulation in blind people encompassed the face and object but not the scene locations in DOT and VOT partitions in both groups of blind participants (Figures 5 (b) and 5(c)). The most significant activity especially overlapped the face or central gaze eccentricity, especially in late-onset blind participants (Figure 5(c)). Only three sighted participants showed small patches of V1 activity that principally involved the parafoveal eccentricity band (Burton, H. *et al.*, 2004).

These results show that a tactile task requiring some discrimination, but no language area involvement, cross-modally activated lower and higher tier visual cortex subdivisions in blindness. Although domain specificity was not observed, activation of foveal and central gaze regions might have reflected focal attention to the stimulated fingertip, which normally is seen in lower visual space.

Vibrotactile activation of visual areas has few parallels with visual stimulus attributes and, therefore, constitutes an unusual cross-modal adjustment to blindness even in higher tier areas that respond to complex tactile features in sighted people (see Section 6.18.5). In contrast, the vibrotactile task evoked a delayed and sustained negative BOLD response in most visual areas in sighted people (Burton, H. *et al.*, 2004), which normally indicates suppressed activity (Haxby, J. V. *et al.*, 1994; Drevets, W. C. *et al.*, 1995; Gusnard, D. A. and Raichle, M. E., 2001). Positive BOLD responses were found in somatosensory cortex of all groups. Hence, the positive BOLD responses in visual areas of blind people represent an adjustment and addition to tactile perceptual processing even of a relatively uncomplicated vibration frequency attribute.

Identifying embossed block letters is a tactile task that incorporates perceptual processing of tactile shapes and a sublexical linguistic task. Tactile reading of letters can readily be accomplished with little training by sighted and blind people (Loomis, J. M., 1981; Vega-Bermudez, F. *et al.*, 1991), even when letters are passively translated across a fingertip (Vega-Bermudez, F. *et al.*, 1991). Compared to findings with vibrotactile stimulation, tactile letter identification

activated a greater bilateral extent of visual cortex in blind and sighted people, but the activity in blind participants was most prominent (Figure 5(c)) (Burton, H. *et al.*, 2006). In V1 and V2, late-onset blind and sighted participants exhibited similar bilateral activity distributions across near foveal and parafoveal eccentricities; early-onset blind participants showed sparing of the foveal eccentricity (Figure 5(c)). Compared to the vibrotactile task data, activity in the remaining lower tier areas was more evident in both blind groups and was greater along the lower bank of calcarine sulcal cortex. Positive BOLD responses occurred in V2d, V3 and V3a, and VP and V4v in early and late blind participants. Activity was suppressed in the same areas in sighted participants. Activity was also relatively enhanced in higher tier visual areas. Highly significant responses were noted in MT+ and adjacent occipital–temporal cortex in all groups. All domains were activated in DOT and VOT partitions in early, but not late blind participants. Known letter identification areas in anterior fusiform gyral cortex (BA 37) (Puce, A. *et al.*, 1996; Garrett, A. S. *et al.*, 2000; Polk, T. A. *et al.*, 2002; Flowers, D. L. *et al.*, 2004) were similarly activated in blind and sighted groups (Burton, H. *et al.*, 2006).

By adding a simple sublexical language task to perceptual processing of tactile shapes, activity was enhanced generally and expanded to several lower and higher tier visual areas. The similar findings in both early and late blind participants indicate cross-modal adaptations persist despite different ages of blindness onset. The contrast between activity distributions with vibrotactile stimulation and letter identification indicate potentially different strategies when processing the letter shapes. For example, MT+ activity plausibly reflected moving tactile letters across the fingertip, an effective feature for MT+ (Hagen, M. C. *et al.*, 2002) in all groups. However, both cognitive recognition of the felt letter and greater skill in attending to tactile motion in blind participants possibly contributed to bilateral and generally more significant activity in MT+. Additionally, activity in V8 and neighboring nonvisuotopic portions of parieto-occipital cortex (BA 19) might indicate attention to tactile shape orientations (Zangaladze, A. *et al.*, 1999). Striking activity differences in the foveal eccentricity between vibrotactile stimulation and letter identification (Figure 5(c)) in late blind might indicate perceptually processing vibration features of focal stimulation compared to extracting multiple tactile object features for letters. Another example of possible special processing was larger responses in VOT in blindness. Prior reports in sighted people observed preferential VOT activation for item viewing (Malach, R. *et al.*, 1995; 2002). Thus, VOT response enhancements in blind people might have contributed to the processing of tactile letters as objects (Garrett, A. S. *et al.*, 2000; Flowers, D. L. *et al.*, 2004), especially when attending to letter identification.

6.18.4.3.4 Regional distribution of visual cortex activity – cognitive processing

Language tasks activated a greater extent of visual cortex than perceptual processing of tactile stimulation, especially in early blind people (Figure 6). For example, a phonological task that involved identifying a common rhyme for heard words (Burton, H. *et al.*, 2003) activated nearly all visual areas bilaterally in early blind, some of posterior V1 in late blind, and nothing in sighted participants. A more difficult language task that required identifying a common meaning for a list of heard words evoked yet more significant and extensive activation of visual cortex in early blind participants than the rhyming task (Figure 6 and Burton, H. *et al.*, 2003). The same semantic task led to a lesser distribution of activity across several lower and higher tier visual areas in late blind and barely any responses in sighted participants. Figure 6 shows that comparable findings were obtained with the semantic task of generating a verb to an offered noun irrespective of whether the noun was heard (Burton, H. *et al.*, 2002b) or read through braille (Burton, H. *et al.*, 2002a). Verb generation to heard words also activated V1 and V2 areas bilaterally in a few sighted people (Figure 6). In early blind participants, especially, any of the semantic language tasks activated the most significant activity in cortex associated with lower tier parafoveal eccentricity bands (Figure 6). Semantic tasks also evoked highly significant responses throughout several higher tier visual areas (e.g., V7, LOC, MT+, and V8). In reference to the selective domains in DOT and VOT partitions, the most significant activity spared the peripheral eccentricity zones normally associated with viewing scenes (Figure 6). Generally, however, activated visual cortex shows no distinctive topography in early blind people in whom semantic language tasks activate nearly all visual areas. In late blind, the affected regions are less extensive and more heterogeneous.

The only substantive topographic distinction was the more significant activity in the left hemispheres of early blind participants for semantic tasks with heard

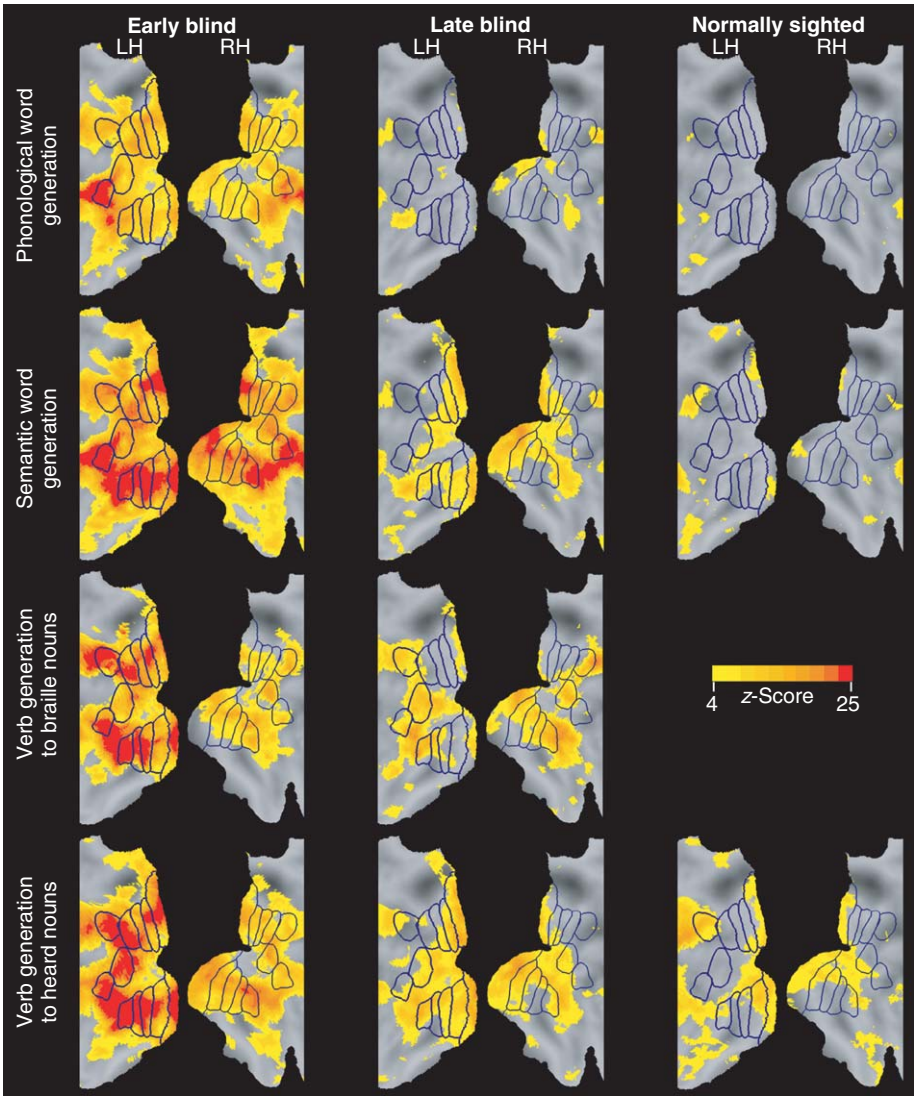

Figure 6 Distribution of increased activity observed in the occipital lobe during four language tasks. Row 1: During a phonological task, participants generated a word that matched the common rhyme in a group of 16 heard words (Burton, H. *et al.*, 2003). Row 2: During a semantic task, participants generated a word that matched a common meaning in a group of 16 words (Burton, H. *et al.*, 2003). During the semantic task of verb generation, participants read through braille (Burton, H. *et al.*, 2002a) (Row 3) or heard (Burton, H. *et al.*, 2002b) (Row 4) the nouns. Word generation was covert in all tasks. Scale is for group average cross correlation magnitude *z*-scores greater than 4. Borders and enclosed visual areas are shown in Figure 5.

words (Burton, H. *et al.*, 2002b; Röder, B. *et al.*, 2002; Amedi, A. *et al.*, 2003; Noppeney, U. *et al.*, 2003), imagery of sounds (De Volder, A. G. *et al.*, 2001), and braille reading (Sadato, N. *et al.*, 1998; Burton, H. *et al.*, 2002a). In contrast, activity predominated in the right hemisphere in late blind participants when they read braille, but was more symmetrically bilateral when generating verbs to heard nouns (Figure 6).

These results plausibly suggest a contribution to semantic language processing from striate and extrastriate visual cortex in blindness. A similar conclusion was proposed to explain greater BOLD response magnitudes with increased semantic and syntactic complexity of heard sentences (Röder, B. *et al.*, 2002) and during a semantic retrieval task (Noppeney, U. *et al.*, 2003). The functional relevance of occipital cortex to semantic processing was demonstrated when rTMS over left striate and extrastriate regions transiently increased errors in verb generation to heard nouns in blind but not sighted

participants; there was little interference with articulation of responses (Amedi, A. *et al.*, 2004). Activation of visual cortex during a variety of high-level language tasks is coupled with activity in traditional left-lateralized frontal, temporal, and parietal language areas (Röder, B. *et al.*, 2002; Burton, H. *et al.*, 2002a; 2002b; 2003; Noppeney, U. *et al.*, 2003); areas that have increased effective connectivity with occipital cortex in blindness (Noppeney, U. *et al.*, 2003).

The role of occipital cortex in language processing possibly needs qualification because any semantic task depends on retrieving word associations (Amedi, A. *et al.*, 2003). Thus, findings from two fMRI studies showed a stronger relationship between retention performance and visual cortex activity, especially in V1, than with verb generation. For example, V1 response magnitudes were more positively correlated with verbal retention performance (Amedi, A. *et al.*, 2003) and the accuracy of long-term episodic memory (Raz, N. *et al.*, 2005) in congenitally/early blind participants. These authors concluded that verbal memory processes underlay findings of visual cortex responses during verb generation.

These studies collectively indicate that reorganized visual cortex contributes to a range of perceptual, cognitive/language, and memory processes. The intensity of activation, however, is possibly greater for higher-order cognitive functions. But much remains unresolved about the spatial pattern of functional specializations in reorganized cortex. For example, there is little evidence of language-specific domains aside from the observation that linguistic tasks preferentially activate left visual areas in congenitally/early blind individuals. Tactile perceptual, sublexical language, and phonological processing all activate fewer visual areas than more demanding higher-level verbal processing. The distinction that more of visual cortex is needed for more complex cognitive processes might reflect effort and level of attention utilized in different tasks. Implied by this suggestion are concerns regarding visual cortex excitability and activity specificity and relevance. In future studies, controls for task difficulty and performance equalization between groups are sorely needed to assess the notion of nonselective visual cortex activity. Additionally, despite evidence of cross-modal auditory activation (Weeks, R. *et al.*, 2000; Arno, P. *et al.*, 2001; Röder, B. and Rösler, F., 2003; Gougoux, F. *et al.*, 2004; Gougoux, F. *et al.*, 2005), the topography of auditory perceptual processing has not been evaluated in the context of defined visual areas. At issue is whether reorganized visual cortex is amodal and the same regions are activated by tactile and auditory inputs. Furthermore, more topography comparisons are needed amongst various groups of visually deprived participants: congenitally/early blind, late-onset blind, low vision, and transiently blindfolded sighted people.

6.18.5 Possible Sources of Cross-Modal Visual Cortex Activity

6.18.5.1 An Innate Network

Findings following short-term visual deprivation of 90 min to 5 days in sighted people show that existing networks are capable of cross-modal processing. These intervals of transient visual deprivation are too brief for growing new connections. Blindfolding made visual cortex more excitable (Boroojerdi, B. *et al.*, 2000) and responsive to tactile stimulation during discrimination of braille letters as well as during a tone-matching task (Pascual-Leone, A. and Hamilton, R., 2001; Pascual-Leone, A. *et al.*, 2005). Blindfolding also induced performance improvements in distinguishing tactile grating orientation (Facchini, S. and Aglioti, S. M., 2003) and braille characters (Kauffman, T. *et al.*, 2002). These alterations reversed within 2 h after restoration of sight. Undoubtedly, visual cortex activity in late blind relies on extant networks. Even in early blind, similar connections probably support cross-modal visual cortex activity, especially when blindness occurred after neuronal migration ended during development. A recent tract tracing study found no new thalamocortical connections to primary visual cortex in early blind individuals (Shimony, J. *et al.*, 2006), which supports the notion that intracortical network changes are probably responsible for cross-modal visual cortex reorganization after permanent blindness. (Subcortical multisensory inputs from the superior colliculus or basal ganglia are also possible sources for cross-modal inputs (Macaluso, E. and Driver, J., 2005). These have yet to be investigated in blind people.)

6.18.5.2 Connections with Multisensory Areas

Projections to occipital cortex from temporal and parietal multisensory areas (Distler, C. *et al.*, 1993; Falchier, A. *et al.*, 2002; Rockland, K. S. and Ojima, H., 2003) possibly provide the anatomical substrate for activity not normally observed without visual

deprivation. These temporal and parietal multisensory areas densely project to peripheral and parafoveal axes of lower tier visual areas (Lewis, J. W. and Van Essen, D. C., 2000; Falchier, A. *et al.*, 2002; Rockland, K. S. and Ojima, H., 2003). Greater activation of the parafoveal eccentricity band illustrated in Figure 6 plausibly reflects these connections. Linkages are also available to prefrontal language areas indirectly through a temporal cortex link from visual to frontal cortex (Distler, C. *et al.*, 1993; Rempel-Clower, N. L. and Barbas, H., 2000), which possibly is a conduit for more complex cognitive operations in reorganized visual cortex, for example, verbal memory or semantics. Even primary sensory areas receive heteromodal inputs, a finding that questions traditional models of unimodal information processing (Cappe, C. and Barone, P., 2005). Additionally, all visual areas are intricately interconnected with feedforward and feedback connections (Felleman, D. J. and Van Essen, D. C., 1991). The higher tier visual areas also have more direct connections with multisensory areas and, as a consequence, are positioned to convey nonvisual information directly to lower tier regions. Visual cortex connections are consequently of sufficient diversity and breadth that a challenge will be to discern the pathways responsible for deprivation induced cross-modal plasticity (Cappe, C. and Barone, P., 2005).

6.18.5.3 Tactile Activation of Visual Areas in Sighted People

A possible functional basis for visual cortex responses to touch is enhanced processing of tactile stimulation in visual areas that already respond to somatosensory inputs in sighted people. For example, the visual motion area, V5/MT+, responds while attending to tactile motion (Hagen, M. C. *et al.*, 2002; Burton, H. *et al.*, 2006); LOC responds to 2D (Prather, S. C. *et al.*, 2004) and 3D macrospatial tactile object features (Amedi, A. *et al.*, 2002; James, T. W. *et al.*, 2002; Stoesz, M. R. *et al.*, 2003); V8/parieto-occipital regions activate when imagining spatial locations of tactile objects (Arno, P. *et al.*, 2001; Vanlierde, A. *et al.*, 2003); and a parieto-occipital area responds to tactile grating orientation (Sathian, K. *et al.*, 1997; Zhang, M. M. *et al.*, 2005). Selected visual area activation in nonvisual tasks are possibly instances where vision and touch involve the same perception, that is, stimulus motion, spatial orientation, and object identification. Normal tactile responsiveness might expand to other tactile stimulation features because visual deprivation removes afferent drive to inhibitory circuits that normally suppress tactile input to these regions.

6.18.5.4 Altered Physiology

Another possible source for reorganized visual cortex activity is altered intracortical flow of information from cortical locations that exhibit multisensory interactions. Example cortical multisensory regions are the ventral intraparietal area, caudal superior temporal region, and ventral premotor cortex, regions shown to contain heteromodal neurons in monkeys and overlapping activation from different modalities in human imaging data (Macaluso, E. and Driver, J., 2005). In sighted people, convergent feedforward information from unimodal sensory regions provides a plausible mechanism for multimodal responses, especially for stimulation occurring in overlapping space (Macaluso, E. and Driver, J., 2005). Additionally, cognitive factors, such as attention to targets in a specified space, might enable cross-modal activity in multisensory regions to affect processing in unimodal visual areas (Macaluso, E. *et al.*, 2000; 2002; Macaluso, E. and Driver, J., 2005). Any enhanced reversal of information flow from multisensory to visually deprived areas might easily funnel auditory or tactile inputs to visual cortex, including presumptive unimodal lower tier visual areas. A demonstration of a change in effective connectivity was increments in lower tier visual cortex rCBF in early but not late blind or sighted blind participants following application of rTMS to S1 cortex (Wittenberg, G. F. *et al.*, 2004). These effects occurred without evidence of rCBF alterations in thalamus. Thus, reorganized visual cortex becomes activated through heightened transfer of intracortical connections to visual cortex (Sadato, N. *et al.*, 2002). Prior evidence for these kinds of transfers was shown in physiological studies where the flow of cross-modal activity in the auditory system and superior colliculus was altered through convergent feedforward connections from specific sensory areas, feedback connections from higher level cortical areas or possible convergent projections to specific sensory areas (Foxe, J. J. *et al.*, 2002; Meredith, M. A., 2002; Schroeder, C. E. and Foxe, J. J., 2002). Rapid and reversible changes in effective connectivity following blindfolding in sighted people indicate that the potential for plasticity is already present and does not necessarily involve structural changes (Pascual-Leone, A. *et al.*, 2005). However, sustained visual

deprivation might cause more permanent shifts in connectivity.

Convergence effects might also entail temporally synchronized multimodal stimulation whose coincidence leads to multisensory interactions that again can affect activity in visual cortex (Macaluso, E. *et al.*, 2004; Macaluso, E. and Driver, J., 2005). An example observed in sighted participants was greater rCBF changes for target detection of a category word while viewing a speaking face and during temporal coincidence of heard words and visual inputs associated with speech (Macaluso, E. *et al.*, 2004). The increases occurred in ventral occipital and multisensory superior temporal sulcal cortex with audiovisual synchrony but not spatial congruency and in dorsolateral occipital cortex with synchrony and congruency (Macaluso, E. *et al.*, 2004). The enhanced visual cortex responses are potentially a model for acquired tactile activation of visual cortex when blind people learn braille. During learning, additive cross-modal effects are associated with prolonged practice that connects the feel of braille fields and heard phonemic information (Nolan, C. and Kederis, C., 1969; Pring, L., 1985; 1994; Millar, S., 1997). The temporal synchrony between sound and touch possibly activates multisensory areas more vigorously, which additionally influences and enhances activity in ventral visual cortex similarly to the events during speech perception. An expected subsequent effect from such training might generalize to tactile activation of visual cortex without braille reading. A secondary consequence with progressive tactile literacy is guidance to braille reading from contextual semantic meaning (Millar, S., 1997). Thus, tactile stimulation is coupled to semantic content, which possibly leads to coincident activation from tactile and frontal language area inputs – thereby developing and enhancing language activation of visual cortex.

6.18.6 Conclusions

New skills for enhanced processing of nonvisual stimuli develop in blind people. Adjustments include tactile reading and attentive skills for all nonvisual inputs. Positively reinforced practice heightens acuity on tasks requiring subtle perceptual and cognitive distinctions. Practice in attending to sensory subtleties also heightens tactile acuity in sighted people. Additionally, short-term visual deprivation alone improves tactile acuity in sighted individuals. Thus, better performance in blind people does not depend on more sensitive peripheral receptors. Nevertheless, especially early blind people have impoverished spatial awareness, presumably because without vision they do not project body-centered coordinates to external topography. A consequence for most early blind individuals is an inability to create representative drawings or sculptures. However, some blind people make tangible drawings that show perspective and external spatial features. Late-onset blind artists with past visual experience are more likely to produce aesthetic works.

Evidence of reorganization is inconsistent in primary somatosensory cortex and absent from any other somatosensory cortical areas in blind people. Reported alterations are potentially an instantiation of transient changes arising from attention effects and not Hebbian in nature. Specifically, in tasks requiring tactile attention and equal performance across groups, S1 shows similar response distributions. However, response dynamics are possibly speeded in early blind people.

Neuroplasticity has been observed in visual cortex of blind individuals at any age of blindness onset. For example, visual cortex metabolic activity in congenital/early blind people is comparable to levels obtained in sighted people with their eyes open. The metabolism is suggestive of normal neuronal activity. Cross-modal activation of visual cortex in blind people has been extensively documented. The activity appears relevant to behavior because disruption of visual cortex by posterior occipital strokes or TMS deteriorates tactile reading and semantic language performance in blind people. These changes garner surprise only when sensory areas are viewed as unimodal processors that funnel computations into a cascade of cortical areas, including multisensory regions. A bias regarding dedicated sensory cortical areas predicts a silent visual cortex following blindness. Heteromodal activity in reorganized visual cortex most parsimoniously reflects innate intracortical connections between cortical areas that normally exhibit nonvisual responsiveness in sighted people. These connections possibly lead to resurgent GABA receptor levels, plausibly normal inhibitory synaptic activity in deafferented visual cortex, and frank metamodal functions (Pascual-Leone, A. and Hamilton, R., 2001; Pascual-Leone, A. *et al.*, 2005).

Two plausible critical factors for heightened tactile acuity in blindness are reorganized visual cortex and altered response dynamics in visual and nonvisual areas. An important question is whether separate

visual cortex areas service different perceptual and cognitive processes and whether any distribution selectivity conforms to that noted in sighted people (Grill-Spector, K. and Malach, R., 2004). Hypothetically, some combination of visuotopic areas and eccentricity axes might apply to reorganized visual cortex. Low-level perceptual processing might only evoke lower tier visual areas wherein nonvisual stimulus features are analyzed; more complex cognitive tasks might evoke occipito-temporal and occipito-parietal areas possibly within selective eccentricity axes. Additionally, activation of dorsal and ventral occipito-temporal cortical partitions in sighted people is invariant with respect to many visual features (Hasson, U. *et al*., 2002; 2003; Grill-Spector, K. and Malach, R., 2004), which thereby suggest a capacity for processes independent of visual input. Thus, the global nature of selective domain specialization is possibly applicable to cognitive processing in blindness.

Glossary

amodal Devoid of sensory modality reference.
cross-modal Reflecting the effect of a stimulus in one sensory modality on processing in another.
encoding With respect to memory, the process of storing information at initial exposure.
extrastriate visual cortex Nonprimary visual cortex.
functional magnetic resonance imaging (fMRI) A method for measuring brain activity using MRI.
haptic Sensing by touch through active manual exploration.
multisensory Reflecting processing of inputs from more than one modality.
positron emission tomography (PET) A method for measuring functional brain activity as indexed by regional cerebral blood flow, using a positron-emitting isotope.
priming Unconscious effect of one stimulus on processing of another.
retrieval The process of recalling previously encoded and stored information from memory.
tactile Sensing by touch through passive stimulation of the skin surface.
transcranial magnetic stimulation (TMS) A method for testing the function of discrete brain regions by applying magnetic pulses to the head.
visual imagery Mental reconstruction of a pictorial representation (seeing with the mind's eye).

6.19.1 Functional Involvement of Visual Cortical Areas in Tactile Perception

6.19.1.1 Macrospatial versus Microspatial Tasks

Activation of extrastriate visual cortical areas during tactile perception was first demonstrated in a positron emission tomographic (PET) study from our laboratory (Sathian, K. *et al.*, 1997), in which participants were asked to discriminate the orientation of gratings presented to the immobilized right index fingerpad. When this task was contrasted with a control task requiring discrimination of grating groove width, activation was found at a focus in the left extrastriate visual cortex, close to the parieto-occipital fissure. Since this focus was known to be active during visual discrimination of grating orientation (Sergent, J. *et al.*, 1992) and spatial imagery (Mellet, E. *et al.*, 1996), it was considered to mediate spatial processes common to vision and touch (Sathian, K. *et al.*, 1997). The location of this activity near the parieto-occipital fissure indicates possible homology with an area in the macaque parieto-occipital fissure known as V6 or PO where a large proportion of neurons appear to be orientation selective (Galletti, C. *et al.*, 1991). Indeed, the focus of activation in our PET study (Sathian, K. *et al.*, 1997) is in the vicinity of the human V6 complex of areas (Pitzalis, S. *et al.*, 2006).

These results suggested that tactile analogs of visual tasks potentially activate the same cortical areas as the visual tasks and that the visual cortex responds to certain tasks independently of the sensory modality in which the task is presented. A fairly extensive series of studies have since established that cerebral cortical areas previously regarded as exclusively visual are activated by haptic/tactile input in a task- and stimulus-specific manner, as reviewed below.

A subsequent functional magnetic resonance imaging (fMRI) study from our laboratory (Zhang, M. *et al.*, 2005) confirmed left parieto-occipital cortical activation during discrimination of grating orientation (relative to discrimination of grating groove width) with the right index fingerpad, and also found selective activation in other cortical areas. Among these areas were the right postcentral sulcus (PCS) and the left anterior intraparietal sulcus (aIPS). The PCS corresponds to Brodmann's area 2 (Grefkes, C. *et al.*, 2001) and is considered to be part of S1 (primary somatosensory cortex), while the aIPS has been consistently identified as a multisensory region, as will become increasingly evident as this chapter progresses. Other groups have corroborated the role of the aIPS in tactile discrimination of grating orientation, using fMRI: one group reported bilateral activity in this region during performance of this task with either hand, relative to discrimination of small changes in grating location on the fingerpad (van Boven, R. W. *et al.*, 2005). Activity was greater on the left than the right in this study, regardless of which hand was used. Another group scanned gratings over the fingerpad and found right-lateralized activity in the PCS–aIPS region during discrimination of grating orientation with either hand, relative to discrimination of grating roughness (Kitada, R. *et al.*, 2006). The right aIPS part of this region was directly established as multisensory by the demonstration that it was also activated by visual discrimination of grating orientation, relative to discrimination of grating color.

At the time we reported cross-modal parieto-occipital cortical activation during tactile discrimination of grating orientation (Sathian, K. *et al.*, 1997) this was an unusual finding and hence we wished to confirm that the finding was not merely epiphenomenal. This possibility was ruled out using transcranial magnetic stimulation (TMS) to test whether disrupting the function of this cortical region was detrimental to performance. Applying single-pulse TMS directly over the parieto-occipital focus and at sites close to it, at the appropriate interval (180 ms after the onset of tactile stimulation), significantly impaired discrimination of grating orientation but not of grating groove width, whilst TMS at more distant sites did not affect performance on either task (Zangaladze, A. *et al.*, 1999). This allowed us to infer that the activation found in the earlier PET study was not accidental but, in fact, functionally meaningful. A more recent study (Merabet, L. *et al.*, 2004) used repetitive TMS (rTMS) at 1 Hz (hertz, unit of frequency (cycles per second)) to decrease local cortical excitability. This study exploited a known dissociation between subjective magnitude estimates of perceived tactile interdot distance, which increase with physical interdot distance (up to 8 mm), and those of perceived tactile roughness, which peak at intermediate values (around 3 mm). The main finding was that rTMS over S1 disrupted judgments of roughness, but not interdot distance, whereas rTMS over medial occipital cortex impaired distance but not roughness judgments. In addition, a congenitally blind patient with bilateral occipital lesions following a stroke was impaired on tactile judgments of interdot spacing but not roughness (Merabet, L. *et al.*, 2004).

Two conclusions can be drawn from these observations, together with the studies of the grating orientation task reviewed above (Sathian, K. *et al.*, 1997; Zangaladze, A. *et al.*, 1999; Zhang, M. *et al.*, 2005). First, visual cortical activation may be necessary for some tactile tasks because performance on these is disrupted when these cortical areas are deactivated by TMS or damaged by lesions. Second, visual cortical involvement occurs in macrospatial (large-scale) tactile tasks, but not in microspatial (small-scale) tasks where the parameters of interest vary in the range of $\leq$3 mm. This conclusion is consistent with psychophysical studies suggesting that macrospatial tactile tasks are preferentially associated with visual processing (Klatzky, R. L. *et al.*, 1987), and that vision seems to be better than touch for perceiving macrospatial features, the reverse being true for microspatial features (Heller, M. A., 1989).

An fMRI study from our laboratory focused on the macrospatial–microspatial dichotomy (Stoesz, M. *et al.*, 2003). As a macrospatial task, we used a global form condition in which participants were asked to distinguish between the upside-down letters T and V, contrasting this with detection of a 3 to 4 mm gap in a bar as the microspatial task. Activity in the lateral occipital complex (LOC) was greater bilaterally in the form task than in the gap task, in agreement with the studies reviewed so far indicating

that macrospatial tactile tasks are more likely to evoke visual cortical activity during tactile tasks. The LOC is located within the ventral visual pathway, which is specialized for form processing and is a visual object-selective area (Malach, R. *et al.*, 1995) thought to be homologous to macaque inferotemporal cortex (Grill-Spector, K. *et al.*, 1998). A recent fMRI study from our laboratory confirmed the conclusion that visual cortical activation during microspatial tasks is minimal (Stilla and Sathian, unpublished observations). In this study, a three-dot array was presented to the immobilized fingerpad with the array oriented along the long axis of the finger, the central dot in the array being offset to the left or right by <2 mm. Subjects were asked to indicate the direction of offset. Activation in this spatial task was contrasted against that due to discrimination of the duration of stimulation with an array that lacked a spatial offset, thus isolating activity associated with tactile microspatial processing. The key point here is that there was only minimal activation of the LOC bilaterally, although there was strong and extensive activation in multiple parietal cortical areas, including the left PCS, bilateral aIPS, bilateral posterior IPS (pIPS), and bilateral posterior insula (Stilla and Sathian, unpublished observations).

6.19.1.2 Motion, Texture, and Form

Several studies have shown that an area involved in perception of visual motion, the human MT complex (which is considered to be the human homolog of macaque MT, a visual motion-processing area), is also active during presentation of tactile motion stimuli, even in the absence of any task (Hagen, M. C. *et al.*, 2002; Blake, R. *et al.*, 2004). Psychophysical studies point to a common representation of motion across vision and touch: tactile motion perception can be used to disambiguate the direction of motion in an ambiguous visual motion display (Blake, R. *et al.*, 2004), and facilitates such disambiguation when presentation of the visual motion display is delayed (James, T. W. and Blake, R., 2004). However, when the direction of motion is unambiguous but incongruent between vision and touch, visual motion disrupts tactile motion perception (Craig, J. C., 2006).

In a recent fMRI study, we contrasted activations during shape and texture perception in both haptic and visual modalities (Stilla and Sathian, submitted). We found somatosensory areas that were selectively activated during haptic texture perception, in the parietal operculum and posterior insula bilaterally. We also found that there was haptic texture selectivity in the right medial occipital cortex, probably in visual area V2. This focus overlapped with a visually texture-selective area that was primarily in area V1 (primary visual cortex), the multisensory overlap being on the border between V1 and V2. This result is interesting not merely because it extends the range of visual areas that respond to tactile tasks into areas quite early in the visual cortical hierarchy, but also because, for the first time, visual areas were shown to be active in a microspatial tactile task. It remains to be seen whether this is an exception to the general rule that microspatial tactile tasks do not recruit visual cortical activity, or whether such tasks might tend to evoke activity in particular early visual cortical areas under the appropriate conditions.

Conversely, the LOC was bilaterally active during shape perception in both haptic and visual modalities (Stilla and Sathian, submitted), consistent with numerous earlier fMRI studies (Deibert, E. *et al.*, 1999; Amedi, A. *et al.*, 2001; 2002; James, T. W. *et al.*, 2002; Stoeckel, M. C. *et al.*, 2003; Reed, C. L. *et al.*, 2004; Zhang, M. *et al.*, 2004). As mentioned above, we found bilateral activation of the LOC during tactile 2D form discrimination, distinguishing between upside-down Ts and Vs, when this task was contrasted with gap detection (Stoesz, M. *et al.*, 2003). We also found activation of the right LOC in the same form task, relative to bar orientation discrimination, in a PET study (Prather, S. C. *et al.*, 2004). Thus, the LOC appears to be consistently active during tactile perception of either 2D or 3D form. Studies of patients with lesions involving the LOC suggest, moreover, that it is actually necessary for haptic as well as visual shape perception. One patient with visual agnosia (inability to recognize objects), following a lesion of the left occipitotemporal cortex that probably included the LOC, also turned out to have tactile agnosia, although somatosensory cortex and basic somatic sensation were intact (Feinberg, T. E. *et al.*, 1986). Another patient who developed bilateral lesions of the LOC was impaired at learning unfamiliar objects using either touch or vision (James, T. W. *et al.*, 2006a). Multisensory object selectivity in the LOC appears to be confined to a subregion, which responds more strongly to graspable visual objects (such as tools) than to other stimuli (such as buildings or faces) but does not appear to be object selective in the auditory modality (Amedi, A. *et al.*, 2002).

Our study (Stilla and Sathian, submitted) also found multisensory shape selectivity bilaterally in

the PCS, and at multiple foci within the IPS, including the aIPS, pIPS, and ventral IPS (vIPS). Multisensory shape selectivity had been reported previously in the left aIPS (Grefkes, C. *et al.*, 2002) and in a caudal region of the IPS located between our pIPS and vIPS foci (Saito, D. N. *et al.*, 2003). Multisensory shape processing in the IPS fits with the description of multisensory responses in various parts of the IPS in monkeys (Iriki, A. *et al.*, 1996; Duhamel, J. R. *et al.*, 1998), although the homologies with humans remain uncertain. The demonstration of extensive multisensory overlap in the cortical processing of shape raises the possibility that both visual and haptic shape perception may engage a unitary neural representation, as in the case of motion perception. This is supported by cross-modal priming effects between visual and haptic object presentations in two fMRI studies, although the effects were in opposite directions in the two studies (Amedi, A. *et al.*, 2001; James, T. W. *et al.*, 2002). Additional psychophysical evidence bearing on the issue of a common visuo-haptic representation of shape is considered in the next section. Of some interest is the finding of multisensory shape processing in the PCS, which, as pointed out earlier in this chapter, corresponds to Brodmann's area 2 (Grefkes, C. *et al.*, 2001), part of S1. Along with the finding of multisensory texture selectivity in V2 described above, this underscores the ubiquity of multisensory processing, with its presence even in regions early in the sensory hierarchies.

Face perception is a special case of form perception. Obviously, sighted humans perform face recognition almost exclusively using vision, but they can also identify faces haptically. Like the patients described in the studies of object perception (see above), a prosopagnosic patient (i.e., one who could not recognize faces visually) was found to be unable to recognize faces haptically (Kilgour, A. R. *et al.*, 2004). Face recognition also occurs cross-modally between vision and touch (Kilgour, A. R. and Lederman, S., 2002), albeit not without a cost relative to within-modal recognition (Casey, S. J. and Newell, F. N., 2007). This cost in cross-modal performance is unrelated to the encoding modality or to differences in encoding procedures and suggests that, unlike object and motion perception, face recognition may not rely on a representation that is common to both vision and touch (Casey, S. J. and Newell, F. N., 2007). Recent fMRI studies fit with this idea: face-selective voxels in ventral and inferior temporal cortex are mostly nonoverlapping between the two modalities (Pietrini, P. *et al.*, 2004); the left fusiform gyrus is activated during haptic face recognition, whereas the right fusiform gyrus is more active during visual face recognition (Kilgour, A. R. *et al.*, 2005); and left fusiform activity increases when the faces are familiar compared to unfamiliar while the right fusiform remains relatively inactive (James, T. W. *et al.*, 2006b). Differential activation of the left versus right fusiform gyrus for haptic versus visual face perception may reflect processing of modality-specific featural face information, whilst modality-independent configural face information is dealt with elsewhere in the brain (Casey, S. J. and Newell, F. N., 2007). Since imagery of visually presented faces produces greater activation in the left than in the right fusiform gyrus (Ishai, A. *et al.*, 2002), another possibility is that haptic face perception may involve imagery mechanisms, although one study found no correlation between performance on haptic face recognition and imagery ratings (Kilgour, A. R. and Lederman, S., 2002). Further studies are needed to resolve the neural basis of multisensory face perception, and its differences from multisensory object perception.

6.19.2 Visual Imagery and Multisensory Representations

The studies reviewed so far establish that visual cortical processing is routinely involved in normal tactile perception in the sighted, especially during macrospatial tasks but potentially during microspatial tasks as well. Such processing is quite task specific, so that extrastriate visual cortical areas known to be specialized for particular visual tasks are involved during performance of the same tasks in touch. So far we have considered whether vision and touch share a common representation (e.g., for objects and motion) or separate representations (e.g., for faces). In this section we consider the nature of these representations in more detail. It was formerly thought that cross-modal performance was mediated by language, but cross-modal abilities have been demonstrated in preverbal infants and in several nonhuman primate and nonprimate species (see Rose, S. A., 1994 for a brief review). However, whilst linguistic competence may not be necessary, it may play a facilitatory role: it is possible to produce a verbal description of unfamiliar objects (Easton, R. D. *et al.*, 1997a) and a verbal secondary task disrupts both visual and haptic encoding of unfamiliar objects such that subsequent

cross-modal recognition is impaired (Lacey, S. and Campbell, C., 2006a).

A more fundamental explanation for cross-modal recruitment of the visual cortex into nonvisual tasks is that these tasks might involve visual imagery. This is an intuitively appealing explanation, especially since subjects consistently report mental visualization of tactile stimuli during macrospatial tasks such as discrimination of grating orientation or tactile form, which are associated with visual cortical recruitment. This is not true of microspatial tasks such as discrimination of grating groove width or gap detection, which tend to not involve visual cortical activity (Sathian, K. *et al.*, 1997; Zangaladze, A. *et al.*, 1999; Stoesz, M. *et al.*, 2003; Zhang, M. *et al.*, 2005). Visual imagery might be triggered by lack of familiarity with the tactile stimuli or tasks used; indeed, such cross-modal translation may be a general phenomenon, especially during complex information processing (Freides, D., 1974). Consistent with the idea that visual imagery mediates visual cortical activity in touch, an fMRI study from our laboratory (Zhang, M. *et al.*, 2004) found that interindividual variations in the magnitude of haptic shape-selective activity in the right LOC (ipsilateral to the hand used for haptic perception) were strongly predicted by ratings of the vividness of visual imagery. In contrast, activation strengths in the left LOC were uncorrelated with these visual imagery scores, pointing to an additional role for factors other than visual imagery in cross-modal visual cortical recruitment (Zhang, M. *et al.*, 2004). Left-lateralized activity has, however, been found in the LOC when either geometric or material object properties are retrieved from memory in the absence of visual or haptic input (Newman, S. D. *et al.*, 2005) and in both the blind and the sighted while generating mental images of shape derived from haptic and visual experience, respectively (De Volder, A. G. *et al.*, 2001). (Although this last report did not specifically identify the LOC, the illustrations and coordinates of activation clearly indicate it.)

If the representation of haptically perceived objects is indeed primarily visual, there should be a relationship between cross-modal memory performance and visual imagery ability. Several studies show that children's visuo-spatial abilities are indeed correlated with cross-modal memory performance for both familiar (Johnson, C. L. *et al.*, 1989) and unfamiliar objects (Stoltz-Loike, M. and Bornstein, M. H., 1987). Furthermore, good imagers (as measured by scores on the Vividness of Visual Imagery Questionnaire, VVIQ; Marks, D. F., 1973) are better at cross-modal memory than are poor imagers (Cairns, E. and Coll, P., 1977). However, this approach has its limitations. One is that visual imagery is a multicomponent process: images have to be generated and maintained, and once retrieved can be inspected, scanned, rotated, or otherwise manipulated (Kosslyn, S. M., 1980; 1994). Furthermore, individuals may vary in ability on one or more of these components (Kosslyn, S. M. *et al.*, 1990; 1984). Thus, a single test of visual imagery ability may not be appropriate since it may not capture the relevant component and thus may not be sensitive to the relevant individual differences. Secondly, it has been argued that the VVIQ only measures a subjective aspect of the experience of imagery rather than imagery processes and abilities *per se* (Pearson, D. *et al.*, 2001; Dean, G. and Morris, P. E., 2003). Moreover, the superiority of good imagers might stem not from greater proficiency at imagery but from better use of strategically important information (Baddeley, A. D. and Andrade, J., 2000). In addition, different aspects of visual imagery may contribute differentially to cross-modal memory and perceptual representations. For example, spatial recall predicts cross-modal performance whereas mental rotation does not (Stoltz-Loike, M. and Bornstein, M. H., 1987).

Some have argued that the LOC activity observed during haptic shape perception is not due to visual imagery since visual imagery evoked less activity in the LOC than did haptic object recognition (Amedi, A. *et al.*, 2001). However, this reduced activation might have been due to object familiarity and/or the lack of a requirement to maintain images online during the entire scan. Nonetheless, other possible explanations should be considered for visual cortical recruitment during tactile perception. Vision and touch can both encode object shape, and visual cortical activation during tactile perception might reflect a multisensory representation rather than a specifically visual image. Psychophysical observations indicate, for example, that cross-modal visuo-haptic priming is essentially as effective as within-modal priming (Easton, R. D. *et al.*, 1997a; 1997b; Reales, J. M. and Ballesteros, S., 1999), and that cross-modal shape matching can be quite effective even when the objects are highly similar (Norman, J. F. *et al.*, 2004). An alternative approach to the relationship between visual and haptic representations argues that vision and touch encode object properties common to both modalities into a single representation that is multisensory (Sathian, K., 2004) or amodal (e.g., Lewkowicz, D. J.,

1994). It is our view that the amodal label is best suited to processing of information that cannot be derived directly from sensory systems and that must be represented linguistically or perhaps propositionally. We prefer instead the term multisensory, referring to a representation that is accessible from multiple sensory systems, but in which the modality tags of the associated inputs are preserved (Sathian, K., 2004). In the case of vision and touch, modality-independent representations can be specified as spatial in format since both these sensory systems can encode spatial information such as size, shape, and the relative positions of different object features. An important question is the precise nature of the modality-independent representation.

The format of visuo-haptic object representation has been investigated behaviorally using interference tasks in a cross-modal memory paradigm. In one study (Lacey, S. and Campbell, C., 2006a), both visual and verbal interference disrupted encoding of unfamiliar objects, significantly reducing subsequent cross-modal recognition, while haptic interference was ineffective and familiar objects were immune to any form of interference. These results suggested that encoding in both modalities resulted in a common representation linked to a strategy of covert verbal description. Since the visual interference task (dynamic visual noise) is known to disrupt visual imagery mnemonics for recall of word lists (Quinn, J. G. and McConnell, J., 1996) and the use of visual imagery in symbolic comparison tasks (Dean, G. M. *et al.*, 2005), these results suggested that the common representation could be a visual image. Interference might have been more important for the unfamiliar objects because cross-modal memory for familiar objects is probably supported by closely interconnected representations in several formats – for example, visual, verbal, and haptic (Lacey, S. and Campbell, C., 2006a).

Lacey S. and Campbell C. (2006b) showed that spatial interference disrupted both encoding and retrieval, independent of the modality in which the interference task was presented, whereas nonspatial interference in either modality had no effect. Thus the common representation could be a modality-independent spatial one, rather than visual. It remains uncertain whether this reflects a single, multisensory spatial representation or separately derived visual and haptic spatial representations that are compared cross-modally. A recent neuroimaging study is instructive in this regard, showing that category selectivity within human inferotemporal cortex is relatively independent of whether the input modality is visual or haptic (Pietrini, P. *et al.*, 2004). Subjects with early-onset blindness had similar patterns of category-selective responses during haptic object perception in this study, although there were some differences in the locations of the category-selective responses between blind and sighted subjects. These findings suggest a single multisensory representation for objects that may be spatially rather than visually based. This interpretation is suggested by the recent work by Kozhevnikov and co-workers (Kozhevnikov, M. *et al.*, 2002; 2005; Blajenkova, O. *et al.*, 2006) showing that visual imagery is of two distinct types. Object imagery refers to images that are more pictorial and detailed in terms of shape, color, brightness, etc., whilst spatial imagery refers to images that are more concerned with the spatial relations of objects and object parts and hence may facilitate spatial transformations. Thus, an interesting question is how these different types of imagery are related to cross-modal performance: for example, are spatial imagers better at haptically deriving representations than object imagers?

If haptic and visual perception engage a modality-independent imagery system, we might expect to see similarities between visually and haptically accessed component processes of this system. For example, scanning times in visual imagery increase with the spatial distance to be inspected in the image, implying preservation of metric spatial information in visual images (Kosslyn, S. M., 1973; Kosslyn, S. M. *et al.*, 1978). The same effect is observed in scanning haptically derived representations, implying that these are also spatial and that similar, if not identical, imagery processes operate in both modalities (Röder, B. and Rösler, F., 1998). Similarly, studies of mental rotation of visual stimuli show that the time taken to judge whether two objects are the same or mirror images increases linearly with increasing angular disparity between the stimuli (Shepard, R. N. and Metzler, J., 1971). This also holds true for haptic and tactile stimuli (Marmor, G. S. and Zaback, L. A., 1976; Carpenter, P. A. and Eisenberg, P., 1978; Hollins, M., 1986; Dellantonio, A. and Spagnolo, F., 1990; Prather, S. C. and Sathian, K., 2002; Prather, S. C. *et al.*, 2004). A PET study from our laboratory (Prather, S. C. *et al.*, 2004) investigated the mental rotation of tactile stimuli – upside-down Js presented in one of two mirror-image configurations. Contrasting a mental rotation condition (stimuli at 135–180° angle with respect to the long axis of the finger) with a pure mirror-image discrimination condition (stimuli at 0°)

revealed activity in the left aIPS, at a focus that is also active during mental rotation of visual stimuli (Alivisatos, S. and Petrides, M., 1997), lending further support to the idea that similar spatial imagery processes operate on both visually and haptically derived representations.

Interestingly, these similarities between visually and haptically derived representations are observed in both the early-blind and the late-blind as well as the sighted (Carpenter, P. A. and Eisenberg, P., 1978; Röder, B. and Rösler, F., 1998). The blind are reported to be slower than the sighted at haptic mental rotation (Marmor, G. S. and Zaback, L. A., 1976) but Hollins M. (1986) suggests that, after controlling for greater variability in the use of frames of reference by the sighted, this difference is more apparent than real. Taken together, these studies indicate that common processes are engaged when generating, retrieving, and manipulating representations derived from both vision and touch.

6.19.3 Top-Down and Bottom-Up Processing

If mental imagery underlies tactile activation of the visual cortex, we would expect to find direct, bottom-up somatosensory projections into the visual cortical areas that are implicated in tactile perception, as opposed to the top-down projections from prefrontal into visual cortical areas that would be required to support a process such as visual imagery (Mechelli, A. *et al.*, 2004). These are possibilities that can be tested empirically, either by studying connectivity in experimental animals or by analyzing fMRI data to reveal effective connectivity. A study from our laboratory (Peltier, S. *et al.*, 2007) probed effective connectivity using structural equation modeling, based on the correlation matrix between the time courses of fMRI activity in various regions. This study revealed both bottom-up and top-down paths in a network of haptically shape-selective areas, including foci in the PCS, the IPS, and the LOC. This suggests that potential neural substrates exist for both visual imagery and multisensory representations, in relation to visual cortical involvement during haptic shape perception.

Neurophysiological and neuroanatomic studies in monkeys have also illuminated understanding of cross-modal visual cortical recruitment. Some neurons in area V4 (a nonprimary area in the ventral visual pathway) were selective for the orientation of a tactile grating when it served as a cue for matching to a subsequently presented visual stimulus, but not when it was task irrelevant (Haenny, P. E. *et al.*, 1988). The requirement for task relevance implicates top-down, rather than bottom-up, inputs. Multisensory inputs have been reported in early sensory cortical areas that are traditionally considered unisensory, including V1 (Falchier, A. *et al.*, 2002; Rockland, K. S. and Ojima, H., 2003) and auditory association cortex (Schroeder, C. E. *et al.*, 2001; Schroeder, C. E. and Foxe, J. J., 2002; Schroeder, C. E. *et al.*, 2003). Analysis of the laminar profile of these projections suggests that both top-down (Falchier, A. *et al.*, 2002; Schroeder, C. E. and Foxe, J. J., 2002; Rockland, K. S. and Ojima, H., 2003; Schroeder, C. E. *et al.*, 2003) and bottom-up (Schroeder, C. E. and Foxe, J. J., 2002; Schroeder, C. E. *et al.*, 2003) inputs exist. Thus, the sum total of the evidence to date indicates the probable existence of multisensory representations that are flexibly accessible via both vision and touch, with the potential to involve interactions between bottom-up sensory inputs and top-down processes such as visual imagery.

6.19.4 Cross-Modal Conflict, Enhancement, and Perceptual Illusions

If vision and touch produce separate representations, how do these affect each other? Classic research suggested that vision dominates touch (Rock, I. and Victor, J., 1964). When the visual width of an object was distorted by a lens, individuals who both saw and felt the object were unaware of the cross-modal conflict and reported the distorted width perceived visually, rather than the true width perceived tactually. Thus this sensory conflict was resolved in favor of the visual percept. More recent research has shown the situation to be more complex and to depend on the specific object property (Klatzky, R. L. *et al.*, 1987). For example, under neutral instructions the haptic salience of object properties is hardness > texture > shape and under haptically biased instructions this changes to texture > shape > hardness. However, in combined visual and haptic perception, and in haptic perception with concurrent visual imagery, this saliency is reversed and changes to shape > texture > hardness/size (Klatzky, R. L. *et al.*, 1987). Visual imagery can therefore influence tactile perception in the absence of visual perception and, moreover, different modalities may be optimal for

different object properties (Klatzky, R. L. *et al.*, 1993). Thus, there is not a simple dominance of visual over tactile perception.

Another interesting phenomenon is the asymmetry normally observed in cross-modal memory performance: in general, performance is better when visual encoding is followed by haptic retrieval than the reverse (e.g., Jones, B., 1981; Streri, A. and Molina, M., 1994; Lacey, S. and Campbell, C., 2006a; 2006b). Asymmetric performance appears to be a consistent aspect of cross-modal memory but, while many studies address the difference between within- and cross-modal performance, the difference between the two cross-modal conditions receives less attention (e.g., Easton, R. D. *et al.*, 1997a; 1997b; Reales, J. M. and Ballesteros, S., 1999; Nabeta, T. and Kawahara, J., 2006). It has been suggested that if cross-modal memory relied on a common representation, based on properties that can be represented equally well by different modalities (Lewkowicz, D. J., 1994), then performance should be similar in the two cross-modal conditions (Freides, D., 1974; Streri, A. and Molina, M., 1994). The fact that asymmetric performance occurs suggests otherwise, but given that the basis for the asymmetry still requires explanation, it would be premature to rule out a common representation solely on this basis. One explanation for asymmetry may be that, although vision and touch are both encoding the same information about an object into the same modality-independent format, this information may not be encoded equally well because of competition from other, more salient, modality-specific information. As noted above, visual imagery instructions alter the haptic salience of object properties (Klatzky, R. L. *et al.*, 1987) – without the imagery-biased instructions it might have been more difficult to encode shape because of the more salient hardness and texture information.

In a study using an *n*-back letter recognition task, Bliss I. and Hämäläinen H. (2005) showed that haptic working memory capacity appears to be limited and variable. A simple explanation for asymmetry may therefore be that haptic working memory is more error prone than visual working memory. An alternative is that haptic representations may simply decay faster than visual representations. Indeed, the decay function in haptic memory, rather than being progressive, appears to occur entirely in a band of 15–30 s poststimulus (Kiphart, M. J. *et al.*, 1992). This suggests that performance might be lower in the haptic–visual condition of the cross-modal memory task because haptically encoded representations have substantially decayed by the time that visual retrieval is required. However, several cross-modal memory studies show that increasing the delay between encoding and retrieval up to 30 s did not affect haptic–visual performance more than visual–haptic performance (Garvill, J. and Molander, B., 1973; Woods, A. T. *et al.*, 2004) and so it seems that the explanation will be more complicated than a simple function of haptic memory properties alone. Interestingly, asymmetry is also observed in cross-modal studies involving very young infants (e.g., Streri, A. and Molina, M., 1994). These studies attribute asymmetric performance to constraints imposed by different stages of motor development (Streri, A. and Molina, M., 1994), but since asymmetry persists beyond early development into more mature motor systems (Easton, R. D. *et al.*, 1997a; 1997b; Bushnell, E. W. and Baxt, C., 1999; Lacey, S. and Campbell, C., 2006a; 2006b), it is likely that other representationally important factors are involved.

Haptic versions of visual illusions have been used to investigate the relationship between vision and touch. In the Müller–Lyer illusion, two lines of identical length and endcapped with fins that point either outward or inward are seen as shorter or longer, respectively, than the true length. This visual illusion has also been demonstrated in a haptic format (Heller, M. A. *et al.*, 2002; Millar, S. and Al-Attar, Z., 2002) and appears to be independent of visual experience since blindfolded, normally sighted individuals as well as those with low vision, late-blind subjects, and congenitally blind individuals were all equally susceptible to the illusion (Heller, M. A. *et al.*, 2002). Length distortion is an illusion that was first described haptically and subsequently found to also occur in vision. Length distortion refers to overestimation of the distance between two points as a function of the increasing length of an indirect pathway between them. The same effect can be observed, albeit of a smaller magnitude, in the visual version of the task (Balakrishnan, J. D. *et al.*, 1989). These studies suggest a common visuo-haptic representation of space that may be based on body-centered reference points (e.g., the body midline or the positions of the hands relative to each other), since instructions to use these in judging Müller–Lyer line length virtually eliminated the illusion in both modalities whilst external reference points (a frame surrounding the illusion figure) had no effect (Millar, S. and Al-Attar, Z., 2002). The use of these body-centered reference points may be a common mechanism for integrating spatial information from vision and touch.

Other approaches have identified interactions between vision and somatosensory representations of the body. One line of research has demonstrated that noninformative vision of the body can improve tactile spatial acuity, as measured using grating orientation discrimination (Taylor-Clarke, M. *et al.*, 2004), and that this cross-modal enhancement is abolished by TMS over S1 (Fiorio, M. and Haggard, P., 2005). In related work, visual stimuli (light flashes from light-emitting diodes (LEDs) on the finger) have been shown to increase the proportion of concomitant electrotactile stimuli that are detected; however, signal detection analyses showed only a small change in perceptual sensitivity – most of the effect apparently arose from criterion shift (Johnson, R. M. *et al.*, 2006). Similarly, a patient with a right hemispheric lesion was reported to perceive touch on the contralesional hand only when viewing the tactile stimulation (Halligan, P. *et al.*, 1996). Another line of research pertains to the rubber hand illusion. When a rubber hand is positioned in alignment with one's own, invisible hand, if one sees the rubber hand being touched, one experiences illusory touch, indicating a feeling of ownership of the synthetic hand (Botvinick, M. and Cohen, J., 1998). Such a feeling of ownership is associated with activity in the ventral premotor cortex (Ehrsson, H. H. *et al.*, 2004), a region where, in monkeys, neurons exhibit visual receptive fields that are anchored to the arm and move with it (Graziano, M. S. *et al.*, 1994).

Yet another line of work stems from observations that tactile stimuli can be referred ipsilaterally from intact body parts to phantoms of resected body parts (Ramachandran, V. S. and Hirstein, W., 1998; Aglioti, S., 1999). Tactile stimuli applied to the intact hand of arm amputees have been shown to evoke contralateral percepts referred topographically to the phantom hand (Ramachandran, V. S., 1995), and similar contralateral mirror-symmetric referral of sensations also occurs in patients with sensory loss due to neurological lesions (Sathian, K., 2000). The referral is evoked for touch but typically not other kinds of somatosensory stimuli, such as pain or temperature (Ramachandran, V. S., 1995; Sathian, K., 2000). The referred sensations tend to be relatively high threshold, crudely localized, and lacking spatial organization, leading to the conclusion (Sathian, K., 2000) that they are unlikely to depend on neurons in area 3b, which exhibit fine-grained spatial resolution and topographic organization (DiCarlo, J. J. *et al.*, 1998). Also, since the hand representation in area 3b has sparse callosal connectivity (Killackey, H. P. *et al.*, 1983) and normally lacks neurons with bilateral receptive fields (Pons, T. P. *et al.*, 1987), transcallosal referral probably occurs more posteriorly in S1, in areas 1 and 2, or in the parietal opercular cortex, where bilateral somatosensory responsiveness (Robinson, C. J. and Burton, H., 1980a; 1980b; Iwamura, Y. *et al.*, 1994) and callosal connectivity (Killackey, H. P. *et al.*, 1983; Manzoni, T. *et al.*, 1984) are found in the hand representation. Interestingly, in both amputees (Ramachandran, V. S., 1995) and patients with sensory loss (Sathian, K., 2000), visual input via a mirror tended to strengthen referred percepts, suggesting a role for multisensory convergence. Use of a mirror to create conflict between the vision of touch (present) and the feeling of touch (absent) enhanced subsequent sensitivity to touch; the effect was eliminated by TMS over posterior parietal cortex (Ro, T. *et al.*, 2004). Provision of illusory visual input using a mirror has been exploited as a rehabilitative method to improve arm function affected by strokes (Altschuler, E. L. *et al.*, 1999; Sathian, K. *et al.*, 2000). These studies point to the existence of intricate and multifaceted interactions between visual and tactile processing that may be beneficial during normal perception as well as in neurological rehabilitation – such interactions offer fertile ground for future basic and clinical investigation.

6.19.5 Conclusions

In this chapter, we have outlined a plethora of cross-modal and multisensory interactions that occur in a variety of circumstances. Such interactions underscore the generality of multisensory processing, and are increasingly being recognized by researchers. The effects of visual deprivation that are reviewed by Burton (see Chapter Visual Deprivation Effects on Somatosensory and Visual Systems: Behavioral and Cortical Changes) should be interpreted in the context of these normal interactions, although a unifying framework is inchoate. The development of this framework remains a major challenge for future work.
